
Gold, nickel, silver, iron oxide, zinc oxide, gadolinium, cerium and titanium dioxide particles constitute most common metallic nanoparticles (Doria et al., 2012). Metallic nanoparticles are extremely

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

small (~50 nm) and thus a large surface area facilitates integration of relatively higher doses of drugs (Tourinho et al., 2012; Xu et al., 2006; Wong and Liu, 2012). These nanostructures can be synthesized and refashioned with discrete functional groups allowing their easy association with drugs of interest, ligands and antibodies thus paving the way for a broad range of potential applications in targeted drug delivery including carriers for gene and drug delivery and more importantly diagnostic imaging.

One of the most significant biomedical applications of metal nanoparticles are being utilized as contrast agents which lead to the development of various imaging modalities such as MRI, CT, PET, ultrasound, SERS and optical imaging as an aid to image various disease states (Qian et al., 2008) as well as photo thermal and thermo lytic laser therapies. Gold nanoparticles (AuNP`s) are the most commonly used metal based nanoparticles as they are nontoxic and biocompatible and because of their negative charge they are easily functionalized by various biomolecules (Bhattacharya et al., 2007; Hainfeld et al., 2006). AuNP`s also have a diverse drug delivery applications. They have been proved to be potent drug delivery vehicles for the delivery of anticancer drugs such as oxaliplatin (Brown et al., 2010) and trans-mucosal insulin delivery (Joshi et al., 2006). Despite the metallic nanoparticles being biocompatible and inert vehicles their use for drug delivery is a concern as a considerable portion of metal particles can be accumulated in the body following drug administration, possibly triggering toxicity (Wang et al., 2012).

Magnetic Nanoparticles

Magnetic nanoparticles are a class of nanoparticles which can be manipulated using an external magnetic field. Magnetic nanoparticle based drug delivery systems have gained importance because of their ability to target a specific site and enhance uptake at the destination thereby reducing the systemic distribution of cytotoxic compounds *in vivo* resulting in efficient treatment at therapeutically optimal doses. Iron oxide nanoparticles are most commonly used magnetic nanoparticles for therapeutic purposes. The super paramagnetic properties of iron (II) oxide particles facilitate directed delivery of microcapsules by external magnetic fields. Another advantage of using magnetic NPs is their hyperthermic properties, which allows heating the particles after internalization, triggering drug release (Brazel et al., 2006). The paramagnetic particles offer a powerful strategy for directed and localized heating of cancerous cells thereby reducing the risk of destruction of the surrounding healthy tissues caused by conventional heating techniques.

Surface coating of the super paramagnetic nanostructures with materials such as silica and PEG renders stability as well as biocompatibility and surface customization with appropriate ligands like oligonucleotides, proteins and antibodies enables targeted delivery and efficient cellular uptake (Bryant, 2007). Super-paramagnetic nanoparticles are widely utilized as contrast agents in magnetic resonance imaging (MRI) as they possess superior magnetic susceptibility than traditionally employed MRI contrast agents, such as gadolinium (Sonvico et al., 2005), can be used for multiplex immunoassays (Ibraimi et al., 2006), and also for separation of pathogenic cells from normal cells (Bryant, 2007). Thus it can be concluded that ease of accessibility to hidden tumors, minimal side effects and minimal invasiveness gives the magnetic nanoparticles a better effect over classical cancer therapies.

Viral Nanoparticles (VNPs)

VNPs are regarded as one of the most versatile nanomaterials produced by nature. Viruses deliver their cargo of genetic materials by infecting specific host cells with great accuracy, thereby providing an ideal

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

foundation for the development of targeted drug delivery vehicles and tissue specific imaging reagents. Virus like particles (VLPs) are the non-infectious counterparts of VNPs expressed in heterologous systems lacking any genomic nucleic acid. VNPs are extraordinarily robust self-assembling organizations that form exceedingly symmetrical, polyvalent, and monodisperse structures. They present programmable scaffolds and can be generated in substantial quantities in a short time span.

VNP`s of bacteriophage and plant virus origin are particularly advantageous as they are less likely to be pathogenic in humans thereby less likely to induce detrimental side effects. Biocompatibility and biodegradability of the virus nanoparticles offers further advantage over synthetic nanomaterials. The basic assembly of the nanoparticles can be engineered in a number of ways to confer diverse functions to the VNPs. Drug molecules/imaging reagents/quantum dots and/or other nanoparticles can be crammed into the internal void, whereas alteration of the external surface with specific ligands allows targeted delivery and their specific tumor targeting ability *in vivo* is mediated by conjugating them with several ligands including folic acid, transferrin and single chain antibodies (Manchester and Singh, 2006; Singh et al., 2006).

VNPs have been engineered for the targeted delivery of drugs and also for targeted photodynamic therapy (PDT). Fluorescent VNPs could be coalesced with targeting moieties to formulate a potent novel ploy for non-invasive disease specific imaging (Lewis et al., 2006; Wu et al., 2005) and more recently many VNP`s have been developed as a contrast agent platforms for non-invasive imaging techniques such as MRI and PET (Liepold et al., 2007). Although mammalian viruses (e.g. adenovirus) have also been scrutinized in the context of nanotechnology, but presently they are only employed in gene delivery, not drug delivery or imaging (Parker et al., 2008; Singh and Kostarelos, 2009; Steinmetz, 2010).

Ceramic Nanoparticles

Ceramic NPs are particles fabricated from inorganic compounds such as silica and other materials like alumina, titania, etc., which are vastly consistent with biological systems and are inert in nature. Their ultra low size, porous framework, high surface area for adsorption of therapeutic or diagnostic agents and ease of functionalization attributes to their becoming important drug delivery vehicles (Amato, 2010).

Because of their small size (~50 nm) they easily evade uptake by RES and also do not demonstrate any pH related conformational change (leading to change in porosity or swelling). Therefore, these particles can efficiently shield diverse bio-macromolecules, such as enzymes, against denaturation induced by changes in the external pH and temperature. Further these nanoparticles have easily modifiable surface characteristics which aid their conjugation to target specific ligands such as monoclonal antibodies (Lal et al., 2000; Bradley et al., 1990).

Diverse types of drugs, such as anticancer drugs, antibiotics etc. have been incorporated into (Di Pisqua et al., 2009; He et al., 2011) a ceramic nanoparticle by chemical or physical absorption and the drug release is usually controlled by diffusion (Li et al., 2010). The amorphous structure of ceramic nanoparticles enables incorporation of both small and large molecules (Di Pisqua et al., 2009; Kim et al., 2011), DNA absorption and gene transfer (Slowing et al., 2008) permitting their use in combination therapy (He et al., 2011). Ceramic nanoparticles are also used as non-viral vectors for efficient *in vivo* gene delivery (Losic et al., 2010; Mainardes et al., 2010) and as a drug carrier for photodynamic therapy (Losic et al., 2010).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Carbon Nanoparticles

Carbon nanotubes (CNT`s) and nanohorns (CNH`s) are the most commonly used carbon based nano-assemblies. They belong to fullerenes, a family of structures made exclusively of carbon (Sanvicens and Marco, 2008). Carbon nanotubes are cylinders made up of coaxial graphite sheets and can be classified into single-walled carbon nanotubes (SWNT) (one graphite sheet) or multi-walled carbon nanotubes (MWNT) (several concentric graphite sheets) (Qiao et al., 2010). Nano horns are a type of the only single-wall nanotubes– demonstrate properties analogous to nanotubes, are highly pure and can be easily prepared with very low cost (Shiba et al., 2006).

Certain health concerns may be raised by the insolubility of carbon based nanoparticles in most solvents but they can be made water soluble by chemical alteration of their surface qualities and multiple covalent functionalization link them to a wide array of molecules such as nucleic acids, peptides and other therapeutic agents (Vardharajula et al., 2012).

Immobilization of drug in carbon nano-carrier can be obtained by encapsulation of drug in the carbon nanotubes (Arsawang et al., 2011), chemical adsorption on the surface or in the spaces between the nanotubes (Chen et al., 2011), and attachment of active agents to functionalized carbon nanotubes. Encapsulation being advantageous over the other two methods as the drug is protected from degradation during its transport and released only in specific conditions. Drug release from carbon nanoparticles can be electrically or chemically controlled.

Carbon nanoparticles are biocompatible and have unique electronic, structural, and thermal physiognomies making them appropriate vehicles for drug delivery systems. Biological application of CNP`s include their use as drug carriers (anticancer drugs, antifungal agent), fluorescent agents (Wu et al., 2005; Pastorin et al., 2005) and biosensors for DNA and protein detection (Vardharajula et al., 2012). However with the increasing evidences exhibiting the toxicity of carbon NPs, the interest to develop carbon NPs for drug delivery has lessened considerably in recent years (Schipper et al., 2008; Drabu et al., 2010).

Quantum Dots

Quantum dots are semiconducting nanocrystals with diameters ranging from 2-10 nm. They consist of a metalloid crystalline core wrapped inside a semiconductor shell having a large spectral band gap. An electron–hole pair is generated when a QD absorbs energy greater than the spectral band gap of the core semiconductor. The exited nanomaterials on reverting back to its ground state emits a photon and produces a strong fluorescence signals which can be detected by diverse techniques like confocal microscopy, total internal reflection microscopy, fluorescence microscopy, wide-field epifluorescence microscopy as well as fluorometry (Michalet et al., 2005).The QD`s have a broad absorption spectrum, narrow emission spectrum and a high photo stability (Azzazy et al., 2007; Azzazy and Mansour, 2009; Michalet et al., 2005).

Quantum dots can facilitate the detection of numerous cancer biomarkers in blood assays or on cancer tissue biopsies. Presently, one of the fastest growing fields of nanotechnology is the use of highly stable, water soluble, functionalized QDs for biological and biomedical applications. QDs offer new prospects for live cells, *in vivo* imaging and diagnostics aided by their stable fluorescent properties. QDs can also be adapted with diverse biomolecules, such as antibodies, streptavidin, and oligonucleotides for specific target recognition. They have also shown displayed substantial usefulness in genomic investigation and

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

nucleic acid detection (Azzazy and Mansour, 2009; Michalet et al. 2005) and are also utilized for surgical guidance applications (Kim et al., 2004). Regardless of its extensive applications their high toxicity and ambiguous defrayal mechanisms from the body possess a major obstacle for their use in *in vivo* imaging.

APPLICATIONS OF NANOMEDICINE

Diagnostics

Disease diagnosis is an essential element of disease care process. Early detection of disease can lead to less severe therapeutic requirements and better clinical results. To achieve advance disease diagnosis, better understanding of biology and medicine at the molecular level with accurate quantification need to be perceived. Nanotechnology combined with advanced instrumentation has the ability to fulfill this goal. A variety of nanomaterials can be used as labels in diagnostics and detection by virtue of a unique combination of chemical and physical properties that allow detection of low concentrations of disease biomarkers. Nanoparticles like gold nanoparticles (AuNPs) and quantum dots (QDs) are most widely used in diagnosis but other nanotechnological devices like nanocantiliver, nanowire as well as nanobiosensers have promising clinical functions. A brief overview of various types of nanoparticles which are being developed for improved diagnostics is given in Table 1.

Table 1. Nanomedicine in diagnosis of diseases (Roy et al.)

Type of Nanomaterials	Diagnostic Strategy	Advantages
Aptamer-AuNP conjugates	Conjugation of aptamer with AuNPs provides selectivity and specific affinity of aptamers and spectroscopic advantages of AuNPs to detect diseased cells	Sensitive detection and differentiation of different types of target and control cells based on the aptamer
Magnetofluorescent particle systems	Bimodal contrast agents with magnetic and fluorescent properties	Noninvasive breast cancer diagnosis
Antibody conjugated AuNPs	Identification by specific targeting of cell surface proteins with specific antibodies conjugated with AuNPs	Quick and efficient identification and quantification of tumor cells
Semiconductor fluorescent QDs	The fluorescence emitted by these biomarkers enables efficient cancer diagnostics	Facilitates speedy and accurate cancer diagnostics
Semiconductor QDs	Detection of cancer biomarkers aided by intense stable fluorescence	Detection of cancer at molecular levels
Aptamer conjugated NPs	Magnetic NP-aptamer conjugates can be used for selective targeted cell extraction and their fluorescent counterparts can play a vital role in cancer detection with high sensitivity	Enables the collection and detection of multiple cancer cells
Fluorescent europium(III)-chelate-doped NP	Europium nanoparticles along with antihexon (high affinity monoclonal antibodies) provides a sensitive immunoassay for adenovirus detection	Has potential in sensitive screening of viral analytes

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Imaging

Nanoparticles can also be successfully exploited to enhance the service of fluorescent markers for medical imaging of diseased tissue and therapeutics. Current fluorescent markers used in research and clinical diagnostic applications have various drawbacks, such as need of color matched lasers, fluorescence bleaching and lack of discriminatory capacity of multiple dyes, etc. Fluorescent nanoparticles have great ability to overcome these problems and a major advancement of these nanoparticles toward clinical applicability is *in vivo* imaging of tumors and other diseases. Currently, functionalized QDs are highly used for the purpose of imaging and diagnostics. These QDs are highly stable against oxidation for biological and biomedical applications and manifest stable fluorescent properties offering new promises for live cells, *in vivo* imaging and diagnostics. Magnetic iron oxide nanoparticles are also attracting novel contrast agents for biomedical imaging considering their ability of deep tissue imaging, noninvasiveness and low toxicity. AuNPs have also been extensively used for cellular imaging. A brief account of different studies involving use of functionalized nanoparticles for imaging of diseased cells is given in Table 2.

Table 2. Nanoparticles as contrast agents (Roy et al.)

Type of Nanomaterials	Imaging Strategy	Advantages
Poly(alkyl cyanoacrylate) NPs	Poly(alkyl cyanoacrylate) amphiphilic copolymer nanoparticles tagged with the fluorescent rhodamine B for imaging	These NPs can be used for human brain endothelial cell imaging
AuNPs	Surface functionalization of NPs with cancer specific monoclonal antibodies or surface antigen specific RNA aptamer enables specific imaging of healthy and cancerous tissue	These multifunctional NPs can be used for quick and efficient identification and quantification of tumor cells
Streptavidin NPs	Biotinylated anti-Her2 Herceptin antibody and biotinylated Cy5.5 fluorophore to a streptavidin NP provides specific imaging of the tumor	Effective for multimodal imaging of tumor in mice
Multifunctional superparamagnetic iron oxide NPs	The superparamagnetic iron oxide NPs serve as excellent MRI contrast agent.	MRI based cancer monitoring
CNPs	Tumor targeted CNPs can be used as single or dual-modality cancer imaging agents (near-infrared fluorescent dye, Cy5.5, and gadolinium (Gd(III)) ions)	Effective as a dual imaging agent (optical/MR) for cancer treatment
QD-loaded micelles	Lipid conjugated QDs together with herceptin augments tumor cell uptake and hence can be used for concurrent tumor therapy and imaging	Can be used for targeting, imaging and cancer management in the early stages
Carboxyl-functionalized silica-coated QDs	The stable fluorescent property of QDs enables specific imaging	Carboxylation renders stability to the QDs in aqueous solution. These nanoparticles provides specific tumor targeting and can be easily fabricated and thus serve as efficient targeting probes for cell imaging
Fluorescent silica NPs	Fluorescent dye loaded silica NPs can be used for cancer cell imaging. In addition these NPs can also be conjugated to specific biomolecules overexpressed on cancer cells	Cancer targeting and imaging
Polymer-Ag@SiO2 Hybrid Fluorescent NPs	Cationic surface and suitable size allows the nano-formulations to be readily internalized into cells, thus aiding cellular imaging	These nanoparticles are useful for efficient cellular imaging as they produce bright fluorescence and are cyto-compatible

Disease Therapy

Cardiovascular Disease

Cardiovascular disease accounts for largest cause of mortality in the general population. The increasing trends in industrialized and developed country have contributed for the cardiovascular disease. Additionally, aging that alter the cardiovascular function which leads to increase in cardiovascular disease even in the healthy asymptomatic individuals (Dantas et al., 2012). The diverse complexity involved in cardiovascular disease has triggered researchers to develop a novel therapeutic concept for the future. The cost and time duration taken to cure this disease has been a challenge for researchers to develop a therapeutics drug. From 1975-2005 there has been a significant decline in the cardiovascular related deaths (Jemal et al., 2009). This is due to improvement in surgical interventions and diagnostics, as well as awareness and change in life style. More effective treatment has to be implemented to improve the patient outcome, as the reason behind cardiovascular disease is unknown.

Nanotechnology has been extensively developed in last decade. The rapid development in nanoscience has shown a new direction for biotechnology research by studying the properties of biological materials in nanometer which is different from properties of both macro and micro particles. In recent year the wide range work in nanotechnology and nanomedicine has been an advantage to synthesize a new material and device for therapeutic purpose, which are applicable in nanodiagnostics, molecular diagnostics and improvements in the drug delivery. The cardiovascular disease can be promisingly addressed by nanopharmaceuticals products (Lanza et al., 2006). These products have wide application in the treatment of patients suffering from cardiological and vascular diseases.

Worldwide, many researchers have been synthesizing the wide range of therapeutic nanoparticles for cardiovascular disease. Liposome is extensively studied for delivery of therapeutic and bioactive agents in vascular system. Liposome encapsulated with phosphotidylcholine will enrich the high density lipoprotein (HDL) at the lesion. These HDL will remove the cholesterol from the foam cells. This was confirmed by injecting the liposomal formulation in cholesterol fed rabbit for 1 week and it showed a significant decrease in atherosclerotic plaque volume. This suggests that liposome can be a therapeutic formulation for cardiovascular treatment (Barter, 2005). Micelle based strategies can be directed towards the atherosclerotic and thrombotic sites in vascular disease (Ding et al., 2006). Gadolinium (GD) loaded in micelle tagged with anti-CD36 antibody was able to target the macrophages in atherosclerotic human and also helped for MR imaging of artherosclerosis. The efficiency of this nanoparticle can be enhanced by conjugating the specific protein or antibody which helps in targeted delivery. Vascular cell adhesion molecule-1 (VCAM-1) is over expressed on endothelial cells in artherosclerosis which can be account for targeted delivery. The poly (sebacic acid)-co-PEG (PSAPEG) microparticles a polymer based nanoparticle tagged with VCAM-1 antibodies exhibited increased adhesion, binding and accumulation at atherosclerotic lesion sites in ApoE-/-mice (Deosarkar et al., 2008). Polymer based nanoparticles have been used because of its biocompatibility and biodegradable property and provide shapes, surface, size modifications and exhibited good drug loading and drug release parameters for targeted delivery to cardiovascular disease. Metal has been playing an important role in our life. Metal nanoparticles have developed a great interest in biomedical application. The unique properties exhibited by gold make it a noble metal to synthesize nanoparticles which can be applicable to treat the cardiovascular disease. Hence gold based nanoparticles by themselves or in combination with other modalities can be implemented for therapeutic and diagnostic strategies on cardiovascular disease (Gupta, 2011).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

The potential of nanoparticles for biomedical application in cardiology is promising to develop fundamentally new methods of diagnosis and treatment. The nanoparticle mediated therapy can offer surgeons and cardiologists a new ways to treat the cardiovascular diseases with higher efficiency. In future, nanoparticle–drug formulation is anticipated to enter clinical trials and will improve the diagnosis and treatment of atherosclerosis and cardiovascular diseases.

Cancer

Cancer is a broad group of disease involving unregulated growth of cells and forming malignant tumors by invading nearby parts and distinct parts throughout the blood stream. It is leading cause of death out of 58 million deaths that occurred in the world in 2005, 7.6 million is due to cancer. Currently cancer has been treated through chemotherapy, radiotherapy and surgical resection.

Initially, many cancer react to currently available chemotherapeutic and chemo preventives agents, but later it develop several side effect, such as anemia and importantly the generation of cellular resistance. Multiple drug resistance is the important factor for drug resistance in cancer cells. Efflux of most of the hydrophobic anticancer drug through ATP Binding Protein (ABC) causes MDR and thus limits the efficiency of treatment (Gottesman, 2002).

Nanotechnology has provided an innovative and promising strategy to overcome the side effect of chemotherapeutic drugs. The ideal diameter of nanoparticle is 1-100 nm which can carry multiple drugs and target a specific cancer. The nanoparticle mediated drug delivery provides an exclusive advantage for cancer therapy over free drug by enhancing the solubility, stability, pharmocodynamic and pharmokinetic properties of drug. Nano-encapsulated drug increases the drug concentration in tumor tissue through passive and active targeting which reduces the toxic side effect in normal tissue (Alberts and Garcia, 1997; Gabizonn et al., 1994; Uziely et al., 1995).

The efficiency of nanoparticle towards tumor tissue has been increased due to enhanced permeability and retention effect (EPR). The unique physiological property of the tumor microenvironment has revolutionized the anticancer therapy through EPR effect (Maeda et al., 2006). This EPR effect driven passive drug delivery occur only in tumor and limited drug penetration in normal tissue results in reduced side effects (Maeda, 2001). The efficiency of nanoparticle can be significantly increased through active targeting. Several strategies can be applied for active targeting. The receptor mediated targeting in which nanoparticle are surface functionalized with ligands to recognize a specific receptor which is over expressed in tumor tissue. The surface sensitive drug targeting designed to respond to environmental changes in microenvironment of tumor which trigger the drug release from nanocarrier (Torchilin, 2006; Couvreur and Vauthier, 2006). The delivery of therapeutic DNA into tumor cells is another application of Nano therapy to cancer therapy. The nanoparticle should be able to protect active DNA from hydrolytic enzyme and deliver the DNA in to the nucleus in transcriptionally active form. Many Nano compounds such as polymer base and porphyrins have been used to deliver the ssDNA in to the nucleus. The stability of ssDNA increased in physiological relevant condition when assembled with meso-tetra-4-pyridyl-porphyrin-DNA nano-complexes (PDN) induce light dependent cytotoxicity *in vitro* and *in vivo* in bladder cancer concluding the therapeutic property of PDN (Gosh et al., 2014). The *in vivo* tumor imaging can be done by cyanin 5.5 conjugated Nano bubble using ultrasound fluorescence imaging (Mai et al., 2013). The side effect of anticancer drug can be reduced by shielding the drug with nanoparticle. Many researchers have been working on this area. Recently it has been studied that bladder cancer can be treated by inhibiting the histone deacetylase in cancer cells. Belinostat,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

a histone deacetylase inhibitor was loaded in poly (lactide-co-glycolide) (PLGA) nanoparticles and these nanoparticles were coated with novel cell penetrating polymer poly(guanidinium oxanorbornene) (PGON). The result showed that NP-Bel-PGON illustrated a significantly lower IC50 in bladder cells compare to unencapsulated belinostat. Xenograft tumor showed 70% reduction in tumor compare to unloaded NP-PGON (Martin et al., 2013). The two different nanoparticles were used to treat the breast cancer. Silver nanoparticles possess cytotoxic effect with apoptotic feature and suggest the reactive oxygen species generated by silver nanoparticle have significant role in apoptosis (Gurunathan et al., 2013). The polymer based approach was applied to overcome the MDR effect of cancer cell. Doxorubin encapsulated chitosan-graft-D-α-tocopheryl polyethylene glycol 1000 (TPGS) (CT) nanoparticles were found to have IC 50 value of 1.5, which is 199-fold higher than Adriamycin. Both pharmacokinetic and *in vivo* anticancer properties were increased in doxorubicin loaded nanoparticle compare to Adriamycin (Guo et al., 2014). In attempt to increase the drug concentration in colon cells pH mediated drug delivery system were used. The synthetic methacrylic acid-ethyl hexyl acrylate (MAEHA) based copolymer indicated pH-sensitive drug-release behavior in the colon. 5 Fluorouracil drug loaded MAEHA Nano gels accumulated in the tumor microenvironment and induce cell death by apoptosis (Ashwani Kumar et al., 2012). The application of star shaped micelle showed a good stability against dilution with water. Star shaped micelle (PEG/PCL) were less toxic, monodisperse and biodegradable and shown to enhance anticancer activity *in vitro* and *in vivo* in colon cancer (Gao et al., 2013). Human epidermal growth factor receptor-2 (HER-2) mediates number of cellular activity in cancer cells so this receptor is highly expressed in cancer. The antibody against this receptor can be used for targeted delivery. Using HER-2 as a marker for targeted delivery a wide variety of imaging techniques can be developed for early detection of cancer and localization of tumor, as well as monitoring of drug delivery and tissues response to drug treatment. Application of HER-2 is rapidly moving towards clinical research (Wang et al., 2013).

Considerable efforts have been taken by researchers to develop multifunctional nanomedicine with high efficacy and minimized adverse effects. Researchers have developed a nanoparticle which will target highly complex disease pathology of cancer and also reduced the toxic effect of anticancer drug to normal cells. They have also designed and developed strategies to improve the cellular uptake of the therapeutic molecules and their delivery to an organelle of interest. The experimental studies suggested that nanoparticles were capable to deliver a high concentration of drug to tumor site in animal model. The high concentration of drug persists in the tumor site for a long period and had a more potent effect less toxicity when compare to free drugs. This research showed that nanoparticle and other nanostructure appeared to hold great promise for future of cancer treatment.

Neurodegenerative Disease

The neurodegenerative disorders (NDs) is a term for the persistent and progressive loss of structure and function of neuronal subtype. The most widely and commonly occurring diseases due to neural degeneration is Alzheimer's disease (AD) and Parkinson's disease (PD). It is a significant challenge to 21st century scientists to discover a medicine which specifically affects the clinical outcome for mind, motor and behavioral abnormalities. The researchers have discovered many similarities, which relate this disease to one another at sub-cellular level. This discovery offers hope to design a new therapeutic model for many neurodegenerative disorders simultaneously (Rubinsztein, 2006; Bredesen et al., 2006). The nanotechnology-directed method that can specifically target to damaged CNS and rule out the unwanted

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

side effect of the drug. Polymeric nanoparticles are currently used to deliver several drugs, including doxorubicin in to the central nervous system (CNS) (Calvo et al., 2001; Alyaudtin et al., 2001; Kreuter et al., 2003). Nanogels are commonly used to increase the drug and oligonucleotide loading efficiency. *In vivo* experiments suggest higher uptake of nanogel in brain when compare to liver and spleen (Friedrich et al., 2005; Kabanov and Gendelman, 2007). In attempt to increase the encapsulation of drugs in nanoparticle, polymeric nano-liposome was synthesized. The surface modification of nano-liposome increases the systemic circulation time, reduces opsonization in plasma and decreases its recognition and removal by the liver and spleen (Shi et al., 2001; Voinea and Simionescu, 2002). Various application of nano-liposome has been studied to target the central nervous system (Mora et al., 2002; Schmidt et al., 2003). Scientist believe the further advance research will provide a scientific resource need to develop innovative nanomedicine. The improved drug delivery system and early detecting method to neurodegenerative disease will certainly change the clinical outcomes.

Diabetes

Diabetes mellitus is rapidly growing problem often referred as diabetes. In 2030 it is expected that 360 million people will be affected by diabetes (Wild et al., 2004). It is a lifelong progressive disease with serious complication such as blindness and cardiovascular disease (US Department of Health and Human Service, 2008). Permanent cure for diabetes is not available but patient can reduce the disease associated complications through tight control of blood glucose level and insulin therapy. The drawbacks like insulin resistance and chronic treatment causes anaeroxia nervosa, brain atrophy and fatty liver limits the insulin therapy for potent treatment of diabetes (Pickup et al., 2008). To overcome the drawbacks of insulin therapy, nanotechnology can be an efficient tool to treat the diabetes. Nanotechnology has a tremendous potential to make important contribution in diabetes prevention and monitoring blood glucose level. Nanotechnology offers some significant advantage owing to their small size to develop a nanosensor for monitoring the blood glucose level. These properties of nanoparticle offer a research to improve the accuracy, size, life time and usability of nanosensor (Wang, 2008). The oral delivery of protein drug such as insulin encounter major difficulty with low pH of gastric medium and digestive enzyme is a major barrier for protein drug to reach the targeted cell for specific action (Clore and Thurby-Hay, 2004). The nanomedicine can be employed for oral insulin delivery includes prodrugs, (insulin–polymer conjugation) micelles, liposome and nanoparticle of biodegradable polymers. Nanotechnology has a greater potential for the management of diabetes in future and likely to be solving many diabetic related problem.

Musculoskeletal Disorder

The musculoskeletal disorder covers mostly injuries (damage or disorder to muscle joints, tendons, ligaments and nerves). This comprises of hundreds of diseases and syndromes including osteoporosis, osteoarthritis, spinal disorders, severe trauma, and crippling disease and deformities in children. Recent advances in technology made it easier to understand the musculoskeletal disorder at molecular level. The muscle loss can be successfully replaced by suitable skeleton muscle grown through advance research in tissue engineering and regenerative medicine. Nanomedicine has the potential to improve significantly the prevention, detection, diagnosis and treatment of musculoskeletal disease. Recent studies showed multinucleated myotubes are more readily formed on carbon nanotube containing scaffolds and skeleton

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

muscle regeneration was determined using electrospun polyurethane carbon nanotubes scaffolds (Sirivisoot and Harrison, 2004). Thus, different strategies have been applied for treatment of musculoskeletal disorder and have a great potential for monitoring and supporting tissue regeneration.

TOXICOLOGICAL AND ETHICAL ISSUES IN NANOMEDICINE

Today, almost fifty years after Richard Feynman's famous talk significant progress has been achieved in the area of nanomedicine. But, it is still facing many challenges regarding toxicological, ethical and social aspects of nanomaterials employed in diagnostics and treatment of disease. There are various issues which need to be resolved to achieve safe and sustainable development of the nanotechnologies for medicine. Since, this book chapter is focused on nanotechnology implemented in medicine; we will discuss the toxicity and ethics of only engineered nanostructures used in biomedical applications.

Toxicity Issues

With the development of nanotechnology in the area of medicine, concerns about the possible adverse health effects of nanomaterials have been increased (Gulumian and Vallyathan, 2010; Kim et al., 2010). These nanomaterials when exposed to biological system may produce oxidative stress, inflammation, immunotoxicity, genotoxicity and carcinogenicity. Generally, researchers do not evaluate the potential toxicological outcomes of the nanomaterials during the development of a nanomedicine product. The chemistry, solubility, degree of agglomeration, size, shape, and charge of particles may influence the toxic properties of the particles. Again, the toxicity profile of nanoparticles is speculated to be different from that of larger particles of the same chemical composition, by virtue of their extremely small size and high specific surface area (Donaldson et al., 2001; Oberdorster et al., 2005). Furthermore, toxicity may also vary with the route of administration of particles. Although, the systemic assessment of acute and chronic toxicity of nanoparticles, especially those used in nanomedicine, such as drug delivery carriers, has not yet been performed, but the adverse health effects of some of the nanomaterials used in nanomedicine has been reported in literature. It has been demonstrated that crystalline SiO2 may cause carcinogenesis, as well as produce inflammation, irritation, fibrosis, and other adverse health effects (Castranova et al., 2002; Nishimori et al. 2009) investigated that the toxicity of SiO2 nanoparticles is size dependent.

In vitro studies on toxicity of gold nanoparticles (AuNPs) have shown that AuNPs could induce apoptosis and necrosis in different cell types (Goodman et al. 2004; Nagender et al. 2009). Goodman et al. (2004) also proved that anionic functionalized AuNPs exert higher cytotoxicity compared to cationic functionalized AuNPs. Moreover, *in vivo* studies demonstrated that AuNPs impart size dependent toxic effects in mice. Cho et al. (2009) revealed that 13 nm sized PEG-coated AuNPs induce acute inflammation and apoptosis in the liver. Chen et al. (2009) found that AuNP ranging from 8 to 37 nm induced severe distress, fatigue, and change of fur color, loss of appetite, and weight loss. Similarly, toxic consequences of silver nanoparticles (Roberts et al. 2011) and fullerene have been investigated by researchers (Kolosnjaj et al. 2007; Chen et al. 1998). The toxic effects of fullerene were found to be dependent upon the route of administration as orally administered fullerene was considered nontoxic in comparison of intraperitoneally injected fullerene where all the rats died within 30 h post injection (Chen et al. 1998).

Research evidence demonstrates that both single walled carbon nanotubes (SWCNT) and multi walled carbon nanotubes (MWCNT) induce cytotoxicity, oxidative stress, apoptosis, and necrosis *in vitro* (Casey et al. 2008; De Nicola et al. 2009; Hu et al. 2010; Kim et al. 2010). Various studies in rat and mice indicated that pulmonary exposure to CNT by inhalation, intratracheal instillation, or pharyngeal aspiration may lead to granulomatous inflammation and persistent interstitial fibrosis (Han et al. 2010; Mercer et al. 2011). It was recommended that CNT induced fibroblast proliferation and collagen production might be the possible reason for fibrosis (Wang et al. 2010).

Various studies in recent years also revealed the genotoxic and carcinogenic outcomes of engineered nanoparticles (Donaldson et al. 2010; Xie et al. 2011). The mechanism of nanoparticle induced genotoxicity is still not clear and specificity of nanoparticle action on DNA is not well interpreted. Nanoparticles can directly damage the genetic material by interacting with DNA, or indirectly by generation of reactive oxygen species (ROS), or by releasing toxic ions from soluble nanopartilces (Kisin et al. 2007; Barnes et al. 2008). It has been observed that small sized nanoparticles (diameter between 1 nm to 10 nm) can interact with DNA directly through diffusion or by transportation through nuclear pore complex (Barillet et al. 2010). Further, large sized nanoparticles may reach out to DNA only in dividing cells, during mitosis where nuclear membrane dissolves (Shukla et al. 2011; Hackenberg et al. 2011; Asharani et al. 2009; Hackenberg et al. 2010). After reaching to the nucleus, nanoparticles could induce genotoxicity depending upon phase of cell cycle. Nanoparticles could interrupt the DNA replication and transcription by directly interacting with DNA during interphase (An et al. 2010). During mitosis the interaction of nanoparticles with chromosomes could generate clastogenic or aneugenic effects. Nanoparticles might introduce breaks into chromosomes or disturb the process of mitosis, mechanically or by chemical binding. In addition to this, nanoparticles could induce genotoxicity by interacting with various nuclear proteins involved in replication, transcription, and repair of genetic material. In silico analysis exhibited that nanoparticle could interact with DNA mismatch repair proteins like PMS2, RFC3 and PCNA, which might disrupt their function and lead to mutation (Gupta et al. 2011). Interaction of nanoparticles with the mitotic spindle apparatus, centrioles or their associated proteins could result in abnormal multipolar spindle formation, chromosomal alignment and segregation during anaphase and telophase (Huang et al. 2009). Moreover, nanoparticles might disturb the cell cycle checkpoint functions by interacting with and affecting the activity of mitotic check point proteins and create aneuploid or multinucleated cells (Huang et al. 2009). Another mechanism of genotoxicity by nanoparticles is generation of reactive oxygen species (ROS). Free radicles may generate from nanoparticle surface in aqueous suspensions or they can be created by toxic transition metal ion released from soluble nanoparticles (Barillet et al. 2010; Kruszewski et al. 2011). In response to stress build by nanoparticles, cell componants like mitochondria can also produce ROS (Asharani et al. 2009). ROS production can also be triggered by activation of inflammatory cells in response of nanoparticle induced inflammatory reaction (Trouiller et al. 2009). ROS attack may lead to oxidative damage to DNA by oxidation of purine and pyrimidine bases giving rise to DNA base lesions and DNA strand breaks. DNA base lesions can cause mispairing during replication resulting in mutations, thus carcinogenicity (Cooke et al. 2003). It is also reported that nanoparticles may inhibit the antioxidants *in vitro* which consequently enhances the accumulation of ROS and lead to DNA damage (Barillet et al. 2010).

In recent years, carcinogenicity and reproductive and developmental toxicity of engineered nanoparticles has also been studied but the data is still limited. It has not yet been established whether human exposure to engineered nanoparticles produces cancer and adverse reproductive or developmental effects.

As the nanomaterial applications are being introduced increasingly in industry, medicine, and pharmacology, elucidation of potential adverse health effects of nanomaterials is necessary. Moreover, with escalating applications of nanomaterials in medicine, urgent systematic and well-designed toxicological studies are further needed.

Ethical Issues

The booming advancements in nanotechnology have made commentators to urge government agencies and private companies to proactively address the ethical, social and regulatory aspects of nanotechnology and develop judicious policies to curtail its detrimental impacts on the environment and public health. Issues arising from the application of nanomedicine have been discussed below in brief.

Before commercialization of nanomedicine products they must first undergo extensive pre-clinical and clinical testing. Scientist suggests that, if society has to take advantage and benefits of nanotechnology first safety and risk issue of nanotechnology must be understood.

The nanoparticles should pass through stringent and multiple clinical trials to minimize risks pertaining to their use. Despite of the numerous preclinical and clinical trials the ambiguity pertaining to the first exposure of a human subject to a particular category of nanomedicine products cannot be eradicated. Substances that are innocuous at particular dose to a particular species may not be safe to human being and vice versa. It is important for a clinical researcher who is conducting the clinical trial of these substances to keep the above point in mind when they begin testing on human subject. All clinical investigations must incorporate a data and safety monitoring board (DSMB) to identify any precarious trends and minimize potential damage to human subjects and also conduct long term follow ups and assessments to monitor the safety of the nanomedicine products. Further, the researchers should educate people about how nanotechnology can be used in medicines and the benefits and risks associated to it.

Once the product is released into the market another set of ethical issues comes to light and needs to be addressed appropriately. Firstly, a nanomedicine product should be priced so that it is within the reach of general public. For this regulatory bodies should be set up by the government to ensure that the manufacturer of a nano product does not enjoy market monopoly and secondly it is to be decided whether it is fair to use nanomedicine for physical enhancement rather than therapy as this may intensify the already existing socioeconomic inequalities providing an unfair advantage or competitive edge to the rich who can afford enhancements.

CONCLUSION

Nanomedicine has shown great potential to address clinical needs in significant diseases. Nanomedicine can make the care process more effective in terms of clinical outcome for the patient and more affordable for society, by enabling prior diagnosis, improved therapy. There is a wide variety of engineered nanostructures which have been studied and proved efficacious in imaging, diagnosis and treatment of various diseases. However, toxicity and ethical issues of nanomedicine are of particular concern but are often ignored. Fortunately, with the outburst of public and scientific awareness of nanotechnology there is a growing intensity of discussions on these ethical and toxicological issues. The potential applica-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

tions provided by nanotechnology for diagnosis, prevention, and treatment of diseases are currently very broad. Therefore, to pursue the practical application of nanomedicine there is a requirement of simple approaches, and systematic development along with creativity and visionary power.

KEY TERMS AND DEFINITIONS

Cardiovascular Disease: Class of diseases involving heart and blood vessels.

Disease Diagnostics: Identification of nature and cause of a disease.

Drug Delivery: Process of transporting a pharmaceutical compound safely in the body with desired therapeutic effect by using various approaches, formulations and systems.

Genotoxicity: Property of chemical agent to damage the genetic information (genetic material).

Musculoskeletal Disorder: Disorder related to body's muscles, joints, tendons, ligaments and nerves.

Nanomedicine: Applications of nanotechnology for treatment, diagnosis, monitoring, and control of biological systems.

Nanoparticle: Particles or structures having dimensions of 1-1000 nm.

Nanoscale: Scale of one billionth of a meter or 10^{-9} m.

Neurodegenerative Disease: A disease occurred due to loss of structure and function of neuron.

Chapter 49
Nanosuspensions in Nanobiomedicine

Muthukrishnan Lakshmipathy
Sathyabama University, India

Anima Nanda
Sathyabama University, India

ABSTRACT

The tremendous success in developing new nanomaterials and fostering technological innovation arises from the focus on interdisciplinary research and collaboration between physical and medical scientists. The concept of nano-medicine is one of the most important and exciting ideas ever generated by the applications of nanoscience. One of the most challenging tasks in the pharmaceutical industry is the formulation of poorly soluble drugs. The implication of conventional techniques for improving the solubility has gained limited success. Nanoparticles facilitate formulation with improved solubility and efficacy mainly through nanosuspension approach. Techniques such as media milling, high-pressure homogenization, and use of microemulsion have been used for production of nanosuspensions for a novel delivery system. Moreover, they are manoeuvred to patient-acceptable dosage forms like tablets, capsules, and lyophilized powder products. Nanosuspension technology has also been studied for active and passive targeted drug delivery systems, which the chapter highlights on various formulational perspectives and applications as a biomedicine delivery system.

INTRODUCTION

In recent years various technological advances have led to unprecedented improvements in lifestyle, productivity and life span. Moreover there has been a significant burden on global economies and public health as shown by the increases in the outbreak of emerging and re-emerging infectious diseases. Transmission of infectious pathogens to the community has caused outbreaks such as influenza (*A*/*H1N*1 – Swine flu), Dengue fever, Diarrhoea *(Escherichia coli),* Cholera *(Vibrio cholera)* etc throughout the world. Societal changes resulting from mass urbanization (with the mechanisation of agricultural practices and industrialization) and population explosion along with poor water supply and environmental

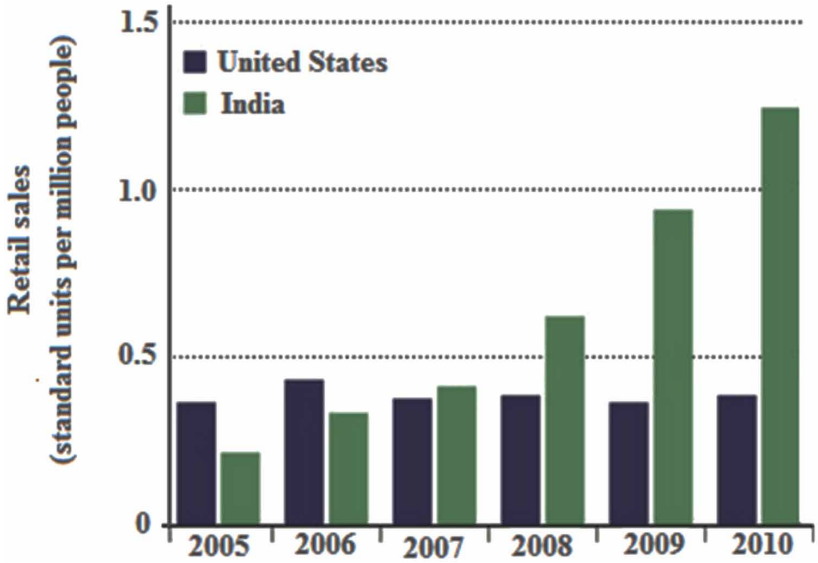
hygiene are the main reasons for the increase in outbreak of infectious pathogens. These events have led to the widespread use of illicit intravenous drugs, which in turn has contributed to the spread of serious blood-borne pathogens like human immunodeficiency virus (HIV) and hepatitis viruses (HBV), and to increased incidence of sub-acute bacterial endocarditis (Hawkey 2008).

The impact of technology on biomedical and clinical practice is among the most valuable changes that have occurred during the twentieth century, notably in the area of prevention and treatment of infectious diseases. The introduction of antibiotics, penicillin (Flemming, 1929) as an antimicrobial agent has pioneered the era of chemotherapy by bringing down the mortality rate with a breakthrough in medicinal field. The different classes of antibiotics that followed served as broad range *wonder drugs* inhibiting the growth of infectious agents by disrupting cell wall synthesis, interfering with DNA replication and protein synthesis (Finberg et al 2004). Furthermore, inappropriate antibiotic usage and inability to produce new antibiotics have introduced extreme selection pressure on bacterial survival. However, the difficulty in identifying the newly proposed crucial bacterial targets by the antibiotics has culminated in the emergence of resistance in the context of antibiotic-mediated stress, an important criterion in bacterial evolution and pathogenesis. The resistance phenomena have several potential mechanisms such as (a) spontaneous / induced mutation, (b) horizontal DNA transfer and (c) alteration of bacterial surface (Figure 1). In addition, bacteria themselves produce a number of antimicrobial products, the most common being the peptide antibiotics. The best studied are the colicins produced by a gram negative bacterium *E. coli* (Riley and Wertz 2002).

The emergence of antibacterial resistance has prompted restrictions on antibacterial use in developed countries like the United Kingdom in 1970 (Swann report 1969), and banning the use of antibacterials as growth-promotional agents by the European Union since 2003. According to US centers for Disease control and Prevention in Atlanta, Georgia drug misuse plays a key factor in the emergence of antibiotic resistance. A survey published earlier this year by the Center for Disease Dynamics, Economics and Policy, found that in developing countries sales of carbapenems ("last resort") increased by nearly six times

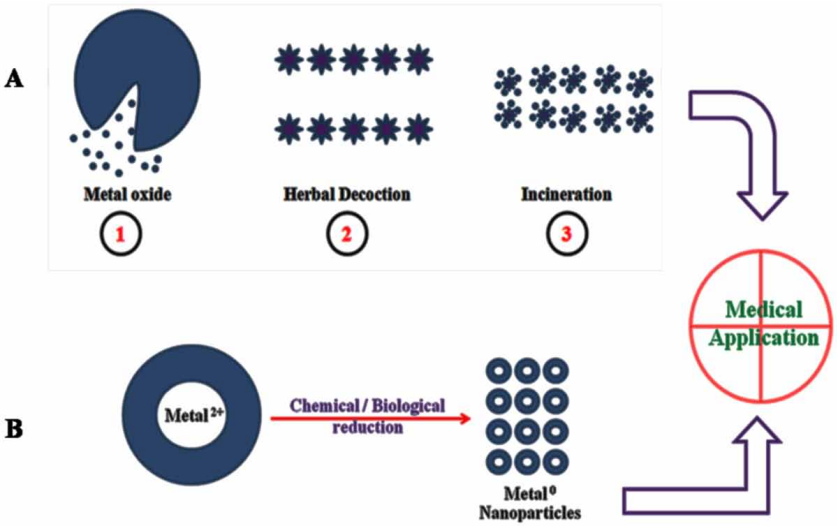
Figure 1. The antibacterial resistance pattern exhibited by a bacterium



EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

between 2005 and 2010 (Figure 2). It is noteworthy to mention that due to limited / poor basic medical facilities, nearly 70% of 1.2 billion rural Indian citizens rely entirely on local pharmacists rather than a Physician and have access to drugs of their sort. The fact that antibiotics have revolutionised medical care in the 20th century has been toppled up by the emergence of superbugs winning the battle against the medical profession. According to reports from Infectious Disease Society of America (IDSA), the containment of emerging superbugs especially the Gram negative bacilli pose a major threat. As a matter of fact, since 2009 only 2 new antibiotics were approved in US and the numbers approved for marketing continues to decline where only few antibiotics were identified in phase 2 or phase 3 trials to contain *E. coli, Salmonella, Shigella* and Enterobacteriaceae members (Boucher et al, 2013).

The increase in bacterial strains that are resistant to conventional antibacterial therapies has prompted the development of bacterial disease treatment strategies which are alternatives to conventional antibacterials. One strategy to address bacterial drug resistance is the discovery and application of compounds that modify resistance to common antibacterials. For example, some resistance-modifying agents may inhibit multidrug resistance mechanisms, such as drug efflux from the cell, thus increasing the susceptibility of bacteria to an antibacterial. Further, phage therapy (Mattery, M 2008), bacteriocins, chelation (Jones 1977), vaccines, biotherapy (Nacar et al 2008), Probiotics (Ljungh et al 2009), Silver (Morones-Ramirez et al, 2013), host defense peptides, antimicrobial coatings – copper alloy surfaces (Samuel 2012) and targeting the trans-translational pathway (Keiler et al 2013) remain some of the strategies in combating the drug resistant microflora.



'Bhasmas' one of the ancient and unique ayurvedic metallic / mineral preparations prevailing since Charak Samhita worked similar to the nanoparticles of modern nanotechnology with the concept of reduction in particle size. The common properties like immune-modulation and anti-aging quality (rasayana) and targeted drug delivery (yogavahi) were observed in all bhasmas that are comparable to the novel medical strategies of modern era (Sanjeetha Paul et al. 2011) (Figure 3). In pharmaceutics, nanoparticles are typically defined as a discrete internal phase consisting of an active pharmaceutical

Figure 2. Sales scenario of carbapenem antibiotics in the United States and India

Figure 3. (A) showing different steps involved in 'Bhasmikarana' converting the zero valent metal to oxide with high medicinal value (1) and mixing it with herbal decoction (2) thereby turning into ashes by incineration (3); (B) shows the metal oxide being reduced by any chemical or biological reducing agent converting it into a zero valent metal nanoparticles

ingredient having physical dimensions, less than 1 micron in an external phase. The use of nanoparticles as a drug-delivery approach for various difficult-to-formulate reagents is an age old practice (Poste et al., 1976; Poste and Kirsh, 1983; Davis et al., 1987; Douglas et al., 1987; Papahadjopoulos, 1988) wherein they can be designed to form *de novo* when exposed to appropriate biological fluid (Shott, 1995).

Nanosuspensions consist of the pure poorly water-soluble drug without any matrix material suspended in dispersion. For a successful formulation, entire range of parameters like solubility, stability, compatibility and photostability need to be considered. Alongside, the switching over to nanosuspensions confers following advantages: enhanced solubility and bioavailability, suitability for hydrophilic drugs, higher drug loading, dose reduction, enhancement of physical and chemical stability and possible passive drug targeting (Vishal R Patel et al. 2011) those of which breach the barriers and resolve issues related to solubility and bioavailiablity.

The current chapter describes the insights about nanosuspensions and also the methods of preparation, merits & demerits, characterization and evaluation parameters. A nanosuspension not only solves the problems of poor solubility and bioavailability but also alters the pharmacokinetics of drug and thus improves drug safety and efficacy.

NANOBIOMATERIALS

Nanostructures

Nanoparticles are gaining scientific interest as they effectively bridge the gap between bulk materials and atomic or molecular structures. A bulk material exhibits a constant physical properties regardless of

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

its size, whereas at the nano-scale level size-dependent properties could be observed: quantum confinement in semiconductor particles, surface plasmon resonance in some metal particles (Ag, Au, Zn) and superparamagnetism (Nanocrystals, quantum dots) in magnetic materials.

- **Nanotubes:** Buckminsterfullerene or bucky balls, single layer of carbon atoms arranged in a cylinder with 1 – 2 nm in diameter and 1mm in length.
- **Nanowires:** Small conducting or semiconducting nanoparticles with a single crystal structure with a large aspect ratio.
- **Quantum Dots:** The number of atoms in a quantum dot range from 1000 to 100,000, makes it neither an extended solid structure nor a single molecular entity.
- **Other Nanoparticles:** It includes a wide range of primarily spherical or aggregated dendritic forms of nanoparticles.

Nanoparticles can be synthesised using variety of methods in order to optimise specific properties of the materials. The properties include, but are not limited, to size (diameter, length, volume) & distribution, symmetry, surface properties, surface coating, purity, ease of manipulation, yield and suitability for scaling up. Nanoparticles used in commercial or deliberate purpose employ methods that are divided into four main groups. These are gas phase processes including flame pyrolysis, high temperature evaporation and plasma synthesis, vapour deposition synthesis, colloidal or liquid phase methods in which chemical reactions in solvents lead to the formation of colloids and mechanical processes including grinding, milling and alloying.

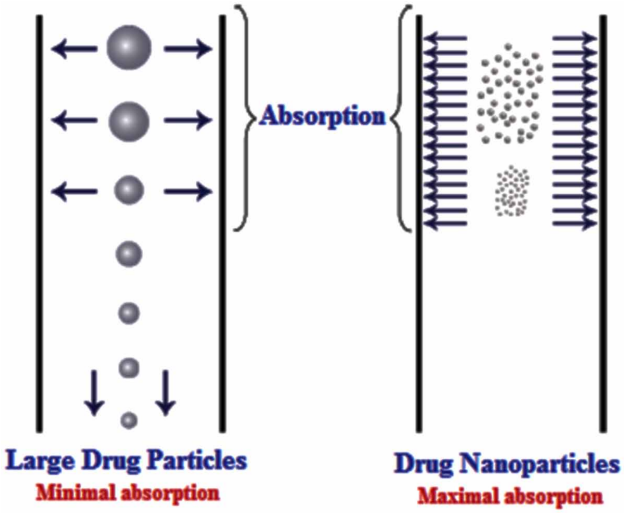
Nanotechnology and Biological Bridge

Most preparations of the building blocks of nanotechnology involve hazardous chemicals, low material conversions, high energy requirements, and difficult, wasteful purifications; thus, there are multiple opportunities to develop greener processes for the manufacture of these materials. Many of the green chemistry principles apply readily to the synthesis or production of nanoscale materials. Green chemistry provides a number of advantages in process development and manufacturing as well as product design. As a result, researchers in the field of nanoparticle synthesis and assembly are focussing their attention on biological systems.

With the bioremediation of toxic metals using bacteria (Stephen and Maenaughton 1999) or yeasts (Mehra and Winge 1991), detoxification often occurs via reduction of the metal ions or formation of metal sulfides. Such microorganisms may then be used as possible nanofactories. Gold particles of nanoscale dimensions can, indeed, be readily precipitated within bacterial cells by incubation of the cells with Au^{2+} ions (Fortin and Beveridge 2000). *Pseudomonas stutzeri*, isolated from a silver mine, when placed in concentrated aqueous solution of $AgNO_3$ formed silver nanoparticles of well-defined size and distinct morphology within the periplasmic space of the bacteria (Klaus-Joerger et al. 2001). See Table 1.

Nanosuspensions: Scope

An important challenge that is being faced by the pharmaceutical industry is the poor solubility of drugs which is now considered to be an area of prime importance in the field of biomedical research. There are about 40% new molecular entities (NMEs) synthesized with advanced drug discovery tools incorporated



EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

with combinatorial chemistry even suffer from solubility and bioavailability related issues (Lipinski 2002). Despite bacterial resistance, tight junctional epithelial cells, transporters and enzymatic barriers also reduce the absorption of drugs. In order to make both ends meet, advanced disinfectant nanomaterials have been proposed as a prime source of prophylaxis. The techniques for solubility enhancement have some limitations for which nanotechnology can be used to resolve the problems associated with these conventional approaches for solubility and bioavailability enhancement (Figure 4).

Figure 4. Absorption rate of drug molecules at nanoscale level (Chaubal 2004)

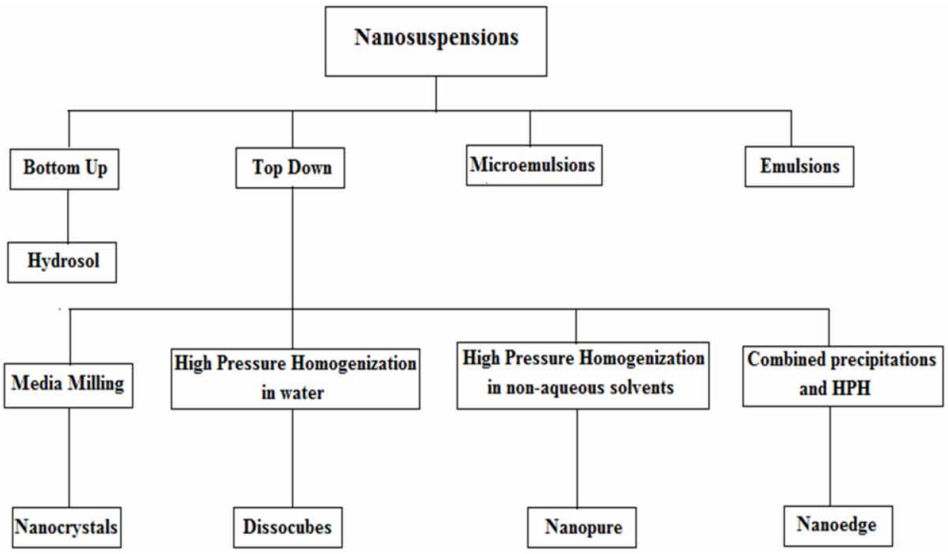
METHODS OF NANOSUSPENSION PREPARATION



There are two methods for preparation of nanosuspensions. The conventional methods of precipitation (Hydrosols) are called 'Bottom Up technology'. In Bottom Up Technology the drug is dissolved in a solvent, which is then added to non-solvent to precipitate the crystals. The basic advantage of precipitation technique is the use of simple and low cost equipments. The basic challenge of this technique is that during the precipitation procedure the growing of the drug crystals needs to be controlled by addition of surfactant to avoid formation of microparticles. The limitation of this precipitation technique is that the drug needs to be soluble in atleast one solvent and this solvent needs to be miscible with nonsolvent. Moreover precipitation technique is not applicable to drugs, which are simultaneously poorly soluble in aqueous and nonaqueous media (Muller et al 2000).

The 'Top Down Technologies' are the disintegration methods and are preferred over the precipitation methods. The 'Top Down Technologies' include Media Milling (Nanocrystals), High Pressure Homogenization in water (Dissocubes), High Pressure Homogenization in nonaqueous media (Nanopure) and combination of Precipitation and High-Pressure Homogenization (Nanoedege) (Chowdary et al 2005; Cornelia et al 2006). Few other techniques used for preparing nanosuspensions are emulsion as templates, microemulsion as templates etc (Patravale et al 2004) (Figure 5).

Media Milling (Nanocrystals or Nanosystems)

The method is first developed and reported by Liversidge et.al. (1992). The nanosuspensions are prepared by using high-shear media mills. The milling chamber charged with milling media, water, drug and stabilizer is rotated at a very high shear rate under controlled temperatures for several days (at least 2-7 days). The milling medium is composed of glass, Zirconium oxide or highly cross-linked polystyrene resin. The high energy shear forces are generated as a result of the impaction of the milling media with the drug resulting into breaking of microparticulate drug to nanosized particles.

Figure 5. Flow chart representing different methods of preparation of nanosuspensions

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Homogenization in Water (Dissocubes)

R. H. Muller developed Dissocubes technology in 1999. The instrument can be operated at pressure varying from 100 – 1500 bars (2800 –21300psi) and up to 2000 bars with volume capacity of 40ml (for laboratory scale). For preparation of nano suspension, we have to start with the micronized drug particle size less than 25μm to prevent blocking of homogenization gap hence it is essential to prepare a presuspension of the micronized drug in a surfactant solution using high speed stirrer (Cornelia et al 2006).

Homogenisation in Nonaqueous Media (Nanopure)

The drugs that are chemically labile can be processed in such nonaqueous media or water-miscible liquids like polyethyleneglycol-400 (PEG), PEG1000 etc. The homogenization can be done at room temperature, 0^{o} C and below freezing point (-20^{o} C).

Combined Precipitation and Homogenization (Nanoedge)

The precipitated drug nanoparticles have tendency to continue crystal growth to the size of microcrystals. They need to be processed with high-energy forces (Homogenisation). They are completely amorphous, partially amorphous or completely crystalline which create problems in long term stability as well as in bioavailability, so the precipitated particle suspension is subsequently homogenized which preserve the particle size obtained after the precipitation step.

NANOSUSPENSIONS AND PROPERTIES

Physical Long-Term Stability

Dispersed systems show physical instability due to Ostwald ripening which is responsible for crystal growth to form microparticles. Ostwald ripening is defined as the tendency for a particle dispersion to grow in diameter over time; by a process in which the smaller particles dissolve because of their higher solubility, with subsequent crystallization onto larger particles to form microparticles. Ostwald ripening is caused due to the difference in dissolution velocity/ saturation solubility of small and large particles.

In nanosuspensions all particles are of uniform size hence there is little difference between saturation solubility of drug particles. The difference in the concentration of the saturated solutions around a small and large particle leads to the diffusion of dissolved drug from the outer area of the large particles. As a result the solution around large particles is supersaturated leading to the drug crystallization and growth of the large crystals or microparticles. Ostwald ripening is totally absent in nanosuspensions due to uniform particle size, which is also responsible for long-term physical stability of nanosuspensions.

Increase in Saturation Solubility and Dissolution Velocity of Drug

Dissolution of drug is increased due to increase in the surface area of the drug particles from micrometers to the nanometer size. According to Noyes-Whitney equation (equation no.1) dissolution velocity increase due to increase in the surface area from micron size to particles of nanometer size.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$Dx/dt = [(D \times A/ h] [Cs\text{-}X/V]$$

where D is diffusion coefficient, A is surface area of particle, dx/dt is the dissolution velocity, V is volume of dissolution medium and X is the concentration in surrounding liquid.

According to the Prandtl equation, for small particles the diffusional distance h decreases with decreasing particle size. The decrease in h increases Cs (saturation solubility) and leads to an increase in gradient (Cs-Cx)/h and thus to an increase in the dissolution velocity. According to Ostwald-Freunddlich equation decrease in particle size below 1μm increases the intrinsic solubility or saturation solubility (Patravale et al 2004; Muller et al 2000).

Internal Structure of Nanosuspensions

The high-energy input during disintegration process causes structural changes inside the drug particles. When the drug particles are exposed to high-pressure homogenisation particles are transformed from crystalline state to amorphous state. The change in state depends upon the hardness of drug, number of homogenisation cycles chemical nature of drug and power density applied by homogeniser.

CHARACTERIZATION OF NANOSUSPENSIONS

The essential characterization parameters for nanosuspensions are as follows. Mean particle size and particle size distribution. The mean particle size and the width of particle size distribution are important characterization parameters as they govern the saturation solubility, dissolution velocity, physical stability and even biological performance of nanosuspensions. It has been indicated by Muller & Peters (1998) that saturation solubility and dissolution velocity show considerable variation with the changing particle size of the drug.

1. **Photon Correlation Spectroscopy (PCS) (Muller & Muller 1984):** Can be used for rapid and accurate determination of the mean particle diameter of nanosuspensions. Moreover, PCS can even be used for determining the width of the particle size distribution (polydispersity index, PI). The PI is an important parameter that governs the physical stability of nanosuspensions and should be as low as possible for the long-term stability of nanosuspensions. A PI value of 0.1–0.25 indicates a fairly narrow size distribution whereas a PI value greater than 0.5 indicates a very broad distribution. Although PCS is a versatile technique, because of its low measuring range (3nm to 3 μm) it becomes difficult to determine the possibility of contamination of the nanosuspension by microparticulate drugs (having particle size greater than 3 μm). Hence, in addition to PCS analysis, laser diffractometry (LD) analysis of nanosuspensions should be carried out in order to detect as well as quantify the drug microparticles that might have been generated during the production process.
2. **Laser Diffractometry:** Yields a volume size distribution and can be used to measure particles ranging from 0.05 – 80 μm and in certain instruments particle sizes up to 2000 μm can be measured. The typical LD characterization includes determination of diameter 50% LD (50) and diameter 99% LD (99) values, which indicate that either 50 or 99% of the particles are below the indicated size. The LD analysis becomes critical for nanosuspensions that are meant for parenteral and pulmonary

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

delivery. Even if the nanosuspension contains a small number of particles greater than 5–6 μm, there could be a possibility of capillary blockade or emboli formation, as the size of the smallest blood capillary is 5–6 μm.

3. **Crystalline State and Particle Morphology:** Assessment of the crystalline state and particle morphology together helps in understanding the polymorphic or morphological changes that a drug might undergo when subjected to nanosizing. Additionally, when nanosuspensions are prepared, drug particles in an amorphous state are likely to be generated. Hence, it is essential to investigate the extent of amorphous drug nanoparticles generated during the production of nanosuspensions. The changes in the physical state of the drug particles as well as the extent of the amorphous fraction can be determined by X-ray diffraction analysis (Muller & Bohm 1998; Muller & Grau 1998) and can be supplemented by differential scanning calorimetry (Shanthakumar et al 2004). In order to get an actual idea of particle morphology, scanning electron microscopy is preferred (Muller & Bohm 1998).
4. **Particle Charge (Zeta Potential):** Determination of the zeta potential of a nanosuspension is essential as it gives an idea about the physical stability of the nanosuspension. The zeta potential of a nanosuspension is governed by both the stabilizer and the drug itself. In order to obtain a nanosuspension exhibiting good stability, for an electrostatically stabilized nanosuspension a minimum zeta potential of ±30mV is required whereas in the case of a combined electrostatic and steric stabilization, a minimum zeta potential of ±20mV is desirable (Muller & Jacobs 2002b).
5. **Saturation Solubility and Dissolution Velocity:** The determination of the saturation solubility and dissolution velocity is very important as these two parameters together help to anticipate any change in the *in vivo* performance (blood profiles, plasma peaks and bioavailability) of the drug. As nanosuspensions are known to improve the saturation solubility of the drug, the determination of the saturation solubility rather than an increase in saturation solubility remains an important investigational parameter. The investigation of the dissolution velocity of nanosuspensions reflects the advantages that can be achieved over conventional formulations, especially when designing the sustained-release dosage forms based on nanoparticulate drugs. The dissolution velocity of drug nanosuspensions in various physiological buffers should be determined according to methods reported in the pharmacopoeia.
6. ***In-Vivo* Biological Performance:** The establishment of an *in-vitro/in-vivo* correlation and the monitoring of the *in-vivo* performance of the drug is an essential part of the study, irrespective of the route and the delivery system employed. It is of the utmost importance in the case of intravenously injected nanosuspensions since the Nanosuspensions: a promising drug delivery strategy *in vivo* behaviour of the drug depends on the organ distribution, which in turn depends on its surface properties, such as surface hydrophobicity and interactions with plasma proteins (Blunk et al 1993, 1996; Luck et al 1997a,b). In fact, the qualitative and quantitative composition of the protein absorption pattern observed after the intravenous injection of nanoparticles is recognized as the essential factor for organ distribution (Muller 1989; Blunk et al 1993, 1996; Luck et al 1997a,b). Hence, suitable techniques have to be used in order to evaluate the surface properties and protein interactions to get an idea of in-vivo behaviour. Techniques such as hydrophobic interaction chromatography can be used to determine surface hydrophobicity (Wallis & Muller 1993), whereas 2-D PAGE (Blunk et al 1993) can be employed for the quantitative and qualitative measurement of protein adsorption after intravenous injection of drug nanosuspensions in animals.

NANOTECHNOLOGY IN MEDICINE: NANOMEDICINE

Applying nanotechnology for treatment, diagnosis, monitoring, and control of diseases has been referred to as "nanomedicine". Although the application of nanotechnology to medicine appears to be a relatively recent trend, the basic nanotechnology approaches for medical application date back several decades. The first example of lipid vesicles which later became known as liposomes were described in 1965 (Bangham et al); the first controlled release polymer system of macromolecules was described in 1976 (Langer et al); the first long circulating stealth polymeric nanoparticle was described in 1994 (Gref et al); the first quantum dot bioconjugate was described in 1998 (Bruchez et al); and the first nanowire nanosensor dates back to 2001 (Cui et al). Recent Studies on new targeted nanoparticle contrast agents for early characterization of atherosclerosis and cardiovascular pathology at the cellular and molecular levels that might represent the next frontier for combining imaging and rational drug delivery to facilitate personalized medicine (Wickline et al 2002) (Table 2).

Nanotechnology-based highly efficient markers and precise, quantitative detection devices for early diagnosis and for therapy monitoring will have a wide influence in patient management, in improving patient's quality of life and in lowering mortality rates, in diseases like cancer and Alzheimer's disease.

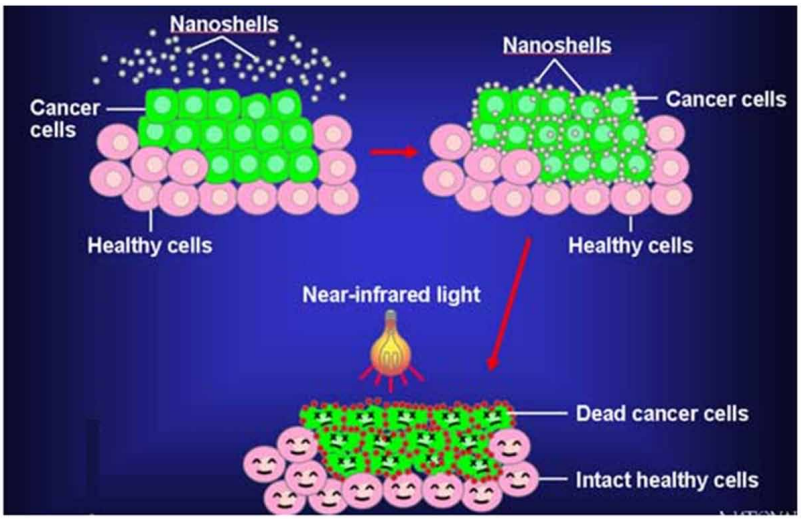
Multi-Functional Nanoparticles

Biodegradable chitosan nanoparticles encapsulating quantum dots were prepared by D. K. Chatterjee and Y. Zhang, with suitable surface modification to immobilize both tumor targeting agent and chemokine on their surfaces. The interactions between immune cells and tumor cells were visualized using optical microscope. Use of Quantum dots in the treatment of cancer is a great advancement in this area. Quantum dots glow when exposed to UV light. When injected they seep into cancer tumour. The surgeon can see the glowing tumour. Nanotechnology could be very helpful in regenerating the injured nerves. During the last decade, however, developments in the areas of surface microscopy, silicon fabrication, biochemistry, physical chemistry, and computational engineering have converged to provide remarkable capabilities for understanding, fabricating and manipulating structures at the atomic level. The rapid evolution of this new science and the opportunities for its application promise that nanotechnology will become one of the dominant technologies of the 21st century.

Table 2. Different categories of Nanoparticles and their applications

Nanostructures	Material	Applications
Nanotubes	Carbon (fullerenes)	Synthetic muscles, Body armor, Nanotube membrane filters, Scaffolds (Haddon et al; Sholl et al 2006;
Nanowires	Metals, semiconductors, oxides, sulphides, nitrides	Real time sensing of biomarker proteins for cancer, Diagnosis of myocardial infarction (Elnathan et al)
Nanocrystals, quantum dots	Insulators, semiconductors, metals, magnetic materials	Fluorescent probes for cellular imaging – Real time tracking
Other nanoparticles	Ceramic oxides, metals	Gene delivery and Tissue engineering

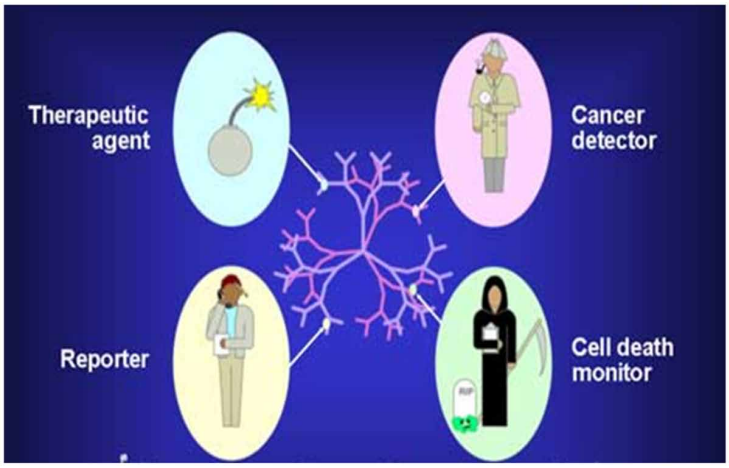
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



Nanoshells

Nanoshells are miniscule beads coated with gold. By manipulating the thickness of the layers making up the nanoshells, scientists can design these beads to absorb specific wavelengths of light. The most useful nanoshells are those that absorb near-infrared light, which can easily penetrate several centimeters of human tissue. The absorption of light by the nanoshells creates an intense heat that is lethal to cells. Researchers can already link nanoshells to antibodies that recognize cancer cells. Scientists envision letting these nanoshells seek out their cancerous targets, then applying near-infrared light. In laboratory cultures, the heat generated by the light-absorbing nanoshells has successfully killed tumor cells while leaving neighboring cells intact (Figure 6).

Dendrimers



Dendrimers are man-made molecules about the size of an average protein, and have a branching shape. They are used to facilitate drug delivery as they behave as a potent diagnostic tool. The shape gives them vast amounts of surface area to which therapeutic agents or other biologically active molecules can be attached. A single dendrimer can carry a molecule that recognizes cancer cells, a therapeutic agent to kill those cells, and a molecule that recognizes the signals of cell death. It has been manipulated in such a way that they release their contents only in the presence of certain trigger molecules associated with cancer. Following drug release, the dendrimers may also report back whether they are successfully killing their targets (Figure 7).

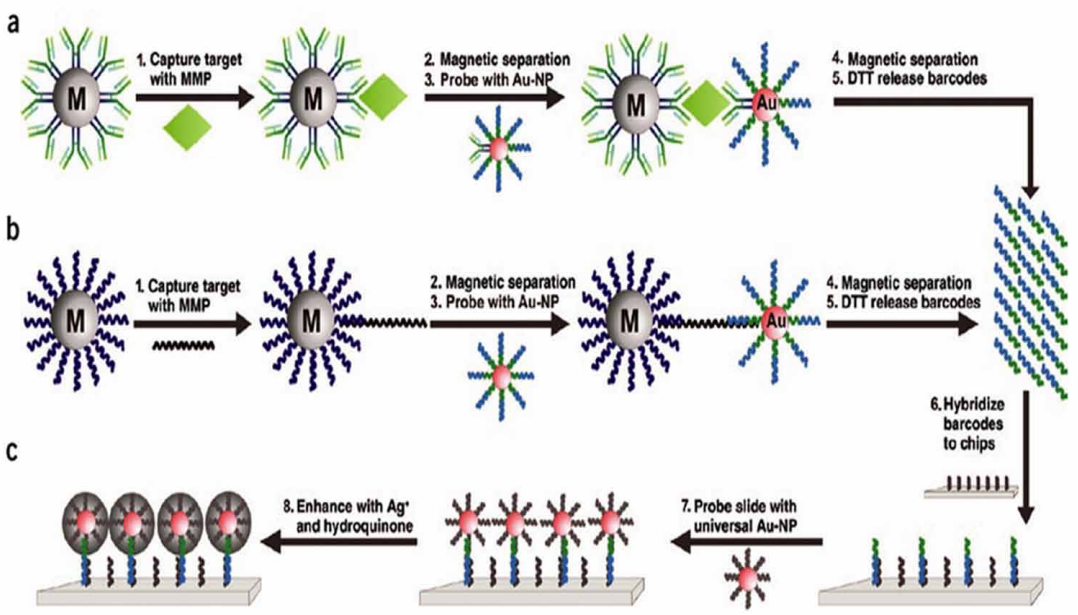
Early Detection of Alzheimer's Disease

Brain represents one of the most complex systems in biomedicine. With an improved understanding of brain functioning, better diagnosis and treatment for neurodegenerative diseases like Alzheimer's is offered by nanotechnology. Presently, the prevailing problem is early detection for effective treatment of the disease. An ideal diagnostic tool for Alzheimer's disease (AD) must have specificity & sensitivity more than 80% for its early diagnosis & excluding other causes. Since the neurodegeneration process begins well before AD becomes symptomatic the potential for early detection is another important characteristic of an ideal diagnostic tool.



Nanotechnology can be the basis of new tools for very early detection of AD. Nanotechnology in the diagnosis of AD came into light after two articles were published in February 2005. The two detection approaches proposed are the Bio-barcode assay (BCA) & Localized surface plasmon resonance (LSPR) technology.

Bio-Barcode Assay

One of the recently developed bio-barcode assay used for the detection of nucleic acid and protein targets without PCR showing high sensitivity for both nucleic acid and protein targets. Two types of particles are used in the assay: (i) a magnetic microparticle with recognition elements for the target of interest and (ii) a gold nanoparticle (Au-NP) with a second recognition agent (which can form a sandwich around the target in conjunction with the magnetic particle) and hundreds of thiolated single-strand oligonucleotide barcodes. After reaction with the analyte, a magnetic field is used to localize and collect the sandwich structures, and a DTT solution at elevated temperature is used to release the barcode strands. The barcode strands can be identified on a microarray via scanometric detection or *in situ* if the barcodes carry with them a detectable marker (Figure 8).

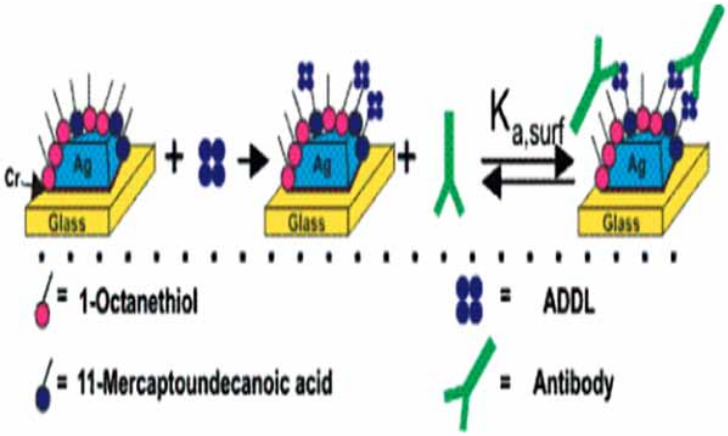
Figure 8. Schematic representation of protein and nucleic acid detection using bio-barcode assay (Hill et al. 2006)

Localized Surface Plasmon Resonance (LSPR) Technology (Heas et al. 2004)



Surface-confined Ag nanoparticles are synthesized using Nanosphere lithography (NSL). Nanoparticle adhesion to the glass substrate is promoted using a 0.4 nm Cr layer. The nanoparticles are incubated in a 3:1 1-octane-thiol / 11-mercaptoundecanoic acid solution to form a self assembled monolayer. Then the samples are incubated in 100 mM 1-ethyl-3-[3-dimethyl-aminopropyl] carbodiimide hydrochloride / 100 nM amyloid-derived diffusible ligands (ADDL) solution. Finally, incubating the ADDL-coated nanoparticles to varying concentrations of antibody completes an anti-ADDL immunoassay. By varying the concentration of anti-ADDL antibody, a surface confined binding constant of 3.0×10^{7} M^{-1} for the interaction of ADDLs and anti-ADDLs measured (Figure 9).

Nanosuspensions in Drug Delivery

Nanosuspensions are also advantageous in achieving quick onset of action for drugs that are completely but slowly absorbed. A study involving a comparison of the pharmacokinetic profiles of a drug in the form of nanosuspension, suspension and tablet forms revealed that the time required to achieve C_{max} was reduced by approximately 50% for the nanosuspension compared to the suspension and tablet. Additionally, the nanosuspension resulted in 2.5 to 4.5 fold increase with improved dose proportionality, reduced variability and increased bioavailability.

Oral Drug Delivery

The oral route is the most preferred route for drug delivery. The efficacy or performance of the orally administered drug generally depends on its solubility and absorption through the gastrointestinal tract. When a drug candidate exhibits poor aqueous solubility or rate limited absorption, it is believed to possess low and/or highly variable oral bioavailability. In such cases, the drug candidate would have to be administered in a larger excess than actually required in order to achieve a therapeutically active concentration, thus making the therapy costly. This could very well be appreciated in case of antibiotics such as atovaquone and bupravaquone.

Nanosizing and Nanosuspensions of such drugs can lead to a dramatic increase in their oral absorption and subsequently bioavailability. The adhesiveness of the drug nanosuspension, increased surface area (due to reduction in particle size by 10–50-fold), increased saturation solubility, leading to an increased concentration gradient between the gastrointestinal tract lumen and blood, and increased dissolution velocity. This enhancement in bioavailability will lead to a subsequent reduction in drug dose, rendering the therapy cost-effective and undue drug dumping in the body.

Parenteral Drug Delivery

The parenteral route is an invasive route and the administration of drugs is critical and often associated with safety issues and biological problems such as allergies and thrombophlebitis (thrombus - blood clot; phlebitis - vein inflammation). Despite all these limitations, the parenteral route still retains its value with special advantages, such as quick onset of action in case of emergency, reduction in dose of the drug and the ability to target the drug quickly to the desired site of action, especially in the case of severe infections. This route is also employed as an alternative to oral administration in case of poor absorption. For administration by the parenteral route, the drug either has to be solubilized or have particle/globule size below 5 μm to avoid the capillary blockade.

The current approaches for parenteral delivery include salt formation, solubilization using co-solvents, micellar solutions (Kim et al 2001), complexation with cyclodextrins and recently liposomes (Dupont 2002). However, there are limitations on the use of these approaches because of limitations on their

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

solubilization capacity and parenteral acceptability. In this regard, liposomes are much more tolerable and versatile in terms of parenteral delivery. However, they often suffer from problems such as physical instability, high manufacturing cost and difficulties in scale-up.

Nanosuspensions appear to be a unique approach to solving the problems mentioned above. From the formulation perspective, nanosuspensions meet almost all the requirements of an ideal drug delivery system for the parenteral route. The nanosized drug particles and absence of any harsh solvents or any toxic ingredient makes the nanosuspensions bypass the limitations leading to improved therapeutic performance. A therapeutic efficacy of paclitaxel nanosuspension against Taxol on mammary 16-C murine tumour model revealed the superiority of paclitaxel nanosuspension over Taxol in reducing the median tumour burden (Merisko-Liversidge et al 2003).

Ocular Drug Delivery

Nanosuspensions support the drugs that exhibit poor solubility in lachrymal fluids. Even though delivery approaches such as suspensions and ointments have been recommended, the therapeutic performance of the water-soluble drugs depends on the intrinsic solubility of the drug in lachrymal fluids. Thus, the intrinsic dissolution rate of the drug in lachrymal fluid (constant inflow and outflow) governs its release and ocular bioavailability. However, nanosuspensions, by their inherent ability to improve the saturation solubility of the drug, represent an ideal approach for ocular delivery of hydrophobic drugs. Moreover, the nanoparticulate nature of the drug allows its prolonged residence in the cul-de-sac, giving sustained release of the drug. To achieve sustained release of the drug for a stipulated time period, nanosuspensions can be incorporated in a suitable hydrogel base or mucoadhesive base or even in ocular inserts. An approach that has recently been investigated to achieve the desired duration of action of the drug is the formulation of polymeric nanosuspensions loaded with the drug. The bioerodible as well as water soluble/ permeable polymers possessing ocular tolerability (Pignatello et al 2002a) could be used to sustain the release of the medication. The polymeric nanosuspensions of flurbiprofen and ibuprofen have been successfully formulated using acrylate polymers such as Eudragit RS 100 and Eudragit RL 100 (Bucolo et al 2002; Pignatello et al 2002b,c).

Pulmonary Drug Delivery

Nanosuspensions compete with the poor soluble drugs delivered as dry powders or as suspension aerosols via pulmonary secretions. The suspension drugs are initially jet milled to achieve particle sizes of microns. As a result, there is a limited diffusion and dissolution of the drug, rapid clearance from the lungs because of ciliary movements, less residence time and deposition of the drug thereby affecting the bioavailability.

The nanoparticulate nature of the drug allows the rapid diffusion and dissolution of the drug at the site of action. At the same time, the increased adhesiveness of the drug to mucosal surfaces (Ponchel et al 1997) offers a prolonged residence time for the drug at the absorption site. This ability of nanosuspensions to offer quick onset of action initially and then controlled release of the active moiety is highly beneficial and is required by most pulmonary diseases. Nanosuspensions could be used in all available types of nebulizer. However, the extent of influence exerted by the nebulizer type as well as the nebulization process on the particle size of nanosuspensions should be ascertained. Budesonide, a poorly water-soluble corticosteroid, has been successfully formulated as a nanosuspension for pulmonary delivery (Muller & Jacobs 2002b).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Targeted Drug Delivery

The need to target specific sites remains one of the major challenges in the drug delivery system. Nanoparticulate systems have shown tremendous potential in targeted drug delivery, especially to the brain (Schroeder et al 1998; Kreuter 2001). Successful targeting of the peptide dalargin to the brain by employing surface modified polyisobutyl cyanoacrylate nanoparticles has been a major achievement in targeted delivery (Kreuter et al 1997).

The shift and drift strategy exhibited by the nanosuspensions makes them a potent candidate for targeted delivery as their surface properties and *in-vivo* behaviour can easily be altered. Natural targeting of macrophages by nanosuspensions has been achieved but could pose an obstacle when macrophages are not the desired targets. Hence, in order to bypass the phagocytic uptake of the drug, its surface properties need to be altered, as in the case of stealth liposomes (Gregoriades 1995; Allen 1997; Lasic et al 1997; Papisov 1998; Woodle 1998; Vyas et al 2000).

The engineering of stealth nanosuspensions by using various surface coatings for active or passive targeting of the desired site is the future of targeted drug delivery systems.

Example 1: *Cryptosporidium parvum*, the organism responsible for cryptosporidiosis was targeted by using surface-modified mucoadhesive nanosuspensions of bupravaquone (Kayser 2001; Muller & Jacobs 2002a). Mucoadhesive bupravaquone nanosuspensions, because of their prolonged residence at the infection site, revealed a 10-fold reduction in the infectivity score of *Cryptosporidium parvum* as compared to the bupravaquone nanosuspensions without mucoadhesive polymers.

Example 2: Similarly, conditions such as pulmonary aspergillosis can easily be targeted by using suitable drug candidates, such as amphotericin B, in the form of pulmonary nanosuspensions instead of using stealth liposomes (Kohno et al 1997). With the advent of polymeric nanosuspensions loaded with drug, it should be possible to target sites, such as the colon, or bacteria, such as *Helicobacter pyroli*, by suitable modifications in the formulation strategy. Overall, nanosuspensions have indicated a good potential in targeted drug delivery.

Pharmacological and Toxicological Aspects

1. **Inhalation:** Exposure to fine particulate dusts leads to pulmonary diseases. The idea that any poorly soluble particles administered in sufficient quantities to the lung can cause an inflammatory reaction has arisen following the demonstration of rat lung overload (Mauderly et al 1994). An important challenge in particle toxicology is to define the quantity that produces inflammation i.e. define the effective dose. Since the late 1980's, toxicological evidence has been emerging indicating that the health effects associated with inhaling ultrafine particles may not be closely associated with particle mass. Early studies with PTFE (polytetrafluoroethylene) particles around 20 nm in diameter showed that airborne concentrations of a supposedly inert insoluble material lower than 50μg m^{-3} could be fatal to rats (Johnston et al., 2000). Since then, many studies have indicated that the toxicity of insoluble materials increases with decreasing particle size, on a mass for mass basis (Faux et al., 2003).

Traditionally the dose of particle administered to the lung, e.g. in an instillation or inhalation situation, is measured in mass. A number of recent studies indicate that the inflammatory response depends on the

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

surface area of particles deposited in the proximal alveolar region of the lungs (Tran et al., 2000; Faux et al., 2003). Thus, particle surface area is a better metric than mass for relating the particle dose to the inflammatory reaction. The precise mechanisms by which these materials exhibit higher levels of toxicity, at smaller particle sizes, have yet to be elucidated, although it is now understood that oxidative stress plays an important role in initiating the chain of events, at the molecular and cellular level, leading to the observed health effects. This was demonstrated in a recent study in which in vitro experiments with a 12 range of poorly soluble particles were conducted (Faux et al., 2003). The data generated by this study were able to demonstrate a relationship between the surface area dose and inflammatory response *in vitro* and the earlier *in vivo* results. This discovery has important practical and theoretical implications.

At the theoretical level, it has highlighted the role of the epithelial cells in the proximal alveolar region, their interaction with the deposited particles and the ensuing molecular events leading to inflammation. At the practical level, it has offered a new approach to interpreting *in vitro* data, a cost effective way of screening new materials for toxicity and an alternative way to animal testing. But particles also exist in a wide range of surface reactivity. Upon deposition in the pulmonary region, such reactivity exerts an oxidative stress on the cells via contact between particle/cell surface area. Consequently, both highly reactive particles with a low surface area and low toxicity particles with a high surface area can exert the same oxidative stress level on the cells they come into contact with. When this inhaled dose reaches a critical level, an inflammatory response occurs. For low toxicity dusts, inflammation will diminish with the cessation of exposure, while for high toxicity dusts, inflammation will persist (Tran et al., 2000). Persistent inflammation is likely to lead to diseases such as fibrosis and cancer. Thus it is important to control inflammation. This can be done by (i) determining the critical dose of particles that initiates inflammation and (ii) setting up exposure limits, according to the relevant metric, so that such a dose cannot be reached within a lifetime exposure scenario. Regulations for the control of airborne particle pollution in the workplaces are currently mass based and vary between particulate types (HSE, 2002b). A proper description of the metric of the particle dose would provide a coherent and consistent body of knowledge on particle toxicity and would, in turn, facilitate a coherent and rational policy for regulating dust exposure in the workplace. Thus, it is apparent that measuring exposures against mass alone is not sufficient. Of the three primary exposure metrics (mass, surface area, and number), there is compelling evidence to suggest that occupational nanoparticle aerosols should be monitored in terms of surface area.

The concentration of nanoparticles might be very small in terms of mass, quite large in terms of surface area and huge in terms of particle number. However, the estimate of surface area does depend on the measurement technique used. Depending on how much detail of the surface is inspected, the measurement can increase significantly. For example, if a prune is seen as approximately a sphere then it has approximately the surface of a smooth sphere of the same diameter; but if the surface of the wrinkles is included then its surface area becomes notably larger. Similarly, with techniques that use adsorption of gas molecules on to the surface of the particle to measure the surface, the smaller the gas molecule chosen, the more it can enter the wrinkles on the particle surface. Nitrogen as the gas molecule for adsorption and measurement of surface area may be a good choice, but other gases (or other surface measurement techniques) are worth considering.

Biologically relevant surface area is likely to be that accessible to biologically relevant molecules in the body. So far, we have assessed the risk of pulmonary disease from inhaled particles. However, it has also been suggested that due to their small diameter, nanoparticles are capable of penetrating epithelial cells, entering the bloodstream from the lungs (Gilmour et al., 2004), and even translocating to the brain via the olfactory nerves (Oberdorster et al., 2004). The ability of inhaled nanoparticles to disperse be-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

yond the lungs suggests that the health effects of nanoparticles may not be confined to the lungs. Also, nanoparticles cleared by macrophages via the mucociliary escalator, can be swallowed and therefore available for transfer to other body organs via the gastro-intestinal compartment. There is also some evidence that smaller particles can be transferred more readily than their larger counterparts across the intestinal wall (Behrens et al., 2002). Little is currently known about the health effects of nanoparticles on the liver and kidneys as well as the correct metric for describing the nanoparticle dose in these organs. Another area which merits further research is the transfer of nanoparticles across the placental barrier.

Exposure to nanoparticles during the critical window of foetal development may lead to developmental damage in the offspring. While a strong case may be made for using aerosol surface area as a dose metric, this may not be universally so. For example, for fibrous aerosols such as asbestos and glass fibre, the currently accepted best approach is to count fibres (i.e. the metric is particle number). Some types of nanoparticle could be considered fibres. Carbon nanotubes for example have high aspect ratios and are durable. They can be manufactured with lengths well within the range conventionally considered to be a fibre (although their diameters are much smaller than we could detect with current standard counting methods which are based on optical microscopy). In any case, it is also necessary to consider characterising exposures against aerosol mass and number concentration until further information and improved methods are available. For each of these exposure metrics, but particularly in the case of mass concentration, size-selective sampling need to be employed to ensure only particles within the relevant size range.

2. **Dermal Exposure:** The importance of dermal exposure to hazardous substances continues to increase. The UK HSE estimate that there are around 85,000 cases of work related skin disease at any one time, with people employed as bricklayers, laboratory technicians and hairdressers being at particular risk (Hodgson et al; 1993). Substances which are considered to be potentially harmful include pesticides such as methyl parathion and solvents such as carbon tetrachloride. Harmful effects arising from skin exposure may either occur locally within the skin or alternatively the substance may be absorbed through the skin and disseminated via the bloodstream, possibly causing systemic effects. Because of this there have been considerable efforts made to develop quantitative methods for monitoring skin exposure.

All of these techniques essentially measure the mass of material deposited onto the skin, either per body part or per unit area of skin exposed. Difficulties in this area are compounded by a multitude of measuring methods which are not easily comparable. The development of a conceptual model of dermal exposure has been beneficial in clarifying some of these issues (Schneider et al; 2000). Systemic effects in particular are unlikely to depend only on the mass on the skin but are more likely to be related to uptake through the skin. Uptake is the flux through the skin and will depend on the concentration through the skin, the area exposed and the duration of exposure. Because of this some authors have suggested that uptake is a more appropriate metric than mass (Robertson and Cherrie, 1995).

A recent review of dermal exposure issues concluded that there was no evidence to indicate that specific health problems are currently arising from dermal penetration of ultrafine particles (HSE, 2000). However, the review conceded that dermal absorption of ultrafine particles (nanoparticles) has not been well investigated and suggested that ultrafine particles may penetrate into hair follicles where constituents of the particles could dissolve in the aqueous conditions and enter the skin. Direct penetration of the skin has been reported by Tinkle et al (2003) for particles with a diameter of 1000 nm, much

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

larger than nanoparticles. It is reasonable to postulate that nanoparticles are more likely to penetrate, but this has not yet been demonstrated. Several pharmaceutical companies are believed to be working on dermal penetration of nanoparticles as a drug delivery route. Any metric proposed to assess dermal exposure to nanoparticles should be biologically relevant and should relate to health effects. Further work including workplace studies and *in vitro* assessment of penetration is required. Based on the current level of knowledge, measurement approaches should include assessment of mass, particle number, concentration, area exposed and duration of exposure.

3. **Ingestion Exposure:** In occupational settings very little work has been done up to now on ingestion exposure. Lead is one of the few materials where the ingestion route has received some attention. Lead paint removal activity can produce high ingestion exposures via hand-mouth contact and food contamination in certain workplaces. A recent study has shown that workers involved in the supply and removal of scaffolding can have particularly high blood lead levels as a result of hand contamination and subsequent ingestion (Sen et al; 2002). No work was identified in relation to ingestion exposure of nanoparticles. Metrics to assess ingestion exposure to nanoparticles should be biologically relevant and (probably) in the first instance should be measures of mass uptake.

In conclusion, scientific evidence, so far, has demonstrated that particle surface area and surface reactivity is likely to be the metric of choice to describe the inflammatory reaction to deposited particles in the proximal alveolar region of the lung. For nanoparticles, their potential dispersal to other organs as well as the possibility of exposure by other routes such as dermal or ingestion mean that possible health risks beyond the lung cannot be ruled out. Further research to generate vital data on the possible mode action of nanoparticles in the extra-pulmonary system is needed in order to assess realistically the health risks to nanoparticle exposure.

CONCLUSION AND SUMMARY

Nanosuspensions appear to be a unique and yet commercially viable approach to combating problems such as poor bioavailability that are associated with the delivery of hydrophobic drugs, including those that are poorly soluble in aqueous as well as organic media. Production techniques such as media milling and high-pressure homogenization have been successfully employed for large-scale production of nanosuspensions. The advances in production methodologies using emulsions or microemulsions as templates have provided still simpler approaches for production but with limitations. Further investigation in this regard is still essential. Attractive features, such as increased dissolution velocity, increased saturation solubility, improved bioadhesivity, versatility in surface modification and ease of post-production processing, have widened the applications of nanosuspensions for various routes. The applications of nanosuspensions in parenteral and oral routes have been very well investigated and applications in pulmonary and ocular delivery have been realized. However, their applications in buccal, nasal and topical delivery are still awaiting exploration. The development of stealth nanosuspensions laced with functionalized surface coatings capable of eliciting passive or active targeting as per the requirement can be regarded as the future step in the nanosuspension research.

KEY TERMS AND DEFINITIONS

Alzheimer's Disease: Alzheimer's disease is a neurological disorder in which the death of brain cells causes memory loss and cognitive decline. A neurodegenerative type of dementia, the disease starts mild and gets progressively worse.

Atovaquone: It is a chemical compound belonging to the class of naphthoquinones with anti-pneumocystic activity.

Bhasmikarana: It is a process of reducing to ashes or calcinations. It is a method employed to convert a metal to its oxide form for a more medicinal application.

Bioadhesive: A property of natural polymeric materials to act as an adhesive or in simple terms any synthetic material designed to adhere to biological tissues.

Bioavailability: It is the measurement of rate and extent to which the administered drug reaches the systemic circulation. It is also one of the essential tools in pharmacokinetics.

Horizontal Gene Transfer: It refers to the transfer of genes between organisms in contrast to the transfer from parent to offspring (vertical). It is considered to be an important factor in the evolution and antibiotic resistance.

Micro-Emulsion: Dispersion made of water, oil and surfactant(s) i.e. an isotropic an thermodyamically stable system with dispersed domain diameter varying approximately from 1 to 100nm, usually 10 to 50nm.

Nanosuspensions: They are defined as a biphasic system consisting of any pure drug particles dispersed in an aqueous vehicle in which the diameter of the suspended particles is less than 1μm.

Phage Therapy: It is defined as the therapeutic use of bacteriophages (virus infecting bacteria) to treat pathogenic bacterial infections. They are more specific in their mode of action compared to antibiotics.

PTFE (Polytetrafluoroethylene): It is a synthetic hydrophobic fluoropolymer used as a lubricant, coating material and a graft material in surgical interventions.

Sustained Release: It is the process of releasing any drug for a predetermined rate and maintaining a constant drug concentration for a specific period of time at minimal side effects.

Targeted Drug Delivery: A method of delivering the drug in such a way that increases the dose in some parts of the body relative to others. It is also an effective and a protective drug interaction strategy against diseased tissue.

Tumor: A condition resulting from the abnormal growth or division of cells forming a mass of tissues (Neoplasm).

Chapter 50
Quantitative Nanostructure–Activity Relationship Models for the Risk Assessment of NanoMaterials

ABSTRACT

In the last few decades, nanotechnology has been deeply established into human's everyday life with a great number of applications in cosmetics, textiles, electronics, optics, medicine, and many more. Although nanotechnology applications are rapidly increasing, the toxicity of some nanomaterials to living organisms and the environment still remains unknown and needs to be explored. The traditional toxicological evaluation of nanoparticles with the wide range of types, shapes, and sizes often involves expensive and time-consuming procedures. An efficient and cheap alternative is the development and application of predictive computational models using Quantitative Nanostructure-Activity Relationship (QNAR) methods. Towards this goal, researchers are mainly focused on the adverse effects of metal oxides and carbon nanotubes, but to date, QNAR studies are rare mainly because of the limited number of available organized datasets. In this chapter, recent studies for predictive QNAR models for the risk assessment of nanomaterials are reported and the perspectives of computational nanotoxicology that deeply relies on the intense collaboration between experimental and computational scientists are discussed.

INTRODUCTION

Due to their small size, nanoparticles, exhibit unique physicochemical properties compared to their bulk counterparts and have already found numerous applications in several biomedical and consumer products. Since the production of nanomaterials increases day by day, the probability that they could

cause adverse effects to human health and the environment rapidly rises. In order to reduce the cost and time demanded for the experimental evaluation of toxicity, computational methods, such as Quantitative Structure-Activity Relationships (QSARs) are being used to predict the potential toxic effects of nanoparticles. In this chapter, the use of Quantitative Nanostructure-Activity Relationship (QNAR) modeling is discussed as a useful tool to predict the biological and toxicological effects caused by diverse types of manufactured nanoparticles (MNPs). Recent studies are reported summarizing the available predictive QNAR models for the risk assessment of nanomaterials (NMs). Finally, the perspectives and the future of computational nanotoxicology that strongly depend on the intense collaborations between experimental and computational scientists are discussed.

BACKGROUND

According to the U.S. National Nanotechnology Initiative (NNI), nanotechnology is defined as the understanding and control of matter at dimensions of roughly 1 to 100 nanometers, where unique phenomena enable novel applications. At this level, the physical, chemical, and biological properties of materials differ in fundamental and variable ways from the properties of individual atoms and molecules or bulk matter (NNI, 2000).

Nanotechnology has become one of the most promising areas of science and it has fairly emerged as one of the central new technologies in the 21st century, drawing worldwide attention (Haase, Tentschert, & Luch, 2012; Fourches, Pu, & Tropsha, 2011). Hitherto, nanotechnology is an important industrial sector in industrialized countries and it has been referred to as the next industrial revolution. The first national nanotechnology program (NNI) was launched in USA in 2000, to serve as the central point of communication, cooperation, and collaboration for all Federal agencies engaged in nanotechnology research, bringing together the expertise needed to advance this broad and complex field (Bondarenko, 2013). Nanotechnology has found numerous applications in materials science, medicine, cosmetics, or clothing, bioimaging, sensing and electronics (Fourches et al., 2011; Makarucha, Todorova, & Yarovsky, 2011). Nanomedicine, for instance, an emerging application of nanotechnology, provides the possibility of delivering small drug molecules to specific cells, by developing novel diagnostics and therapeutics (Wang, Byrne, Napier, & DeSimone, 2011).

Up to date, several classifications of nanomaterials have been proposed. According to the European Committee for Standardization (CEN) Technical Specification, nanomaterials can be classified into two broad categories, namely nanoobjects and nanostructured materials (Figure 1) (Haase et al., 2012).

According to Hansen, Larsen, Olsen and Baun (2007) and depending on the location of the nanoscale structure in the system, nanomaterials are organized into three broad categories, as it depicted in Figure 2.

For simplicity, nanomaterials can generally be organized into four types (Messina, Olsina, & Stege, 2013):

1. Carbon-based materials,
2. Metal-based materials, including metal oxides and quantum dots,
3. Dendrimers, and
4. Composites.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 1. Classification of nanomaterials according to CEN/ISO TS 27687; Nanoplates have one external dimension, nanorods two orthogonal dimensions, and nanoparticles all three orthogonal dimensions in the nanoscale.
(ISO 2008).

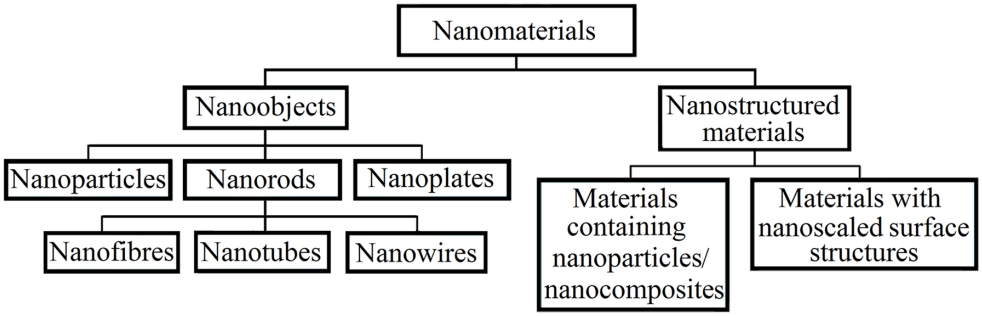

Figure 2. Classification of nanomaterials according to Hansen et al.

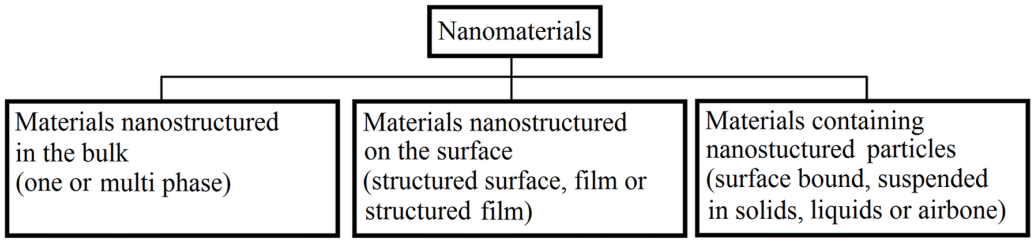

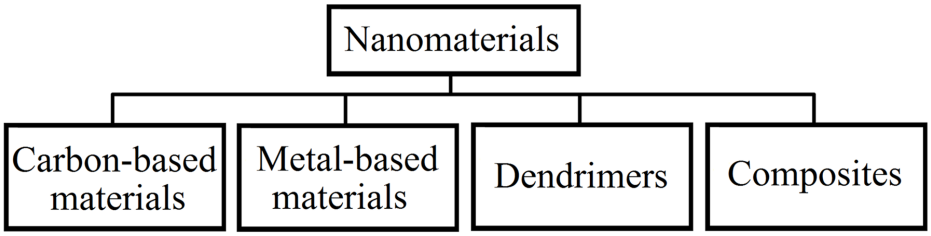

Figure 3. Classification of nanomaterials according to Messina et al.

Nanomaterials can be naturally present as dust from forest fires and volcano's activities, biogenic magnetite, viral particles, and even protein molecules, such as ferritin. Nano-sized materials can also be produced unintentionally by anthropogenic sources, such as from combustion by-products. Engineered nanomaterials (ENMs) designed for a specific purpose or function are useful due to their small size and large surface-area to volume ratio, which makes them important as catalysts in chemical reactions, and they have desirable properties as drug delivery devices, as imaging agents in medicine, and in consumer products such as sunscreens, textiles and cosmetics (Clark, White, & Silbergeld, 2011).

A limited number of nanoparticles are known about their toxicity, including possible mutagenic and/or carcinogenic effects (Dreher, 2004). Recent studies have shown evident toxicity of some nanoparticles to living organisms, including human body, as well as their potentially negative impact on environmental

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

ecosystems and highlight the potential risk related to the development of nanoengineering (Gajewicz et al., 2012). It is expected that nanomaterials can become present in the environment, including air, water and soil, during their life cycle of production, distribution, or usage. In the last decade, a new subdiscipline of ecotoxicology has been developed, that is called nanoecotoxicology with the first scientific papers emerged in the literature in 2006. The ecotoxicological problems derived from the use of NMs and their present in the natural environment and the ecosystems are challenging tasks for environmental toxicologists and ecological risk assessment specialists (Kahru, & Ivask, 2013). It is commonly accepted that there is insufficient knowledge regarding the harmful interactions of nanoparticles with biological systems as well as with the environment.

Since the manufacture and use of nanomaterials are increasing, humans are more likely to be exposed occupationally or via consumer products. Workers in nanotechnology-related industries and small workshops have an increasing risk to be exposed to ENMs. Likewise and as any new technology, the main concerns are about environmental pollution, the toxicity in aquatic organisms and their environmental impact in ecosystems. Lack of available data and low adequacy of experimental protocols prevent comprehensive risk assessment. Toxic effects of nanomaterials on different organisms have already been described (Klaine, 2008; Baun, Hartmann, Grieger, & Kusk, 2008), but measurements of environmental concentrations of ENMs are almost completely absent. The high cost and the long time of the *in vivo* toxicological studies are barriers on testing all of the marketed consumer products incorporating nanoparticles. Our knowledge of the human health effects and environmental concentrations of engineered NMs or NPs is incomplete and also the mechanisms of the interatomic interactions between nanoparticles and biological molecules are not sufficiently understood.

Natural and manufactured/engineered nanoparticles due to their unique properties and biological activity gain the access into the human body through the main ports of body's entry, such as the skin, the gastrointestinal tract and the lungs. Starting from these entries and through the fine capillaries, NPs may also permeate deeper in the organism and tissues, and travel throughout the body interacting with other tissues and organs. Several pharmacokinetic studies have showed that nanoparticles can be found in various cells, in mitochondria, fibroblasts, lipid vesicles, nuclei and macrophages. They have direct contact with cell surface and may lead to the formation of reactive oxygen species (ROS) that results in oxidantive stress and inflammation. Furthermore, they can cause peroxidation of lipids in cellular membranes, resulting in cell damage, and the up-/down-regulation of genes encoding a specific protein involved in inflammatory processes (Gajewicz et al., 2012). Nanoparticles are associated with genotoxicity and neurotoxicity. The effects of nanoparticles on the immune system are still unclear.

Concerning to the ecosystem, there are numerous review articles on the behavior of nanoparticles in aquatic environments (Delay, & Frimmel, 2012), whereas, up to date there are no published reports on the concentration of manufactured nanoparticles in the air (Handy, & Shaw, 2007). Nanoparticles in aquatic systems can be formed by natural abiotic or biotic processes, of natural origin but induced by human activity (e.g. mining), engineered NP that enter aquatic systems incidentally, or engineered NP that are intentionally added to these systems, including nanoscale zero-valent iron ($Fe^{(0)}_{(NP)}$) for removal of As(III) from groundwater (Delay, & Frimmel, 2012). Toxicology studies on animals showed that some types of nanoparticles in the air could cause lung disease.

The potential negative health effects of particles depend on some key parameters, such as the dose, dimension, and durability. Nonetheless, it has been showed that the astonishing physical and chemical properties of nanoparticles that are attributable to their small size differ from these properties of particles at the micro or macro scale (Gajewicz et al., 2012; Nel, Xia, Madler, & Li, 2006). Especially,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

ultrafine particles are known to have greater adverse health effects than larger particles. In addition, by decreasing for instance the size of gold samples induces color changes from bright yellow through reddish–purple up to blue. The novel and unique properties of nanoparticles (i.e. physicochemical and/or biological characteristics) are often determined by the relationships between their size, surface, and structure. Recent studies have shown that the reduction of particle size increases the surface area and so, smaller nanoparticles have greater surface area (Gajewicz et al., 2012). The toxicity of nanoparticles according to Oberdörster *et al.* (2005) may depend not only on the particle size but on other features with vital importance, such as size distribution, agglomeration state, shape, porosity, surface area, chemical composition, structure-dependent electronic configuration, surface chemistry, surface charge, and crystal structure. To date, the interrelationship between nanoparticles properties and their biological effects remains unclear.

The fact that nanomaterials consist of many substances (primarily composed of carbon, silver, zinc, silica, titanium and gold) and can be found in many sizes and shapes and with a variety of surface coatings, complicates the risk assessment. Studies have showed that nanomaterials after their release of into the environment may tend to agglomeration, aggregation, adhesion, diffusion, dissociation, degradation, adsorption of different species, and bioaccumulation in organisms as well as biomagnifications in trophic pyramids, processes that depend not only on their size/shape, but also on the local environmental and cellular conditions (Gajewicz et al., 2012). Therefore, an assessment of the physical, chemical and biological properties of nanoparticles in each state and case must be made in order to consider their exposure, fate, transport, and transformation in the environment.

Most researchers have focused on the adverse effects to human health and the environment of one single type of particle or several particle types of the same substances, such as,

1. Metal oxide nanoparticles and
2. Carbon nanoparticles, respectively.

Metal oxides (MO_x) is an important group of engineered NPs due to their limited size and a high density of corner or edge surface sites, which allow them wide applications. They can adopt a vast number of structural geometries with an electronic structure that can exhibit metallic, semiconductor or insulator character. They are produced in large quantities and used frequently in cosmetics, sensors and sunscreens, self-cleaning coatings, and textiles. In addition, MO_x's can be used as catalysts for redox reactions in engineered systems and natural environments, water-treatment agents and materials for solar batteries (Puzyn et al., 2011). The most studied oxide systems are Al_2O_3, MgO, ZrO_2, CeO_2, TiO_2 and SiO_2. Less studied nanostructured oxide systems include Zn, Fe, Cu and Sn.

In the last quarter of century, various carbon nanostructures such as fullerenes, carbon nanotubes (CNTs) and graphene have been given great importance in the field of nanoscience and nanotechnology.

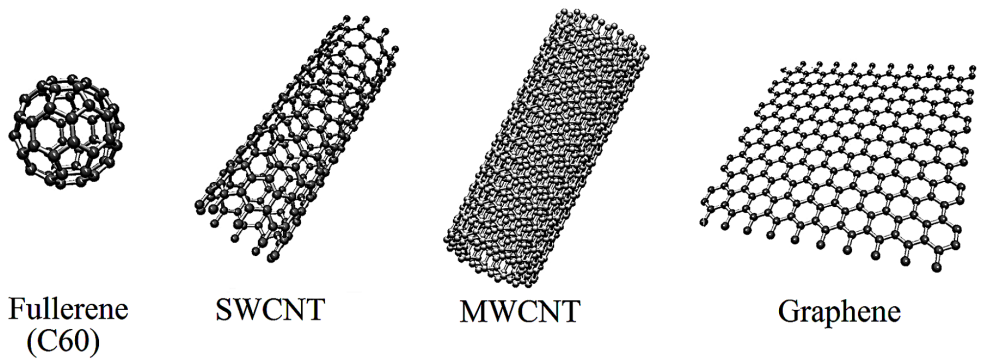
Fullerenes are ball shaped hollow structures composed of carbon atoms. The most important fullerene is known C_{60} that has a football-like structure comprising 12 pentagons located around the vertices of an icosahedron and 20 hexagon rings placed at the centers of icosahedral faces (Figure 4). Fullerenes have numerous applications in personal care products, as well as they have several potential uses in medicine.

Carbon nanotubes' potential applications in medicine are reported in several studies (Zhou et al., 2008). CNTs can enter various organs and cells, so they can function as intracellular probes, drug carriers, imaging agents, DNA modulators, and other medical devices on the condition that they are biocompatible. There are two structural forms of carbon nanotubes (Figure 4):

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

1. Single-walled carbon nanotubes (SWCNTs) and
2. Multi-walled carbon nanotubes (MWCNTs).

Graphene, the thinnest but strongest material, is a 2D-sheet composed of carbon atoms characterized by sp^2 hybridization (Figure 4). Some of the applications of carbon nanotubes and graphene are in photodetectors, drug systems, and bioimaging.



It is interesting that the unique properties of metal oxide nanoparticles can be the cause of potential toxic effects. The general results of a study showed that there was a high variation among different metal oxide nanoparticles concerning their ability to cause toxic effects (Karlsson, Cronholm, Gustafsson, & Möller, 2008). It has been showed that nano-TiO_2 causes ROS stress and DNA damage in lymphocytes (Kang, Kim, Lee, & Chung, 2008). Furthermore, similar to TiO_2 nanoparticles, nano-sized silicon oxide (SiO_2), and zinc oxide (ZnO) can induce pulmonary inflammation in rodents and humans (Gordon et al., 1992; Rehn, Seiler, Rehn, Bruch, & Maier, 2003; Chen, Chen, Dong, & Jin, 2004).

Similarly, the carbon-based nanomaterials have adverse effects to human's health and ecosystem. Potential short- and long-term toxicity of fullerenes, CNTs and graphene should be carefully investigated before full implementation of these in various biological and commercial applications. Although fullerenes, CNTs and graphene are carbon-based nanomaterials, each of them has different distinctive properties. Different studies have showed that fullerene particles C_{60} suspended in water are characterized by antibacterial activity against *Escherichia coli* and *Bacillus subtilis* (Lyon, Fortner, Sayes, Colvin, & Hughe, 2005) whereas they exhibit cytotoxicity to human cell lines (Sayes et al., 2004). In particular, the cytotoxicity of C_{60} is lower than that of SWCNTs, MWCNTs and graphite (Gajewicz et al., 2012). Therefore, risk assessments of carbon nanomaterials are to be taken on a case-by-case basis to assure high safety.

Quantitative Nanostructure-Activity Relationship (QNAR)

As aforementioned, the traditional toxicological evaluation of the different developmental stages involves expensive, time-consuming and labor-intensive technical procedures. To reduce all above factors, computer-based approaches have been widely developed. The computational methods are a significant tool since they can be utilized to predict the toxicological (biological generally) effects of nanoparticles

Figure 4. The structures of carbon nanoparticles: fullerene ($\mathbf{C}_{60}$), single-walled carbon nanotube (SWCNT), multi-walled carbon nanotube (MWCNT), and graphene

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

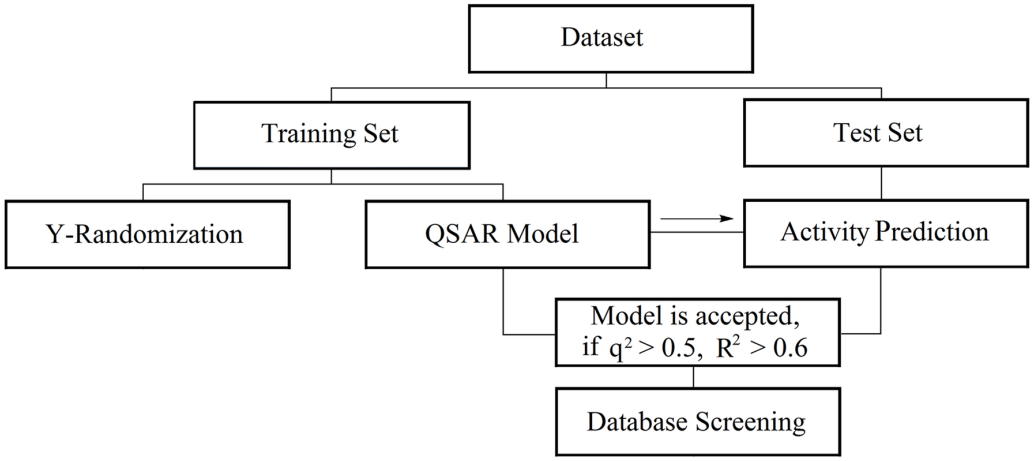
solely from their physical and chemical properties. Subsequently, by screening *in silico* libraries of virtual nanomaterials, the NMs with the most promising predicted properties can be prioritized. Thus, the costly toxicological studies focus only on a small number of selected and/or rationally designed NPs.

Since 2007, REACH (Registration, Evaluation and Authorization of CHemicals) established by European Parliament and Council, is formally a new chemical management system. One of REACH's key goals is to reduce the number of compounds that require toxicity testing in animals (Schaafsma, Kroese, Tielemans, Van de Sandt, & Van Leeuwen, 2009). REACH legislation has encouraged and foresees the use of alternative *in silico* methods, such as the Quantitative structure-activity relationship (QSAR), to avoid using the animals for the risk assessment of chemicals.

The modeling of manufactured nanoparticles (MNPs) is a major challenge for scientists especially due to the high structural complexity and diversity of MNPs. Therefore, it is very difficult to develop quantitative parameters capable of characterizing the structural and chemical properties of MNPs. The difficulty becomes greater with the absence of experimental data that is required for the validation of computational methods. Puzyn Leszczynska and Leszczynski (2009) first suggested that QSAR modeling can be applied in computational nanotoxicology studies but indicated that no universal QNAR model can accurately assess the toxicity of all possible MNPs.

Similar to general QSAR modeling strategies, the overall objective of QNAR modeling is to develop a mathematical and statistically significant model. To enable the modeling of MNPs, every particle should be described by numerical parameters, called descriptors that are calculated or experimentally measured. The model describes the relationship between the measured biological or toxicological activity profiles of MNPs. The properties such as size, shape, morphology, surface area are usually measured experimentally. Unfortunately, these data for the nanostructures are often absent, so there is an obvious need to develop and employ computational descriptors of MNP structure. To date, thousands of zero-dimensional (0D, referred to atom and bond types counts), 1D, 2D, and 3D (even 4D and 5D!) descriptors have been invented and there are several commercially available software packages (i.e. MOE, DRAGON, CODESSA, SYBYL) to compute several descriptors for any single compound. However and at the moment there are no software packages applicable to MNPs due to their complexity of structure (mixture of organic and inorganic patterns in the same molecule, repetition of structural motifs). Therefore, the descriptors for MNPs have to be measured experimentally until novel and more appropriate types of the descriptors will be developed. To enable QNAR studies, there should be sufficiently large amount of data and a well-defined protocol for model selection and validation should be used.

Models can be built using complex machine learning algorithms, linear or non-linear methods, such as Multiple Linear Regression (MLR), Artificial Neural Networks (ANN), Support Vector Machine (SVM), Random Forest (RF), and k Nearest Neighbors (kNN) or Naïve Bayesian Classifier (NBC), Linear Discriminate Analysis (LDA), and Logistic Regression (LGR).



The QSAR modeling workflow consists of three steps (Figure 5):

1. Data preparation (compounds and corresponding descriptors),
2. Model building, and
3. Model validation.

Initially, the set of compounds is divided into training and test set. The training set contains the majority of the data, whereas the test set is smaller (~25-30%). The model is derived using only the compounds of training set, and then it is applied to test set to assess their properties. The splitting of the dataset

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 5. The workflow of QSAR modeling

can be done randomly or using a variety of selection techniques. Leave-one-out (or Leave-many-out), cross-validation and Y-randomization are applied to evaluate both prediction and robustness of model. A good model should predict both training and test set (Golbraikh, & Tropsha, 2002) and satisfy some conditions. Finally, the QSAR model can be used increasingly in chemical data mining and combinatorial library design.

A QSAR model to be appropriate validated in a regulatory environment should comply with the OECD guidelines:

1. A clear definition of the endpoint,
2. The use of an unambiguous algorithm,
3. Necessity of defining applicability domain,
4. Calculating appropriate measures of goodness-of-fit, robustness and predictivity, and
5. Providing a mechanistic interpretation, if possible (retrieved from http://www.oecd.org).

Predicting biological effects of MNPs prior to their synthesis is of outmost importance, and therefore the development of efficient computational approaches is very significant. With the QSAR methodology, if toxicological data are available only for some compounds in a group, the toxicological properties of the other compounds in the same group can also be determined using only calculated molecular descriptors and a suitable mathematical model.

Analyzing data presented in the literature, it is concluded that even if a class of nanoparticles with a similar structure is tested with the same assay and protocol, the number of tested compounds is often insufficient to perform comprehensive internal and external validation of a model and to calculate the appropriate predictivity in QSAR. For instance, Limbach *et al.* (2005) studied the *in vitro* cytotoxicity of seven metal oxide nanoparticles in human and rodent cells and proposed two different rankings: (i) Fe_2O_3 ≈ asbestos > ZnO > CeO_2 ≈ ZrO_2 ≈ TiO_2 ≈ $Ca_3(PO4)_2$ and (ii) ZnO > asbestos ≈ ZrO_2 > $Ca_3(PO4)_2$ ≈ Fe_2O_3 ≈ CeO_2 ≈ TiO_2, respectively. In another study (Brunner et al., 2006), the same research group found that the formation of reactive oxygen responsible for the toxicity of four metal nanoparticles (TiO_2, Fe_2O_3, Mn_3O_4, and Co_3O_4) toward the human lung epithelial cells was their chemical composition. It

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

must be highlighted that a dataset containing a significant number of compounds is essential to build an appropriately validated QNAR model.

To date, a limited number of QNAR studies and only few reviews concerning the risk assessment of nanoparticles have been reported in the literature (Puzyn et al., 2009; Cattaneo et al., 2010; Burello, & Worth, 2011; Luan et al., 2014). The majority of published QNAR models focus primarily on the predictions of physicochemical properties of nanoparticles (QSPR), e.g. solubility and Young's modulus of carbon-based nanostructures (Toropov, & Leszczynski, 2007; Toropov, Leszczynska, & Leszczynski, 2007; Martin, Maran, Sild, & Karelson, 2007). In this chapter, only the QSAR models for nanotoxicity are reported. In Table 1 eleven datasets available in the literature for QNAR modeling are listed. From these only three satisfy the criterion of relatively large sample size (n>50) and are highlighted in the Table.

In 2011, Cohen and his co-workers (Liu et al., 2011) developed a classification-based cytotoxicity nanostructure–activity relationship (nano-SAR) using the high-throughput toxicity screening data for transformed bronchial epithelial (BEAS-2B) cells exposed to nine metal oxide nanoparticles. The model was based on a logistic regression and is validated following accepted QSAR validation guidelines. The High Throughput Screening (HTS) data were first processed to identify and label toxic versus non-toxic events relative to an unexposed control cell population. The best-performing model with 100% classification accuracy was based on three descriptors: the atomization energy of the metal oxide (E_{MeO}), the period of the nanoparticle metal (P_{Me}), and the nanoparticle primary size (d), in addition to the nanoparticle volume fraction (θ_{v}) and was expressed by the following equation:

$$ln\frac{\mathrm{P}\left(NP \in T\right)}{\mathrm{P}\left(NP \in N\right)} = 3600.6 \; + \; 103.5 \; \times \; d \; + \; 9.5 \; \times q_v + \; 97.6 \; \times P_{Me} - 58.5 \; \times E_{MeO}$$

where P($NP \in T$) and P($NP \in N$) are the probabilities of a nanoparticle being toxic and nontoxic, respectively.

Table 1. List of available nanoparticles datasets

No.	Dataset	Sample Size	Description	Endpoint
1	Liu et al., 2011	9	Metal oxide NPs	Cytotoxicity
2	Zhang et al., 2012	24	Metal oxide NPs	Cytotoxicity
3	Weissleder et al., 2005	**146**	1 metal core	Cellular uptake in PaCa2
4	Shaw et al., 2008	**51**	4 metal cores	Apoptosis
5	Puzyn et al., 2011	17	Metal oxide NPs	EC_{50} of *E. coli*
6	Sayes et al., 2010	24	MNPs	Cellular membrane damage
7	Gaudin et al., 2012	10	MIL-88B(Fe) MOFs	Caffeine uptake
8	Shinohara et al., 2009	20	fullerene C_{60} NPs	Mutagenicity
9	Zhou et al., 2008	**84**	f-MWCNTs	Protein binding, cytotoxicity, immune responses
10	Tassa et al., 2010	20	MNPs	Ka, Kd of aurora A kinase
11	Luan et al., 2014	41	Metal oxide NPs	Cytotoxicity

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

The authors suggested this successful modeling approach on the basis of the HTS data in order to establish metal oxide nanoparticle hazard ranking. However, they recognized that a significantly larger data set is required in order to improve the reliability of and increase confidence in the nano-SAR approach.

Two years later, nano-SARs for metal oxide NPs toxicity were investigated by the same group using metrics based on dose-response analysis and consensus self-organizing map clustering (Liu et al., 2013). A dataset of 24 metal oxide NPs provided a multiparametric toxicity profile for two different cell lines consisting of seven different toxicity assays (Zhang et al., 2012). Initially, 30 descriptors were used and the best performing nano-SAR model built with support vector machine (SVM) was based on two descriptors. These descriptors, namely conduction band energy (EC) and ionic index (Z^2/r), had a high classification accuracy of ~94%. According to the authors, the class probabilities provided by the nano-SAR enabled the construction of decision boundaries with respect to toxicity classification under different acceptance levels of false negative relative to false positive predictions.

Fourches *et al.* (2010, 2011) developed a QSAR model to predict the cellular uptake of 109 NPs in pancreatic cancer cells (PaCa2). Each NP had the same metal core (iron oxide/NH_2 cores) but diverse surface modifiers; an organic small molecule conjugated to the NP surface (Weissleder, Kelly, Sun, Shtatland, & Josephson, 2005). Accordingly, each NP was represented by a unique set of descriptors determined by the organic molecule. In total, 150 MOE descriptors were calculated. For the developed QNAR model k-nearest neighbors (kNN) method was employed to correlate biological activity of NPs with the calculated descriptors. Their average external prediction power was shown to be high (R^2= 0.72). The authors concluded that QSAR is a useful tool to predict the cellular behavior of a common core-based NP library and their obtained model can be utilized to design a specific coating material to control the cellular uptake.

In the same study (Fourches et al., 2011; Fourches et al., 2010), the researchers studied also a dataset of 51 iron oxide- and quantum dot-based nanoparticles with four different metal cores and surface modifications. The various NPs were tested *in vitro* against four cell lines in different assays by Shaw *et al.* (2008) to study their induced biological effects. The model was built using the support vector machine (SVM)-based classification. An arbitrary threshold was utilized to divide the data set into two groups with the same number of NPs, and four experimental descriptors were used to classify the NPs into two clusters: size, relaxivities, and zeta potential. The model was developed for averaged toxicity responses relative to a control (i.e., unexposed) cell population. The data were classified into two equivalent groups, being below or above an arbitrary threshold. A model classification accuracy of 73% was reported, but without a definitive identification of true toxic end points. The authors suggested that QNAR models can be employed for predicting biological activity profiles of novel nanomaterials, and prioritizing the design and manufacture of a whole NM towards better and safer products.

Similarly, Winklert and his co-workers (Epa et al., 2012) performed a first computational modeling study using the two large sets of experimental nanoparticle data by Weissleder *et al.* (2005) and Shaw *et al.* (2008). They studied all possible combinations of biological assays and cell types, and generated robust models of cellular uptake and induction of apoptosis by metal oxide NPs using Bayesian methods. According to the authors, QNAR is a promising modeling technique, and it can be useful for the analysis of the biological effects of NPs and can capture the effects of different environments of body such as serum, plasma, or lung fluids on nanoparticle composition, as well as NP cellular uptake and interaction with cellular biochemical systems.

Chau and Yap (2012) studied the ability of QNAR models to predict the cellular uptake of Weissleder *et al.*'s NPs dataset with a single metal core in pancreatic cancer (PaCa2) cells. They used four different

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

modeling methods, naïve Bayesian, logistic regression, k-nearest neighbor and support vector machine, to develop candidate models. A final consensus model was developed using the top 5 candidate models, which was able to accurately predict 86.7 to 98.2% of the nanoparticles with good cellular uptake and 67.3 to 76.6% of the NPs with poor cellular uptake. Thus, the authors suggested that it is practical to use the physical, chemical and/or geometrical activity to develop predictive QNAR models.

In 2011, Puzyn *et al.* (2011) investigated the cytotoxicity of 17 metal oxide NPs towards Escherichia coli bacteria. Based on toxicity data they computed structural descriptors. Although the number of NPs used was small, they built a model to predict the cytotoxicity of other nanomaterials. More specifically, the authors calculated 12 descriptors quantitatively describing the variability of the NPs' structure. The descriptors were calculated in MOPAC software package using the quantum-chemical PM6 method. The dataset was divided into training (10 metal oxides) and validation (seven metal oxides) sets. The EC_{50} values of the studied NPs were consequently predicted using the multiple linear regression (MLR). It is notable that Tthe best MLR model was built using only one descriptor selected by genetic algorithm. The model was expressed by the following equation:

$$\log(1/EC_{50}) = 2.59 - 0.50 \times \Delta H_{Me+}$$

where ΔH_{Me+} represents the enthalpy of formation of a gaseous cation in the same oxidation state as that in the metal oxide structure.

The results indicated predictive ability of the model (R^2=0.85, Q^2= 0.77, externally Q^2=0.83). Thus, the authors suggested that their developed QSAR model can be used reliably to predict toxicity of untested nanomaterials, particularly metal oxides in computational nanotoxicology studies.

Leszczynski and his co-workers (Toropov et al., 2012) continued studying the cytotoxicity of the metal oxide NPs to bacteria *Escherichia coli*, and a year later, using CORAL software and the same data set of metal oxide NPs, they boosted the QNAR modeling. In this approach, the pEC_{50} values of the metal oxide nanoparticles' cytotoxicity to bacteria E. coli were used and six random splits into the training and test sets were examined. All the obtained models were satisfactory. According to the authors, CORAL, a convenient application and an available on the Internet software (http://www.insilico.eu/coral), was proved as a reliable tool for the QSAR analysis of the toxicity of metal oxide NPs.

The CORAL software was also used by Toropov *et al.* (2013) in order to build a QSAR model for prediction of cellular uptake of the 109 NPs in pancreatic cancer cells (PaCa2). The software gave satisfactory and stable predictions of the cellular uptake of NPs in PaCa2 cancer cells for five random splits. The optimal molecular descriptors, provided by CORAL, were calculated directly from simplified molecular input-line entry system (SMILES) and are used to correlate with various endpoints. The SMILES gradually has become the most popular representation of the molecular structure in the databases available on the Internet, and SMILES-based optimal descriptors can become attractive alternative to ''classic'' descriptors. Thus, the authors suggested this concept of QSAR as a random event and the alternative to build up QSAR.

Another attempt was made by Ghorbanzadeh, Fatemi, and Karimpour (2012) to build a model for the prediction of the cellular uptake of 109 magnetofluorescent NPs in pancreatic cancer cells. An artificial neural network was employed and the descriptors were calculated using Hyperchem program and Dragon. Six descriptors chosen by combining self-organizing map and stepwise multiple linear regression (MLR) and multilayered perceptron neural network (MLP-NN) modeling techniques were used to correlate the nanostructure of the studied particles with their bioactivity. For the MLR and MLP-NN

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

models, the correlation coefficient and the Root Mean Square (RMS) error were 0.769 and 0.934 and 0.364 and 0.150, respectively. The results obtained after a leave-many-out cross-validation test revealed the credibility of MLP-NN for the prediction of cellular uptake of NPs. Additionally, sensitivity analysis of MLP-NN model indicated that the number of hydrogen-bond donor sites in the organic coating of a NP is the predominant factor responsible for cellular uptake.

Similar to their previous study (Toporov et al., 2013), Toporova and Toporov (2013) worked on TiO_2 nanoparticles. Experimental data on the physicochemical features of TiO_2 nanoparticles and their influence on the membrane damage were taken in the literature (Sayes, & Ivanov, 2010). The optimal descriptors calculated with the Monte Carlo method led to a built up of a predictive model for the membrane damage. The authors suggested that optimal descriptors based on representation of TiO_2 nanoparticles by their physicochemical features can be a tool for modeling of membrane damage.

In a recent study (Sayes, & Ivanov, 2010), nano-SAR classifiers based on nanoparticle properties such as primary size, aggregate size in different media, and zeta potential were developed to predict cell membrane damage induced by TiO_2 and ZnO. The authors compared two approaches to develop mathematical models that have the potential to predict the damage to cellular membranes, as measured by lactate dehydrogenase (LDH) release, of the two metal oxide NPs resulting from several physicochemical features. Given the relatively small number of samples, relatively simple multiple linear regression models were used to probe for possible QSARs related to the endpoint of interest—cellular membrane state. In the cases where the application of the regression models did not produce a good fit, linear discriminant analyses (LDA) classification was applied, and all possible combinations of one, two, and three feature sets were searched and ranked according to how well they are discriminated between different degrees of cellular responses of the biological test system.

A QSAR approach has been undertaken by C. Gaudin *et al.* (2012) for predicting and further interpreting the caffeine uptake, experimentally measured by HPLC and TGA techniques, in a series of functionalized MIL-88B(Fe) materials. Especially, the series of 10 materials consist of MIL-88B(Fe) iron(III) dicarboxylate metal-organic frameworks (MOFs) wherein the organic linker is functionalized by a large variety of polar and non-polar functional groups, such as –H, –Br, –F, $–CF_3$, $–CH_3$, $–NH_2$, $–NO_2$, and –OH. These MOFs were investigated as potential carriers for encapsulating drugs, using the cosmetic amphiphilic caffeine as a model molecule. The two individual but consensus QSAR models were built using the MLR method and a wide range of molecular descriptors calculated for the series of the investigated grafted organic linkers. The obtained models, validated with the leave-one-out cross-validation and the Y-randomization procedures, led to a good correlation between the observed and calculated values of the caffeine loading for the series of modified MIL-88B(Fe) iron dicarboxylate MOFs.

Recently, a study in computer-aided toxicology of nanomaterials was carried out by Luan *et al.* (2014). The aim of the researchers' work was the prediction of the cytotoxicity of diverse nanoparticles using a QSTR (Quantitative Structure Toxicity Relationship) – perturbation model. The measurements were performed against several mammalian lines and under different experimental conditions, such as the chemical composition of nanoparticles, size, shape and time of exposure of the cell lines. The dataset contained 41 nanoparticles and was retrieved from the literature. Four descriptors were measured;

1. Molar volume (*V*),
2. Electronegativity (*E*),
3. Polarizability (*P*), and
4. Size (*L*) of nanoparticle.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

1681 cases (nanoparticle-nanoparticle pairs) were used and randomly divided into training and prediction sets. The training set included 1261 cases (802 cytotoxic and 459 non-cytotoxic), and the prediction set included the remaining 420 cases (156 cytotoxic and 264 non-cytotoxic). The model was obtained using the LDA method and its statistical quality was examined by Wilks' lambda (λ), chi-square (χ^2), and p-level. The best QSTR-perturbation model was given by the following equation:

$$\mathrm{CTox}_i(c_j)_{\mathrm{nw}} = 1.616\mathrm{CTox}_i(c_j)_{\mathrm{rf}} - 0.229\Delta\Delta V(c_a) - 0.322\Delta\Delta P(c_a) + 0.044\Delta\Delta L(p_s) + 0.502\Delta\Delta V(d_m) - 0.004\Delta\Delta L(t_e) - 0.450$$

According to the authors, the LDA statistics ($\lambda = 0.305$, $\chi^2 = 1490.86$ and $p < 10^{-16}$) showed a very good significance and an accuracy higher than 93% was exhibited for both training and prediction sets. It is of paramount importance that authors in order to prove the significance of the model, predicted correctly the experimentally measured cytotoxicity of new nanoparticles not included in dataset.

Most recently, Kar, Gajewicz, Puzyn, Roy and Leszczynski (2014) using the dataset of Puzyn *et al.*'s (2011) with 17 metal oxides developed and validated a QSTR model. In their effort to encode the cytotoxicity profile of metal oxides to bacteria *E. coli*, they used simple molecular descriptors. More specifically, they calculated seven descriptors based only on the molecular formula and periodic table information:

1. Number of metal atoms (N_{metal}),
2. Number of oxygen atoms (N_{oxygen}),
3. The charge of the metal cation corresponding to a given oxide (χ_{ox}),
4. Metal electronegativity (χ),
5. Sum of metal electronegativity for individual metal oxide ($\sum\chi$),
6. Sum of metal electronegativity for individual metal oxide divided by the number of oxygen atoms present in a particular metal oxide ($\sum\chi/nO$), and
7. Molecular weight (MW).

The dataset was randomly divided into training and test sets, including eleven and six metal oxide NPs, respectively. Ten combinations of splitting were performed and the models were developed using stepwise MLR. The best MLR model was built using only one descriptor and expressed by the following equation:

$$\mathrm{pEC}_{50} = 4.781 - (1.380 \times \chi_{ox})$$

with $N = 17$, $R^2 = 0.84$, $Q^2 = 0.81$, and $\mathrm{R}^2_{\mathrm{p}} = 0.82$.

Despite the obtained statistically significant model, the authors considered it necessary to also perform the partial least squares (PLS) method. More specifically, analyzing the results of MLR they found that for two different metal oxides containing same descriptor value, the predicted value of pEC_{50} was the same. According to authors, the prediction of cytotoxicity of metal oxides using only one parameter had limited ability, and an additional descriptor was needed. The obtained final PLS equation is the following:

$$\mathrm{pEC}_{50} = 4.401 - (1.324 \times \chi_{ox}) + (0.176 \times \chi)$$

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

with $N = 17$, $R^2 = 0.82$, $Q^2 = 0.75$, and $R^2_p = 0.79$.

The authors were satisfied as they succeeded to build up a significant QSTR model using simple descriptors, in no time, and without any software for calculation of descriptors. Furthermore based on this model, Kar *et al.* attempted to provide a most probable mechanism of action of cytotoxicity of metal oxide NPs to bacteria *E. coli*.

Zhou *et al.* (2008) have discovered functionalized multiwalled carbon nanotubes with reduced protein-binding, cytotoxicity, and immune response. They utilized a combinatorial synthesis technique to decorate CNTs' large surface area with a series of organic molecules and investigated the overall toxicity of obtained series of NPs. All CNTs had the same core structure and so their biological/toxicological behavior could depend only on the surface modification. The set of 84 f-MWCNTs was tested in several *in vitro* toxicological assays at two different doses, including protein binding assays, acute toxicity assays, and immune toxicity assays. The authors observed a significant, high stability of experimental measurements for all f-MWCNTs, and suggested further QNAR modeling investigations.

Three years later, Tropsha and his colleagues (Fourches et al., 2011) developed a statistically significant and externally predictive model based on the previous results. Initially, they calculated 2D Dragon descriptors, proceeding to chemoinformatics analysis of the data set. Their findings validated the hypothesis that any f-MWCNT can be modeled using a single, organic molecule from its surface only if all NPs have the same core. They subsequently proceeded to a binary toxicity class to each NP (1 as toxic and 0 as non-toxic) based on the acute toxicity assay and the toxicity measured for CNT with no surface modifiers. 38 strong toxicants (class 1) *versus* 35 weak toxicants (class 0) were subjected to their QNAR random forest (RF) approach and were carried out in a 5-fold external cross-validation. The results were satisfactory and the authors proposed the virtual screening of a library with 240,000 potential CNT surface modifiers in order to identify those materials with desired properties. For inorganic nanoparticles, such as metal oxides, there are some toxicity data available, mainly: EC_{50}, IC_{50}, LC_{50}, LD_{50}, NOEC, zeta-potential, electrophoretic mobility and surface area or solubility. Carbon-based nanoparticles, such as fullerenes, SWCNTs and MWCNTs can also be characterized by available toxicological data, zeta potential and electrophoretic mobility. For carbon nanotubes, there are significantly more data for endpoints, such as surface area, porosity and solubility (Gajewicz et al., 2012). The number of QNAR studies for metal oxide nanoparticles' toxicity is bigger than the one for carbon-based NPs. This may be justified due to the lack of available in the literature datasets of carbon-based nanoparticles with toxicity data. The multiple linear regression (MLR) is the most popular and more applied method of building a QNAR model followed by the support vector machine.

Recently, Toropov and Toropova (2014) worked as in their previous studies (Toporov et al., 2013; Toporova, & Toporov, 2013) also using used optimal descriptors in order to build a QNAR model to predict the mutagenicity of fullerene C_{60} nanoparticles under various conditions using data taken from the literature (Shinohara, Matsumoto, Endoh, Maru, & Nakanishi, 2009). The descriptors were calculated with the Monte Carlo method and the model of 20 fullerene C_{60} NPs was the mathematical function describing the contributions of

1. Dose (g/plate),
2. Metabolic activation, and
3. Illumination (i.e. dark or irradiation).

PERSPECTIVES AND FUTURE OF COMPUTATIONAL NANOTOXICOLOGY

To date, many theoretical studies have been reported on the prediction of mechanical, chemical, and electronic properties of NPs, whereas there have been relatively few published studies on the computational modeling of toxicity. Although quantitative structure–activity relationship (QSAR) methods can play an important role in designing novel and potential drugs and predicting their risk to human health and the environment, the unique properties of nanomaterials and their still unknown toxicity make the implementation of these methods more complicated in comparison with the small organic chemicals. QSAR models usually cover the biological profile of small organic molecules and have been proven accurate in predicting the biological effect for a wide range of molecular scaffolds. QSAR models own a great proportion of their success in the presence of organized databases but no such databases are available for the vast majority of NPs. Experimental data on NPs are scarce and produced by different groups of scientists following different protocols and it is often difficult to select and combine the available information from different sources. On top of that, the structural characteristics of NPs cannot be encoded by the "conventional" widely used 2D and 3D molecular descriptors. NPs include organic as well as inorganic elements with sometimes unknown composition and highly complex structures that demand new approaches for developing molecular descriptors.

In this chapter, we attempted to explain the importance of QNAR modeling and we outlined some of the latest and more significant QNAR studies, especially related to toxicity. As it is demonstrated by several studies QNAR methodologies have emerged as important tools in producing reliable models for the evaluation of MNPs' biological properties and toxicity and can provide valuable information for the design of safer products in nanotechnology.

In an effort to computationally explore data on the effects of nanostructures to human health and the environment, several limitations much be addressed. As already emphasized above nanotechnology, and especially nanotoxicology, is an emerging field of science but unfortunately in this new field of science there is a significant lack of systematic experimental data that characterize structural, geometrical and physicochemical properties of large series of NPs and their effects. To assess risk, regulatory authorities need organized experimental data that are produced to assess properties and effects for a wide range of NPs. When such data are available QNAR studies can then emerge as a useful tool in the identification of the most relevant properties for modeling toxicity of NPs and produce robust and predictive models.

The availability of quantitative toxicity studies and models is strictly bonded to the availability of high-quality and well organized nanotoxicity data but unfortunately due to the paucity of such data this task is significantly restricted. However, since these limitations have been well recognized, several efforts are now ongoing to select and organize relevant experimental data that are produced under the same protocol and are organized in a common format. For example ISA TAB Nano is a standard tab-delimited format for describing data related to: Investigations, Nanomaterials, Studies (Specimens) and Assays with the goal to develop a specification to facilitate the import/export of data on nanomaterials and their characterizations to/from nanotechnology resources.

It is important to highlight that the conditions and protocols, under which researchers should work, have not been yet clearly defined. There is a variety of *in vitro* measurement techniques and biological endpoints, and each laboratory has its own criteria to test the MNPs. To overcome this barrier, it is required that researchers working in the fields of chemistry, toxicology, biology and chemoinformatics of MNPs collaboratively work together and establish a set of good practices to characterize MNPs and

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

test them in appropriate biological assays under fixed criteria so that data are ready available for in silico exploitation.

As already mentioned, nanomaterials consist of various structures, such as nanotubes, nanorods, fullerenes, crystals, and chemical species of metals, organic compounds, inorganic compounds, etc. This variety could potentially be a problem with the modeling of nanoparticles since we do not know how accurately we can describe the structure of nanomaterials. It is simply impossible to combine all nanoobjects in one description. Since NPs are not structurally homogenous, the properties and the mechanism of toxicity should be studied separately, and thus every group should be analyzed separately. For this reason, sub-classes of structural and physicochemical similarities have been defined and an eight-step procedure is recommended by the Organization for Economic Co-operation and Development (OECD) guidance document on the grouping of chemicals (OECD, 2007).

It is important while developing a QNAR model in order to estimate the potential hazard of ENMs to overcome several common QSAR errors, such as the use of inappropriate tools and methods or use of limited or inappropriate validation procedure. It is important to follow all proposed criteria that can be used to critically assess the suitability of input data and modeling methods and tools for QNAR analysis. Lessons learned from the long standing 'classic' QSAR modeling have to be taken into account from the very beginning when building a QNAR model. It is very important that all five principles recommended by OECD including robust validation and interpretation of results are addressed when the modeling of NPs' biological profile is requested.

Computational methods could address several significant questions emerging from the experimental testing of NPs. An important outcome that needs to be explored is that nanoparticles interact with DNA, proteins, and membranes and establish a series of nanoparticle-biological interfaces. These interactions lead to the formation of protein coronas, particle wrapping, intracellular uptake and biocatalytic processes that could have biocompatible or bioadverse effects. Therefore, it could be a promising approach studying the forces and interactions which occur at the interface between NPs and biological materials to be developed the predictive relationships between structure and activity of nanomaterials.

Up to date, there are several efforts to enable these intensive collaborations between experimentalists, toxicologists, modelers, etc., from both academia and industry. SRC/SEMATECH Engineering Research Program (Retrieved from http://www.erc.arizona.edu/) constitutes a very good example of such collaborative efforts. SRC Engineering Research Center for Environmentally Benign Semiconductor Manufacturing is a dynamic framework with numerous research teams from different U.S. universities and industrial companies. The researchers have synergistic activities by sharing and testing samples of MNPs in different laboratories, creating datasets of them and corresponding QNAR models.

The NanoPUZZLES project (Retrieved from http://www.nanopuzzles.eu/) is another such of activity which focuses on two groups of compounds:

1. Inorganic engineered nanoparticles (metal oxides NPs), and
2. Carbon-based nanoparticles (carbon nanotubes (single-walled and multi-walled), fullerenes and fullerene derivatives).

The project aims to develop a package of computational algorithms for the comprehensive modeling of the relationships between the structure, properties, molecular interactions and toxicity of selected classes of engineered nanoparticles. The *in silico* approaches that are used to predict the harmful effects of NMs are based on mainly QSARs. In addition, NanoPUZZLES is contributing to the development

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

of an electronic database of well-characterized NMs consisting of physicochemical and toxicological information.

A research project for safe nanotechnology, called NanoMILE and funded by the European Union's Seventh Framework Programme, has been launched from March 2013 (Retrieved from http://www.nanomile.eu-vri.eu/). The aim of this work is the understanding of the mechanisms of nanomaterial interactions with living systems and the environment in order to lead to the development of a single framework for the classification of NM safety and the creation of a universally applicable framework for nanosafety. The MNMs, both metal and carbon-based NMs, will be characterized physicochemically across their entire life cycle and in a wide range of target species. Using a high throughput screening process, a streamlined testing and selection platform will be developed and applied to refine the MNMs selection. The selected MNMs will undergo focused testing relative to their mechanism(s) of effects on living systems and the environment. An iterative experimental/modeling process will integrate the data obtained into quantitative structure or properties/effects relationships.

NANoREG (Retrieved from http://www.nanoreg.eu/) is an enabling project with the cooperation of 60 partners around the Europe. Its aim is to provide the guidance and tools by which a new nano-based material can be tested, evaluated, and approved for commercial use. The partners emphasized that their QSAR modeling should be clearly defined in order to be used as an *in silico* way to predict the behavior of nanaparticles in the human health and environment.

An important aspect that, in the vast majority of examples presented in literature, remains forgotten is the dissemination of the results to the wider community. It is very crucial that the developed model does not remain within the developers' group but is widely disseminated to the community so that it could immediately serve as an important source of information as it was initially designed to be. We should not omit to highlight recent attempts using open source tools for developing *in silico* models for the risk assessment of NMs and moreover the importance of the dissemination of these tools through web applications that could be easily expanded and adjusted to the special needs of each project.

In 2011, Sushko et al. (2011) created a web-based platform that aims to automate and simplify the typical steps required for QSAR modeling. The Online Chemical Modeling Environment (OCHEM) is free for web users and it is available online at http://www.ochem.eu. The OCHEM database was extended to incorporate nanoscale objects and it will be filled continuously with data on the nanotoxicity of metals and metal oxides. Since then, several changes were made to update the OCHEM to be used as a user-friendly database for the nanotoxicity data collection. For the description of the toxic properties of the nanoparticles an abbreviation was used. More specifically, for each property "Nano" prefix was used to separate the nano-properties from all others. The basic characteristics of nanoparticles are chemical composition, average particle size (APS) and shape of the nanoparticles.

Another attempt in this direction is Enalos InSilicoNano platform (Enalos). In this effort KNIME workflows were made available online through Enalos InSilicoNano platform, a web service based solely on open source and freely available software that was developed with the purpose to make the models available to interested user wishing to generate evidence on potential biological effects in the decision making framework. This web service facilitates the computer aided nanoparticles design as it can serve as a source of activity prediction for novel nano-structures. With this tool in hand external databases can be screened within a virtual screening framework to identify novel potent nanoparticles from a prioritized list of compounds. This online tool could be a useful aid for the decision making of both research groups and regulatory bodies interested in NPs' design and screening.

CONCLUSION

It is obvious that nanotechnology has the best prospects to evolve but it should be done in the right way. The unique properties of nanomaterials have several applications in science, and significantly in medicine, but the same properties might result in new pathways and mechanisms of toxic action. For safer nanoscale products QNAR modeling can emerge as a useful tool for the understanding of the relationships between the structure and biological activities of MNPs. To enable safety-by-design using predictive QNAR models, some barriers must be addressed. Datasets on the effects of MNPs need to be enriched and extended with well-defined and consistent experimental measurements. Moreover there is a strong need to supplement the existing set of molecular descriptors with novel "nanodescriptors" that can represent size-dependent properties of nanomaterials. The descriptors have to be both theoretical/computational and experiment-based structural descriptors in order to correlate with biological endpoints. An intense collaboration between the experimentalists (chemists, biologists, toxicologists, etc) and QSAR modelers must be established, and, there is no doubt that the use of QNAR modeling will provide critical support to experimental studies aimed to identify safer nanoparticles with desired properties.

ACKNOWLEDGMENT

This project has received funding from the European Union's Seventh Framework Programme for research, technological development and demonstration under grant agreement no 310451 (Project NanoMILE).

KEY TERMS AND DEFINITIONS

Engineered Nanomaterials: Any intentionally manufactured material/particles, designed with specific properties and for specific purpose.

Nanomaterials: The new materials defined as those with one or more dimensions at the nanoscale, which can exhibit novel characteristics compared to the same materials without nanoscale features.

Nanoobjects: Materials with at least one dimension in the nanoscale (1–100 nm).

Nanoparticles: A subset of nanomaterials, with one or more dimensions at the nanoscale level. One of their dimensions has at least length below 100 nm.

Nanoscale: A scale of measurement that uses nanometers (nm) or microns (μm) as units of measure.

Nanostructured Material: Material with an internal or surface structure in the nanoscale.

Risk Assessment: The process of determining the likelihood of a threat or hazard.

ABSTRACT

Nanotechnology is a newly emerging field, posing substantial impacts on society, economy, and the environment. In recent years, the development of nanotechnology has led to the design and large-scale production of many new materials and devices with a vast range of applications. However, along with the benefits, the use of nanomaterials raises many questions and generates concerns due to the possible health-risks and environmental impacts. This chapter provides an overview of the Quantitative Structure-Activity Relationships (QSAR) studies performed so far towards predicting nanoparticles' environmental toxicity. Recent progresses on the application of these modeling studies are additionally pointed out. Special emphasis is given to the setup of a QSAR perturbation-based model for the assessment of ecotoxic effects of nanoparticles in diverse conditions. Finally, ongoing challenges that may lead to new and exciting directions for QSAR modeling are discussed.

INTRODUCTION

The 21th century has witnessed a fast-dynamic growth of the nanotechnology field, leading in turn to the development of an innumerable number of nanomaterials with unique properties and a variety of applications in many sectors. However, the large-scale production and increasingly likelihood exposure to novel nanomaterials has spurred great concern regarding their potential adverse effects to humans and the environment. This chapter will provide an overview of *in silico* approaches developed so far for the prediction of nanomaterials environmental toxicity; from the use of classical approaches forward-

establishing Quantitative Structure−Activity Relationships (QSAR) to the applications of more evolved computational models. Particular attention will be paid to the setup of a new *in silico* perturbation-based model aimed at reliable predicting the ecotoxicity of metal-based nanoparticles under a wide range of experimental conditions.

NANOMATERIALS AND ENVIRONMENTAL RISKS

The idea that launched the new field nanotechnology started with the famous lecture "There's plenty of room at the bottom" given by physicist Richard Feynman at the Annual Meeting of the American Physical Society in 1959 (Feynman, 1960). In that meeting, Feynman wondered: "What would the properties of materials be if we could really arrange the atoms the way we want them?", foreseeing the production of materials at the nanometer scale with promising technical, industrial and biological applications. But the term "nanotechnology" was only coined decades later, firstly by Norio Taniguchi in 1974 within his inspections of ultra-precision machining (Taniguchi, 1974), and then by K. Eric Drexler in his 1986 book *Engines of Creation: The Coming Era of Nanotechnology* (Drexler, 1992). Though the real burst of nanotechnology didn't come until the early 1990s, with the development of sophisticated techniques for the characterization and manipulation of individual atoms such as scanning probe microscopy.

Nanomaterials are usually considered to entail materials that have single units with at least one dimension between 1 nm and 100 nm (Oberdörster et al., 2007). Nanomaterials can additionally be classified as one-dimensional (1-D), two-dimensional (2-D) and three-dimensional (3-D), according to the number of dimensions that are confined to the nanoscale range (< 100 nm). 1-D materials include nanofilms, nanolayers, and nanocoatings, while 2-D include nanotubes, nanorods, and nanowires. Finally, the most common 3-D materials are nanoparticles (NPs), the building blocks for nanotechnology applications. Nanomaterials can be amorphous or crystalline, be composed of single or multi-chemical elements, and exhibit various shapes and forms.

The advances in nanotechnology have made possible the development of many new materials and devices with a vast range of applications in medicine, cosmetics, electronics, biomaterials and energy production. Indeed due to the rapid pace at which nanotechnology is evolving and expanding into society via its applications, it is expected that many new innovative products containing manufactured nanomaterials will continue to vastly grow. Commonly, manufactured nanomaterials fall generally into two categories: carbon-based and metal-based materials (Bréchignac et al., 2007). Regarding carbon-based nanomaterials, these usually involve diamond, carbon-nanotubes, graphene and fullerenes, the latter being a class of allotropes of carbon that conceptually are graphene sheets rolled into tubes or spheres. Most of these nanomaterials are of interest for their mechanical strength and electrical properties (De Volder et al., 2013). Moreover, fullerenes in general are under study for potential medical applications, ranging from specific binding of antibiotics on resistant bacteria to even target certain types of cancer cells such as melanoma (Bakry et al., 2007; Simon et al., 2007). Carbon nanotubes for instance, have already been used as drug, gene, or protein carriers (Bianco et al., 2005). Nanoscale materials are being further developed in therapeutic modalities for advanced selective drug delivery systems and targeted nanotherapy (Ravi Kumar, 2000). Many of these modalities include polymeric NPs (Stupp et al., 2005), micelles (Kim et al., 2005), liposomes and dendrimers (Popat et al., 2007; Portney & Ozkan, 2006), hydrogels (Vinogradov et al., 2002), nanoshells (Zahr et al., 2005), and smart surfaces. The key performance characteristics of these materials are the high loading capacity, release kinetics, circulation time,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

bio-distribution, size distribution, and stability (Allen et al., 1999). Furthermore, a recently published review shows that different carbon-based nanomaterials, including nanodiamonds, fullerenes, carbon nanotubes, graphene, carbon nanofibers, carbon nanocones/disks and nanohorns, as well as their functionalized forms, can be used in sample preparation processes in analytical chemistry (Zhang et al., 2013). With regard to metal-based nanomaterials, these include metal and metal oxide NPs based on titanium, zinc, silver, copper, aluminium or cerium among others. For instance, oxides TiO_2 and ZnO have been used in cosmetics, sunscreens, solar-driven self-cleaning coatings, and textiles for enhanced product transparency, as well as in paintings, water treatment and food (Cai et al., 2006; Serpone et al., 2007; Yuranova et al., 2007). As to nanosized silver, it is used today in an increasing number of consumer and medical products. Typical examples include band aids, cosmetics, food complements, anti-odour textiles, dental materials, bone implants, water disinfectants, as well as antibacterials, antivirals, etc. agents (Rai et al., 2014; Wijnhoven et al., 2009). On the other hand, CuO nanocrystals have been found that could replace noble metals in newer catalytic converters for the car industry (Zhou et al., 2006). Further, metal salts including CdSe quantum dots and iron (Fe) NPs have been exploited in many practical applications related to electronics and biomedical imaging techniques (Alivisatos, 2004; Chen & Gerion, 2004). Other specialized industrial applications of nanomaterials involve for instance aluminium (Al) NPs as fuel additives and MnO as a catalyst or in battery technology (Schrand et al., 2012).

Manufactured nanoparticles (MNPs) are receiving a great deal of attention lately both from the basic sciences and industry, as well as from the public at large, since existing and potential applications are almost endless. But along with the benefits, the use of MNPs raises many questions and concerns due to the lack of knowledge regarding their health and environmental impacts (Borm et al., 2006; Olson & Gurian, 2012; Schrand et al., 2012; Walker & Bucher, 2009; Warheit et al., 2008). In fact, uncertainties regarding those are high since the properties exhibited by NPs are often completely different from those of bulk forms, affecting their physicochemical and biological behavior, which may well result in greater toxicity. At the same time, the use, production and disposal of nanoscale materials raises concerns about nano-pollution, taking into account that NPs can be released in the air or water during production or as waste by-product of production, and ultimately accumulate in the soil, water or plant life, endangering the health of living organisms and ecosystems. There is thus an increasingly need to address the overall environmental impact of released NPs to support the development of a sustainable and safe nanotechnology.

IN SILICO STUDIES OF NANOMATERIALS IN THE ENVIRONMENT

As can be judged, while prompt development of nanomaterials will certainly continue, the application of these materials might be limited by their potential health-risks and environmental impacts (Bar-Ilan et al., 2009; García et al., 2011; Gong et al., 2011; Griffitt et al., 2008; Heinlaan et al., 2008; Hund-Rinke & Simon, 2006; Kasemets et al., 2009; Lin & Xing, 2007; Ma et al., 2011; Ma et al., 2010; Marsalek et al., 2012; Sadiq et al., 2011; Zhu et al., 2010; Zhu et al., 2012; Zhu et al., 2009; Zhu et al., 2008). And indeed, there have been already several reports on the deleterious effects of nanomaterials to human health and ecosystems (Arora et al., 2012; Bussy, C. et al., 2013; Liu et al., 2013; Schrand et al., 2012; Tsoy et al., 2013). For example, carbon nanotubes have been shown to produce oxidative stress and being just as toxic as asbestos (Liu et al., 2013; Schrand et al., 2012).

Similarly to any other manufactured chemicals, toxicity evaluation studies of nanomaterials have been carried out on a few cell lines or species that have been accepted by regulatory agencies as models for

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

defining toxicological effects. As a rule, an initial screen of toxicity is accomplished by resorting to *in vitro* methodologies, even though the bridge between *in vitro* and *in vivo* remains. Nevertheless, *in vivo* mimicry of higher order organisms is difficult due to the complex nature of biological interactions, and often insurmountable differences between laboratory animals and humans do exist (Eisenbrand et al., 2002; Oberdorster, 2010; Schrand et al., 2012; Shvedova & Kagan, 2010). Alternatively, since *in vivo* experiments are expensive, slow and ethically questionable, low-cost *in vitro* assays without reducing the efficiency and reliability of the risk assessment are usually carried out. One should notice here that some test models and standard testing protocols applied for non-nanoform substances may not necessarily be appropriate or optimal for the testing of MNPs, but nevertheless ongoing efforts in the research community are currently addressing such issues (Holden et al., 2013; Liu et al., 2013; Nel et al., 2013; Schrand et al., 2012).

To date, many important aspects regarding the ecotoxicity profiles of NPs are not well understood, and sometimes experimental assays carried out by different groups on the same NPs have showed a remarkable lack of reproducibility and consistency (Lanone et al., 2009). Powerful experimental techniques focused on high-throughput/content screening (HTS/HCS) could be essential for the fast and efficient evaluation of many toxic effects of NPs (Holden et al., 2013). Nevertheless, even with the use of HTS/HCS, there is a very low probability of covering and filtering the huge "nanotoxicity space". This comes from the fact that there are many combinations of factors such as chemical compositions, sizes and conditions under which the sizes were determined, shapes, coating agents, measures of the toxic effects, living systems (cell lines, crustaceans, algae, bacteria, fungi, plants, fish, etc.), and times at which living systems were exposed to NPs. Computational methods may offer a magnification of the 'sweet spot' regarding the virtual screening of NPs for prediction of toxicity profiles, helping to rationalize the experimental assays by diminishing time and financial resources. Among these methods, Quantitative Structure–Activity Relationships (QSAR) models have been used as promising tools for modeling different biological effects of chemicals (Estrada et al., 2004; Estrada et al., 2006; Estrada et al., 2000; Gonzalez-Diaz et al., 2014; Luan et al., 2013; Prado-Prado et al., 2011; Speck-Planche & Cordeiro, 2014; Speck-Planche et al., 2013a; Speck-Planche et al., 2013b; Tenorio-Borroto et al., 2014), including diverse toxicity profiles (Cruz-Monteagudo et al., 2013; Cruz-Monteagudo et al., 2008; Cruz-Monteagudo et al., 2006; Estrada et al., 2001; Estrada & Uriarte, 2001; Estrada et al., 2003; Helguera et al., 2007; Morales Helguera et al., 2008; Speck-Planche et al., 2012; Tenorio-Borroto et al., 2013). In the field of nanotechnology, QSAR models have provided deeper insights regarding the most relevant aspects of NPs (Poater et al., 2009). Nevertheless, only a few studies have been carried out thus far aiming at the *in silico* prediction of nanotoxicity by resorting to QSAR models (Fourches et al., 2010; Kar et al., 2014a; Kar et al., 2014b; Liu et al., 2011; Liu et al., 2013; Puzyn et al., 2011; Toropov et al., 2012). From now on, this chapter will be devoted to summarize the main progresses in the computational risk assessment of nanomaterials. Towards that goal, prediction of both cytotoxicity (against mammalian cell lines) and ecotoxicity (involving bio-indicator species such as bacteria, algae, fungi, crustaceans, fish, and plants) will be discussed because of their potential direct or indirect implications in environmental risk assessment.

Classical QSAR Models for Prediction of Toxic Effects of Nanoparticles

In general terms, QSAR approaches aim to establish mathematical models disclosing possible parallelisms/relationships between a set of predictor variables X, known as molecular descriptors, and the

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

response variable *Y*, which describes a certain type of biological effect (Hansch & Leo, 1995). From one side, molecular descriptors can be viewed as the final result of a defined mathematical procedure that transforms chemical information encoded within a symbolic representation of a molecule into a useful number or the result of some standardized experiment (Todeschini & Consonni, 2000). On the other hand, the biological effect can be associated with the inhibitory activity of a chemical against different types of targets (biomacromolecules, microorganisms, cell lines, etc), the toxicological profile, or any property related with the absorption, distribution, metabolism, and elimination (ADME). QSAR models are obtained by means of statistical methods (van de Waterbeemd, 1995), which include regression techniques such as (but not limited to) multiple linear regression (MLR) and partial least squares (PLS), or classification techniques such as (but not limited to) linear discriminant analysis (LDA). In addition, powerful machine learning methods like artificial neural networks (ANN), support vector machines (SVM), random forest (RF), consensus clustering (CC) and many others can be employed (Hill & Lewicki, 2006).

Classical QSAR models are based on assumptions, which describe the structural dependence of biological activities (or any other biological effect) either by local physicochemical descriptors such as hydrophobicity, molar refractivity, and electronic factors (Hansch analysis), or by indicator variables (discrete descriptors) encoding different structural features (Free-Wilson analysis) (Kubinyi, 1993). Current classical QSAR models maintain the same principles in the way that small datasets of structurally related chemicals are used. However, other groups of local and global molecular descriptors such as those derived from quantum-mechanics calculations or exhibiting graph-theoretical nature have been widely employed (Todeschini & Consonni, 2009).

Several works focusing on predicting nanotoxicity have been reported in the scientific literature, in which the fundamental principles of QSAR studies have been adapted to the computational assessment of different biological effects of NPs. The first of these works was inspired by the idea that the evaluation of biological effects of MNPs is extremely important for nanotechnology sustainability, and there is thus an urgent need for efficient *in silico* approaches able of predicting biological effects of MNPs. Therefore, the authors developed statistical significant QSAR models by establishing relationships between the toxicities of nanomaterials and their corresponding physical, chemical, and geometrical properties, either measured experimentally or computed from the structure of MNPs (Fourches et al., 2010). Towards that end, two representative sets of MNPs involving *in vitro* cell-based assays have been employed. The first set was formed by 51 various MNPs with diverse metal cores (Shaw et al., 2008), and 44 of them were used to derive the nano-QSAR models. Each NP was tested against 4 cell lines, employing 4 doses, and through 4 different assays (64 responses of biological activity). The authors condensed the entire biological effects (cytotoxicities) of each NP into one average response. At the same time, experimental properties such as size, relaxivity, and zeta potential were used as descriptors for the MNPs. Afterwards the SVM technique was used to develop the QSAR models. The whole dataset was split 5 different times, creating 5 different training (80%) and prediction (20%) sets. The best model yielded an external accuracy of 73%. In the case of the second dataset, 109 MNPs with the same core (cross-linked iron oxide with amine groups) but decorated with different organic molecules (Weissleder et al., 2005) was studied. The uptake of the NPs in PaCa2 cells was used as biological response, while 150 different computational molecular descriptors were used to characterize the chemical structures of the different molecules in the surface of the MNPs (coating agents). Then, QSAR models based on the *k*-nearest neighbors (*k*NN) regression technique were setup, and the best model displayed a reasonable external prediction power ($R^2 = 0.72$). The results of this work clearly demonstrate that nano-QSAR models can be used for two

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

main purposes: prediction of the biological activity profiles of novel nanomaterials, and prioritization in the design and manufacturing of nanomaterials towards better and safer products.

As a continuation of the work involving the last dataset mentioned above, *i.e.*, that formed by 109 magnetofluorescent NPs, Roy and coworkers built up a new nano-QSAR model using the MLR technique (Kar et al., 2014a). For deriving the model, a pool of 307 descriptors was calculated using different computer programs. The best model contained 6 molecular descriptors, and was rigorously validated internally and externally according to the guidelines established by the Organization for Economic Cooperation and Development (OECD). Accordingly, the values of R^2 and Q^2_{LOO} for the training set (89 cases) were 0.806 and 0.758 respectively, while for the external set (20 cases) R^2_{pred} had a value of 0.879 with a $R^2_{m(test)Scaled} = 0.793$. In this work, the applicability domain was also determined in an attempt to confirm the reliability of the predictions (Dimitrov et al., 2005; Dragos et al., 2009; Fechner et al., 2010; Kulkarni & Zhu, 2008; Netzeva et al., 2005; Weaver & Gleeson, 2008). Additionally, molecular fragments present in the different coating agents were analyzed, and their contributions were calculated. The main purpose underpinning the calculation of fragments contributions was to study the most important molecular features associated with the highest (or the lowest) values of cellular uptake of NPs. One should emphasize here that even when the calculation of quantitative contributions of fragments to different biological effects have been widely reported by different authors (Estrada et al., 1998; Estrada & Peña, 2000; Estrada et al., 2000; Helguera et al., 2005; Helguera et al., 2007; Prado-Prado et al., 2010; Speck-Planche & Cordeiro, 2013), this work introduces for the first time essential and rich information *via* the attained fragment contributions, expanding the horizons for risk assessment in the context of virtual screening of relevant NP libraries.

Another nano-QSAR model has also been developed by employing periodic table-based descriptors to encode cytotoxicity profile of metal oxide NPs (Kar et al., 2014b). In such work, metal electronegativity (χ), the charge of the metal cation corresponding to a given oxide (χ_{ox}), the atomic number, and the valence electron number of the metal were used as simple descriptors to setup QSAR models aiming at predicting the cytotoxicity of metal oxide NPs against the bacterium *Escherichia coli*. As the measure of cytotoxicity, the effective concentration at 50% (EC_{50}) was employed. Then, MLR and PLS were used as statistical regression methods to search for the best QSAR models, which could account for at least 82% of the variance of the cytotoxicity in the training set, with $Q^2_{LOO} \geq 0.75$. In the prediction set, an average R^2_{pred} for the ten derived models (due to random splits) was 0.78 (or higher). Many other statistical indices were calculated, corroborating the quality and predictive power of the nano-QSAR models. A prominent aspect of the latter research work is that the descriptors used to characterize the metal oxide NPs can be obtained easily and quickly from the molecular formula (composition) and the information retrieved from the periodic table. On the other hand, the authors demonstrated that a simple but useful descriptor such as χ_{ox} can efficiently encode the cytotoxicity of metal oxide NPs, leading to models with clear interpretability. Lastly, the authors also hypothesized the possible mechanisms of action of the NPs. Finally, this work served to uncover the fact that the bacterium *Escherichia coli* can be used as a useful target for the study, analysis and prediction of cytotoxicity of NPs. Indeed, two more works have been published previously, and they were focused on modeling the same phenomenon: cytotoxicity of metal oxide NPs against *Escherichia coli* (Puzyn et al., 2011; Toropov et al., 2012). The first of these works was based on the calculation of descriptors derived from quantum-mechanics calculations (Puzyn et al., 2011), while the second one used SMILES-based optimal descriptors, which were calculated from the CORAL software (Toropov et al., 2012). In both cases, the MLR technique was used to derive QSAR models with excellent performance when compared with the research work referred to above.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Another interesting report focused on the computational assessment of cytotoxicity of NPs by means of nano-QSAR models based on statistical classification methods (Liu et al., 2011). Towards that goal, the authors built up a model to predict the cytotoxicity of 9 metal oxide NPs against bronchial epithelial cells (BEAS-2B), which were exposed to different concentrations of the NPs (0.375-200 mg/L) during a period of time of 24 hrs. The study was realized by using cytotoxicity data from a high-throughput screening assay that was processed to identify and label toxic (through the propidium iodide uptake of BEAS-2B cells) versus endpoints relative to an unexposed control cell population. A total of 14 different physicochemical descriptors were used as input variables. The best nano-QSAR classification model based on logistic regression contained the following descriptors: atomization energy of the metal oxide, period of the metal in the NP, and NP primary size, in addition to NP volume fraction (in solution). This model had 100% classification accuracy in both internal and external validations. Thus, one can undoubtedly infer that nano-QSAR models based on classification tasks can be very useful for risk assessment of NPs. Furthermore, when classification models are used, there is no need to predict the exact value of biological effect of NPs. Consequently, the uncertainty of data can be better controlled.

Finally, a research work dealing with another nano-QSAR classification model has been reported in the last year (Liu et al., 2013). The generation of such a model was inspired by the idea regarding the integration of multi-parametric toxicity/bioactivity assays to arrive at statistically meaningful class definitions, that is, bioactivity/inactivity endpoints. Another purpose of that work was to determine and analyze the decision boundaries and the applicability domain. Towards that end, by applying diverse statistical and machine learning methods, different nano-QSAR models were developed from a set of 44 iron oxide core NPs used in molecular imaging and nano-sensing. These NPs contained bioactivity profiles for four cell types and four different assays. Class assignments were pursued by means of bioactivity identification analysis and self-organizing map based consensus clustering, which permitted the setup of nano-QSAR classification models with acceptable performance (classification accuracy >78%). This is, a naive Bayesian classifier (NBC) containing spin-lattice relaxivity and zeta potential as descriptors was employed. The authors successfully established an applicability domain by using the concept of probability density, and decision boundaries were determined for the above NBC by considering different acceptance levels of false negative to false positive predictions.

Despite the fact that the nano-QSAR models discussed above convey great advances for the regulatory risk assessment of diverse biological effects of NPs, several major drawbacks can be noticed. From one side, some of these models use only experimental descriptors, and taking into account that measurements overall embody experimental errors, this may introduce a great uncertainty when the QSAR models are built up (Fourches et al., 2010). On the other hand, whole QSAR models up to now have been based on limited datasets of NPs, in which toxicity tests have been accomplished by considering only one living system (bio-indicator species, cell line, etc.) and only one reported measure of toxic effects. Additionally, such QSAR models did not provide information regarding important factors such as the shape and medium under which the sizes of the NPs have been measured, as well as other experimental conditions such as the time during which the living systems have been exposed to the NPs. Finally, we would like to emphasize that the previously developed QSAR models in nanotechnology have generally focused on the prediction of cytotoxicity, and thus, no model has been reported so far with the aim of performing virtual screenings of ecotoxic effects of NPs. Therefore, the setup of a QSAR model able to predict the ecotoxicity of NPs by considering different experimental conditions would be of great importance in nanotoxicology, an in general terms, for nanotechnology. Bearing in mind all these ideas, and the fact that many NPs are released into the environment in their bare forms due to processes such as manufacture,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

manipulation and use, we dedicate the next section of this chapter to the analysis of QSAR-perturbation models which are focused on the simultaneous prediction of dissimilar ecotoxic effects of uncoated NPs under multiple experimental conditions.

Perturbation Models: A New Paradigm in QSAR Studies

Recently, it has been reported the possibility to apply perturbation theory to QSAR models (Gonzalez-Diaz et al., 2013). In this context, several QSAR-perturbation models have been developed and thoroughly validated, forward-allowing the prediction of different biological effects of chemicals species in diverse fields such as organic synthesis, computational pharmacokinetic modeling, and the study of process of self-aggregation of drugs into micellar NPs. Taking into consideration the importance of QSAR-perturbation models, we will summarize their main aspects.

These innovative models allow the integration of different kinds of chemical and biological data. One of the principal aspects of QSAR-perturbation models is the use of ontologies, which can be viewed as experimental conditions, *i.e.*, the results of the combinations of different elements or factors. For instance, the ontology c_j can be expressed in the form c_j => (b_t, p_s, d_m, t_e), where b_t characterizes the different biological targets (assay organism, cell line, etc.), p_s describes the diverse shapes (morphologies) of the NPs, d_m represents the conditions under which the sizes of the NPs have been measured (in aqueous solution, culture medium, or for the dry powder), and t_e refers to the different periods of time during which the biological targets have been exposed to the NPs.

The main purpose of the QSAR-perturbation models is to describe two principal aspects. From one side, the model should be sensitive to the variation in both the chemical composition of the NPs and the different sets of experimental conditions. But if the descriptors originally calculated (or experimentally determined) for NPs are used, they will not be able to differentiate the toxic effect of the NPs whenever the experimental condition c_j is modified. In an attempt to accomplish this task, the moving average approach (MAA) can be applied (Hill & Lewicki, 2006), and new descriptors can be generated as follows:

$$DX_i(c_j) = X_i - X_i(c_j)_{avg} \tag{1}$$

In the previous equation, X_i is a defined descriptor or physicochemical property, and $X_i(c_j)_{avg}$ is calculated as the average of all the X_i values, which were tested under the same experimental condition c_j. Equation 1 should be applied to each element of the ontology c_j. In any case, only descriptors of type $DX_i(c_j)$ are employed because they take into account both the chemical composition (or any other property) and the experimental condition c_j under which cases/NPs have been tested.

The second aspect focuses on overcoming the limitations of current classical QSAR models. The main hypothesis assumed by such models is that modifications in the structure and/or composition of the chemicals will produce changes in the activities/toxicities with respect to a hypothetical reference chemical (intercept). This assumption is simple but very weak, due to the fact that, in principle, even more than one chemical could be used as reference at the same time. To overcome such assumption, let us first consider a set of NPs along with their respective toxicities [$TE_i(c_j)$] and descriptors $DX_i(c_j)$. If we generate pairs of NPs, then we can consider the following equation:

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$TE_i(c_j)_{nw} = a_0 \cdot TE_i(c_j)_{rf} + \sum b_j \cdot \left[DX_i(c_j)_{nw} - DX_i(c_j)_{rf} \right] + d_0 \quad (2)$$

where for each pairs of NPs, $TE_i(c_j)_{nw}$ is the toxic effect a defined NP in the new state (experimental condition to be predicted), while $TE_i(c_j)_{rf}$ is the toxic effect of the NP of the same pair selected as reference. The term in Equation 2 involving the descriptors of type $DX_i(c_j)$ can be viewed as the perturbation term [$DDX_i(c_j)$], which expresses the differences between the two NPs in terms of chemical compositions (physicochemical properties), sizes, shapes, biological targets, conditions under which the sizes have been measured, and times during which the biological targets have been exposed to the NPs. Also, the a_0, b_j, and d_0 coefficients can be determined by resorting to regression or classification statistical techniques. Notice that regression will be used if $TE_i(c_j)_{nw}$ and $TE_i(c_j)_{rf}$ are the exact values of toxic effects of the NPs. If these two variables just mentioned are instead categorical variables (defining classes according to certain cutoff values), then, classification methods are to be used.

The application of perturbation theory to nano-QSAR problems is very recent. For this reason, only two works have been reported up to date. The first of these works was devoted to the prediction of the cytotoxicity of NPs under different experimental conditions (Luan et al., 2014). Therein, the authors developed a QSAR-perturbation model aiming at simultaneously predicting the cytotoxicity of 41 different NPs by considering assays against at least 1 out of 15 mammalian cell lines and within 1 out of 5 exposure times. From the physicochemical point of view, the NPs exhibited at least 1 out of 5 possible shape labels, and their sizes were measured in at least 1 out of 4 conditions. The measure of biological effect was TC_{50}, which is the concentration of NPs leading to 50% reduction in cell viability. The NPs were assigned to 1 out of 2 possible classes named "non-cytotoxic" and "cytotoxic". Thus, the NPs were only considered as non-cytotoxic for $TC_{50} \geq 503.572$ μM, otherwise, they were considered as cytotoxic. The descriptors used were the following: molar volume, electronegativity, polarizability, and NP size. These were then transformed to descriptors of the type $DX_i(c_j)$ (Equation 1). Afterwards, by applying the perturbation approach (Equation 2), the authors generated a database of 1681 cases (pairs of NPs), which was randomly split into training (1261 cases) and prediction (420) sets. Then after, LDA was used as the statistical technique to setup the QSAR-perturbation model. The accuracy of the model was higher than 93% for both training and prediction sets. The practical applicability of the model was demonstrated by predicting the cytotoxicity of different NPs such as those formed by silica (SiO_2), nickel (Ni), and nickel(II) oxide (NiO). Each NP was predicted 41 times, and the results of the predictions converged with the reports of the literature. This work represents a great advance in the computational risk assessment of NPs, because, to the best of our knowledge, the present research is the first attempt to simultaneously predict the cytotoxicity of NPs under multiple experimental conditions by applying a single unified QSAR model.

The second work was based on a very similar QSAR-perturbation methodology, but with a different purpose. In this sense, the objective therein was to predict the ecotoxicity of NPs under dissimilar sets of experimental conditions (Kleandrova et al., 2014). Thus, 85 initial NPs were retrieved from the literature, and these have been tested by at least 1 out of 4 measures of ecotoxicity, against at least 1 out of 20 assay organisms (bio-indicators), and within 1 out of 9 intervals of time of exposure. The different NPs displayed at least 1 out of 7 labels related to their shapes, and their sizes were measured in at least 1 out of 5 conditions. The same physicochemical properties employed on the mentioned previous work

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

were used. The QSAR-perturbation model was derived from a database containing 5520 cases, and its accuracy was *ca*. 99% in both training and prediction sets. Three different nickel-based (Ni) NPs with experimental values reported in the literature were predicted 85 times. As in the case of the first work referred to above, the predictions were also found to be in very good agreement with the experimental evidences, confirming that Ni NPs are not ecotoxic when compared with other NPs. The results of this study thus provided a valuable tool towards an efficient multi-tasking prediction of one of the most important aspects of risk assessment of NPs: *ecotoxicity*. Until now, this work constitutes the only report that really deals with the ecotoxicological profiles of nanomaterials.

The two QSAR-perturbation models reported here have a common detail that is of outstanding importance, since another major limitation of classical QSAR models is overcome. This is related with the fact that in classical models, each endpoint-case to be classified – if the dataset comprises only a single prediction to be made, as well as any future decision to classify a chemical species (external prediction) are based on the reliability of the predictions according to certain criteria belonging to the applicability domain (Dimitrov et al., 2005; Dragos et al., 2009; Fechner et al., 2010; Kulkarni & Zhu, 2008; Netzeva et al., 2005; Weaver & Gleeson, 2008). In the specific case of the QSAR-perturbation models, random pairs of NPs were generated, in which each NP was used many times in both conditions, that is, as one NP in the initial state (reference NP) and as one NP in the new (output or final) state. Therefore, each NP used as reference participated in many predictions of other NPs, and simultaneously, the very same NP was predicted many times using the others. This procedure breaks the boundaries of the classical QSAR models, allowing one to obtain more precise and realistic results. On the other hand, the decision to classify NPs using the QSAR-perturbation models is based on consensus predictions. For this reason, the new (external) NPs were predicted 41 times in the first work referred, and 85 times in the second one, since those are the number of NPs which were originally used to setup the QSAR-perturbation models. Thus, any NP is correctly predicted/classified according to its experimental value of toxicity (compared with the cutoff values) when the consensus percentage is higher than 50%. For a percentage lower than 50% the prediction is considered to fail, while a percentage equal to 50% is considered to be a random prediction. Notice that the consensus percentage is the ratio of the number of times that a NP was correctly classified with respect the total number of possible predictions (*i.e.*, the number of NPs originally used in the dataset).

A QSAR PERTURBATION-BASED MODEL FORWARD-TARGETING ECOTOXITICY OF METAL-BASED NANOPARTICLES

Here, one should emphasize that often no strong linear relationships between the descriptors of the chemical species and their biological activities/toxicities are found. One of the principal motives is that sometimes the process or phenomenon understudy is very complex. In such cases, machine learning methods like ANN can be used because they have become useful tools for virtual screening (Prado-Prado et al., 2010; Speck-Planche & Kleandrova, 2012; Tenorio-Borroto et al., 2012). Indeed, even when simple statistical methods yield good results, ANN can be employed in order to coverage more chemical space in terms of predictive capability. As a contribution for the advancement of our understanding on ecotoxicological profiles of NPs, we present here for the first time, a QSAR-perturbation model based on ANN aimed at predicting the ecotoxicity of metal-based NPs by taking into account the following

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

varying factors: chemical composition, size, conditions under which the size is measured, shape, type of measures of the ecotoxicity, biological targets (bio-indicators), and time during which the biological targets are exposed to the NPs.

Dataset, Descriptors, and Set-Up of the QSAR-Perturbation Model

The dataset employed for setting the current QSAR model was the same as that discussed in the second report focused on establishing a QSAR-perturbation model (Kleandrova et al., 2014). So we will limit ourselves here to a brief outline highlighting only the most important aspects. Each of these 85 NPs were assayed by considering at least 1 out of 4 measures of ecotoxicity (m_e), against at least 1 out of 20 biological targets/bio-indicator species (b_t), where NPs exhibited at least 1 out of 7 types of shape labels (p_s). At the same time, the NP size was measured in at least 1 out of 5 conditions (d_m), and at least 1 out of 9 different times (t_e) during which biological targets were exposed to NPs in the ecotoxicity tests.

In the dataset, all the 85 cases/ NPs were associated to two possible categories related with its ecotoxicity in a specific experimental condition c_j. Each of the NPs was assigned to the category "non-ecotoxic" [$ETOX_i(c_j) = +1$] when it had a large value of the measure of ecotoxicity, otherwise, the NP was assigned to the category "ecotoxic" [$ETOX_i(c_j) = -1$]. We need to point out here that $ETOX_i(c_j)$ is a binary (categorical) variable which is employed to classify non-ecotoxic or ecotoxic NPs, according to certain cutoff values of ecotoxicity (Table 1). Another important element is the use of the experimental condition c_j, embodying the ontology with the form c_j => (m_e, b_t, p_s, d_m, t_e). That is, the combination of these five elements describes a specific experimental condition. Each NP was characterized by four descriptors. The first three were the molar volume (V), the electronegativity (E), and the polarizability (P), thus based on the chemical composition of the different NPs. These physicochemical descriptors were retrieved from the public source Chemicool Periodic Table (Hsu, 2013). In the case of the NPs composed by more than one element, the descriptors mentioned above were normalized; that is, the descriptors for such kind of NPs were computed as the sum of the descriptors of all the atoms forming the NPs, and the result of the sum was divided by total number of atoms. The fourth descriptor was the size L (expressed in nm) of each NP, which has been experimentally measured. All chemical and ecotoxicological data were deposited in an excel file, shown in Supporting Information (file **SM1**).

As explained before, Equation 1 was applied to calculate the descriptors of the type $DX_i(c_j)$, and $X_i(c_j)_{avg}$ for the entire set n_j was calculated as the average of all the X_i values for only those cases/NPs that were considered as non-ecotoxic cases (subset of n_j) in the same element of c_j. Then after, the 85 NPs

Table 1. Cutoff values used for the different measures of ecotoxicity

Measure of Ecotoxic Effect	Cutoff[c]	Meaning
EC_{50} (μM)[a]	≥ 168.45	Effective concentration of the nanoparticle which inhibits at 50% the growth of the assay organism.
IC_{50} (μM)[a]	≥ 177.62	Concentration of the nanoparticle which inhibits the root elongation of the assay organism (plants) at 50%.
TC_{50} (μM)[b]	≥ 225.81	Concentration which causes toxic effects in 50% of the assay organisms.
LC_{50} (μM)[b]	≥ 334.08	Lethal concentration which causes mortality in 50% of the assay organisms.

[a] Based on tests with bacteria, algae, and fungi; [b] Based on tests with crustaceans and fish; [c] Condition under which a nanoparticle was assigned to the category of non-ecotoxic.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

were used to setup 5939 random pairs of NPs. Notice now that Equation 2 expresses the perturbation approach when there is a linear dependence between the toxic effect of the NP in the new state and the toxic effect of the NP in the reference state together with the perturbation terms. A more general expression for any type of dependence would be:

$$ETOX_i(c_j)_{nw} = f[ETOX_i(c_j)_{rf}, DDX_i(c_j)] \quad (3)$$

In Equation 3, the ecotoxicity $ETOX_i(c_j)_{nw}$ of any NP in the new/final state can be obtained from the corresponding ecotoxicity $ETOX_i(c_j)_{rf}$ of another NP selected as reference, and the perturbations terms $DDX_i(c_j)$. In addition, *f* is a very complex function used to model the dependence of $ETOX_i(c_j)_{nw}$ with respect to $ETOX_i(c_j)_{rf}$ and $DDX_i(c_j)$. Notice that both $ETOX_i(c_j)_{nw}$ and $ETOX_i(c_j)_{rf}$ are binary variables, and the terms $DDX_i(c_j)$ are calculated according to the following formula:

$$DDX_i(c_j) = DX_i(c_j)_{nw} - DX_i(c_j)_{rf} \quad (4)$$

Thus, $DDX_i(c_j)$ describes the differences between any two NPs (new and references states) in terms of their variations in chemical composition, size, shape, conditions under which the sizes are measured, biological target that is tested, measures of ecotoxicity, and times of exposure of the biological targets to the NPs.

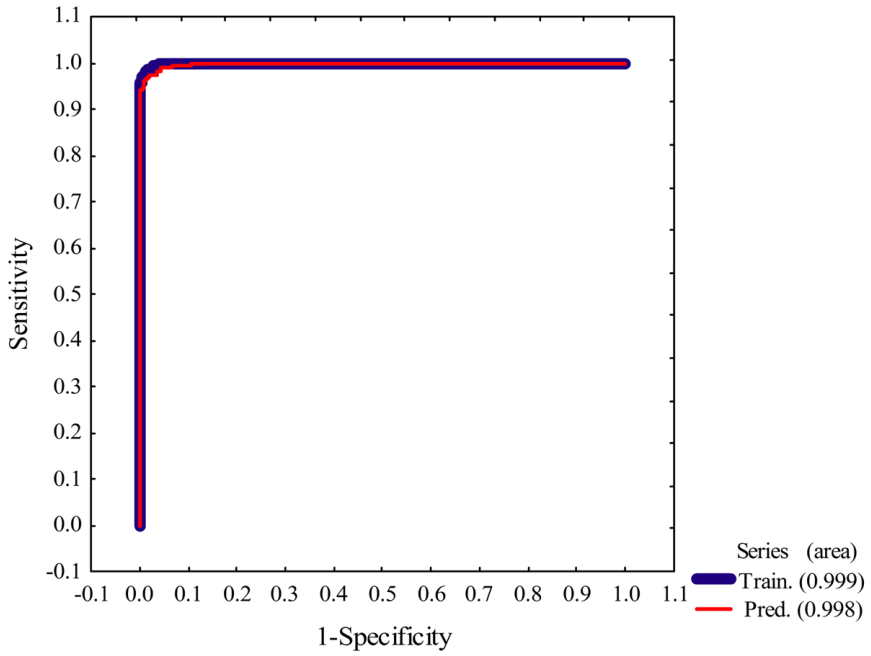
The dataset containing the 5939 cases (pairs of NPs) was randomly split into training and prediction sets. The training set was used to seek for the best QSAR-perturbation model and being formed by 4439 cases, in which 2081 cases correspond to NPs in the new state considered as non-ecotoxic and 2322 cases assigned ecotoxic. As to the prediction set, it contained 1500 cases with 715 cases considered as non-ecotoxic and 785 ecotoxic, and it was used to validate the model. The function *f* of high complexity appearing in Equation 3 was modeled by using different types of ANN. The program employed to perform this task was STATISTICA 6.0 (Statsoft-Team, 2001). In order to select the most appropriate descriptors to build up the QSAR-perturbation model, we performed a sensitivity analysis. In this sense, the neural network module of STATISTICA defined a missing value substitution procedure, which is used to allow predictions to be made in the absence of values for one or more input variables (Statsoft-Team, 2001). Thus, to define the sensitivity of a particular input variable (descriptor) *v*, in a first step, each ANN is run on a defined set of cases (training cases), where a network error is accumulated (Hill & Lewicki, 2006). Then, in a second step, the network is run again using the same cases, but this time replacing the observed values of *v* with the value estimated by the missing value procedure. So, a new network error is accumulated. Taking into account that some information that each network uses, has effectively been removed (*i.e.* one of the input variables), it is logical to expect some error' deterioration to occur (Hill & Lewicki, 2006). Then, the sensitivity of any input variable is calculated as the ratio of the error with missing value substitution to the original error. The more sensitive the network is to a particular input variable (descriptor), the greater the deterioration one can expect, and therefore the greater the ratio. The larger the value of sensitivity, the greater the importance/influence a descriptor has in the model. For this reason, only variables with the largest values of sensitivity were selected. Also, we attempted to avoid collinearity between the descriptors. The statistical quality of the QSAR-perturbation model was assessed by examining some statistical indices such as the percentages of correct classifications for both

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

non-ecotoxic and ecotoxic cases, the overall correct classification in the whole dataset, the Matthews correlation coefficient (MCC) (González-Díaz et al., 2007), and the areas under the receiver operating characteristic (ROC) curves for the training and prediction sets (Hanczar et al., 2010).

In order to search for the best QSAR-perturbation model, we tested different kinds of architectures for the ANN, namely: linear neural networks (LNN), probabilistic neural networks (PNN), radial basis function (RBF), and multi-layer perceptron (MLP). The ANN with the highest quality identified had the profile MLP 8:8-12-1:1. The symbols and meanings of the descriptors of the final QSAR-perturbation model are shown in Table 2.

In the training set, our model correctly classified 2036 of 2081 (97.84%) cases in the category of non-ecotoxic, and 2322 of 2358 (98.47%) cases in the ecotoxic category. At the same time, the results in the prediction set showed that the model rightly classified 97.20% (695 of 715) of cases assigned as non-ecotoxic, and 97.45% (765 of 785) of cases considered as ecotoxic. The accuracies displayed by this QSAR-perturbation model were 98.18% and 97.33% for the training and prediction sets, respectively. The results of the classifications can be found in the Supporting Information (**SM1** file). On the other hand, we calculated the MCC values since these measure the strength in the correlations between the observed and predicted values of categorical variables. Thus, MCC values of 0.963 and 0.947 were found for the training and prediction sets, respectively. Accordingly, in both cases there was a very strong linear correlation between the observed and predicted values of the categorical variable $ETOX_i(c_j)_{nw}$, confirming the quality and predictive power of our model.



Finally, the areas under the ROC curves (see Figure 1) served as a final check-up of the very good performance of the derived QSAR-perturbation model. The values found were 0.999 and 0.998 for the training and prediction sets, respectively, indicating that the present model is not a random classifier because the areas under the ROC curves are very different from 0.5 – *i.e.* the value for a random classifier. The indices examined here demonstrate in terms of statistical quality and predictive power that

Table 2. Descriptors that entered into the final QSAR-perturbation model

Descriptor	Meaning
$\boldsymbol{ETOX_i(c_j)_{rf}}$	Categorical variable reflecting the ecotoxicity of the nanoparticle used as reference.
$\boldsymbol{DDV(m_e)}$	Perturbation term which accounts for the changes in the molar volume between the new (output or final state) nanoparticle and that used as reference, also depending on the measures of ecotoxicity.
$\boldsymbol{DDV(b_t)}$	Perturbation term based on the variations in the molar volume between the new (output or final state) nanoparticle and that used as reference, also depending on the biological targets.
$\boldsymbol{DDE(b_t)}$	Perturbation term focused on the changes in the electronegativity between the new (output or final state) nanoparticle and that used as reference, also depending on the biological targets.
$\boldsymbol{DDP(p_s)}$	Perturbation term which describes the changes in the polarizability between the new (output or final state) nanoparticle and that used as reference, also depending on the shapes of the nanoparticles.
$\boldsymbol{DDE(d_m)}$	Perturbation term which characterizes the variations in the electronegativity between the new (output or final state) nanoparticle and that used as reference, also depending on the conditions under which the sizes of the nanoparticles were measured.
$\boldsymbol{DDL(d_m)}$	Perturbation term which takes into consideration the changes in the size between the new (output or final state) nanoparticle and that used as reference, also depending on the condition under which the sizes of the nanoparticles were measured.
$\boldsymbol{DDE(t_e)}$	Perturbation term which describes the variations in the electronegativity between the new (output or final state) nanoparticle and that used as reference, also depending on the times during which the biological targets were exposed to nanoparticles.

Figure 1. ROC curves obtained from the QSAR-perturbation model based on ANN

this QSAR-perturbation model is comparable with those reported in the literature (Concu et al., 2009a; Concu et al., 2009b; Garcia et al., 2011; Gonzalez-Diaz et al., 2013; Tenorio-Borroto et al., 2013). One should notice here that all the statistical indices reported for the QSAR-perturbation model based on ANN are very similar to those reported in the second mentioned work (Kleandrova et al., 2014). However, for the present QSAR-perturbation model a considerably larger number of pairs of NPs was generated and correctly classified. These simple but essential details confirm the idea that ANN can cover a wider "nanotoxicity space".

By definition, each descriptor present in any QSAR model has a degree of importance, which ensures its influence in the performance of that model. On the other hand, QSAR models should embody very useful interpretation in terms of structural and/or physicochemical properties, forward-giving an explanation regarding the changes in the activities/toxicities of the chemical species. In the case of our QSAR-perturbation model, we computed the corresponding sensitivity values of the descriptors (Figure 2). As commented before, sensitivities in ANN represent the relative importance of the variables (descriptors). Generally, for any ANN-based model built, no equation can be obtained and thus, it is very difficult to know how the descriptors should be varied to trigger particular changes in the activities/toxicities. Despite the lack of equations, one can interpret the variations of the different descriptors in such kinds of models following the procedure recently suggested by some of the present authors (Speck-Planche & Kleandrova, 2012). That is to say, if the mean values of the perturbation terms for non-ecotoxic cases are compared to the same values for ecotoxic cases, then, the analyst can have an idea about the tendency of variation of the descriptors in the model. Hence, by analyzing Figure 2 and Table 3, we can make this kind of deductions by considering how the different factors in the NP should be modified in order to decrease its ecotoxic effect.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 2. Relative influence of the descriptors in the QSAR-perturbation model

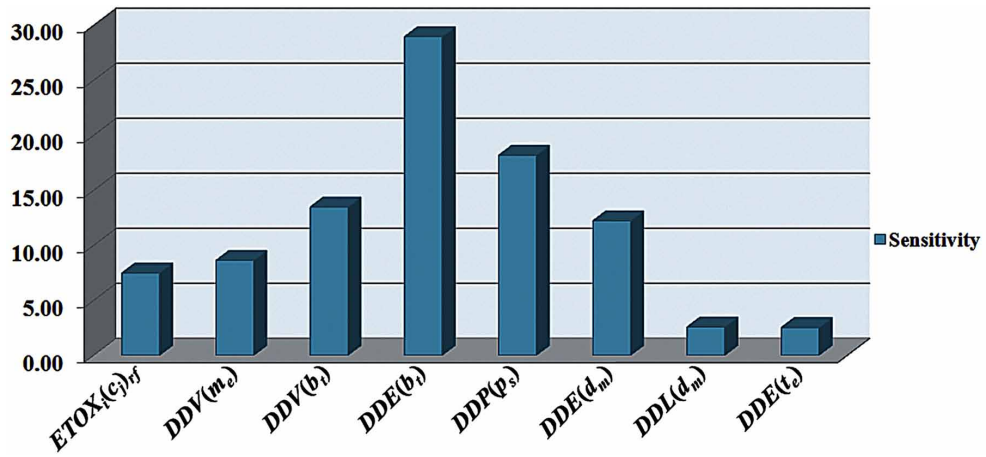

Table 3. Mean values of the perturbation terms

Descriptor	Mean (Non-Ecotoxic)	Mean (Ecotoxic)
$DDV(m_e)$	+0.742	−1.092
$DDV(b_t)$	−0.161	+0.460
$DDE(b_t)$	−0.213	+0.261
$DDP(p_s)$	−0.517	+1.090
$DDE(d_m)$	−0.154	+0.175
$DDL(d_m)$	+9.677	−7.286
$DDE(t_e)$	−0.043	−0.012

The descriptor $DDE(b_t)$ has the greatest influence in the QSAR-perturbation model based on ANN. This descriptor depends on the differences between the electronegativities of the NPs used as new and reference states, and the biological targets which were tested. Inspection of Table 3 tells us that the electronegativity of the elements that constitute the NPs should diminish, *i.e.* the presence of oxygen atoms should be avoided. Diminution of $DDE(b_t)$ will thus decrease the ecotoxic effect of the NPs. The same variation in the electronegativity characterized by $DDE(d_m)$ (4th in raking) will produce a similar effect in the ecotoxicity. This descriptor also depends on the conditions under which the sizes of the NPs have been measured. However, these changes in the electronegativity are constrained by $DDE(t_e)$ (having the smallest influence in the model) which additionally describes different times of exposure of the biological targets to the NPs.

The second most important descriptor is $DDP(p_s)$, which is based on the differences of polarizability between any two NPs, as well as in their shapes. Therefore, diminution in the polarizability of the NPs should make them less ecotoxic. With the aim of diminishing the ecotoxic effect of NPs, the values of $DDV(b_t)$ (3rd in raking) are also to be decreased. This descriptor has a similar interpretation as $\Delta\Delta E(b_t)$, with the differences between NPs involving molar volume instead of electronegativity. In any case, $DDV(b_t)$ is remarkably constrained by $DDV(m_e)$ (5th in raking) that depends on the diverse

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

measures of ecotoxicity with which the NPs have been assessed. Notice that the combined interpretation of $\boldsymbol{DDV(b_t)}$ and $\boldsymbol{DDV(m_e)}$ indicates that there should be an equilibrium between the ability of the NPs to penetrate the cells of the biological targets and the possibility to undergo agglomeration. By considering the information provided in Table 3 for the case of the descriptor $\boldsymbol{DDL(d_m)}$ (7th in raking), one sees that the increment in the size of the NPs will diminish its potential ecotoxicity. This physical variable will depend on the difference in size of the NPs, and the conditions under which such sizes have been measured. As final aspect, we would like to emphasize that our approach depicted in Table 3 strongly converge to the physicochemical interpretation of the descriptors discussed in the previous report (Kleandrova et al., 2014).

Virtual Screening Using the QSAR-Perturbation Model

Even when any QSAR model is built on, its applicability should be demonstrated. Although the classical variants of such models restrict their use to try to understand the behavior of the chemical species, a more promising application can be realized, *i.e.* to perform virtual screening. For the specific case of our QSAR-perturbation model, we were able to give very simple physicochemical explanations about the characteristics of the NPs that can be desirable and/or detrimental to lessen the ecotoxicity. Following on, we will use our model to predict the ecotoxicity of different NPs extracted from external sources.

The first case of study is focused onto the prediction of ecotoxic effects of nickel (Ni) NPs, which have been reported experimentally a couple of years ago (Ispas et al., 2009). In such work, three different spherical Ni-NPs with sizes 30 nm, 60 nm, and 100nm (dry powders) were tested against zebra fish (*Danio rerio*) embryos during a period of 120 hrs. The acute toxicities (LC_{50}) were measured, exhibiting value of 328 mg/L (5588.40 μM), 361 mg/L (6150.65 μM), and 221 mg/L (3765.36 μM) for the sizes 30 nm, 60 nm, and 100 nm, respectively. The second case of study is devoted to predict the ecotoxicity of a CuO-NP with size 30 nm, which has been experimentally evaluated against *Pseudokirchneriella subcapitata* (Aruoja et al., 2009). This microalga was exposed to the CuO-NP (dry powder) during a period of 72 hrs, and the effective concentration leading to 50% reduction in the growth (EC_{50}) had a value of 0.71 mg Cu/L, which represents 0.889 mg/L (11.18 μM) for the CuO-NP. If we compare all these ecotoxicities with the corresponding cut off values, then, Ni-NPs should be classified as non-ecotoxic by our QSAR-perturbation model based on ANN, while the CuO-NP should be predicted as ecotoxic.

We need to emphasize that the decision of considering these new NPs as non-ecotoxic or ecotoxic by using our QSAR-perturbation model was not based on one single prediction. All the NPs were predicted 85 times, because the 85 NPs belonging to the original dataset were used as reference NPs. Accordingly, as commented in the previous section, the decision of considering NPs as non-ecotoxic (for the case of Ni-NPs) or ecotoxic (for the case of the CuO-NP) depends on the percentages of correct classification extracted from a consensus prediction, according to certain rules.

The particular results of predictions for each NP can be found in the Supporting Information (file **SM2**). Nevertheless, the summary of the results of the predictions are depicted in Table 4. The spherical Ni-NPs with sizes 30 nm, 60 nm, and 100 nm were correctly predicted as non-ecotoxic with very high consensus percentages. Of particular interest are the differences in the consensus percentages between the three Ni-NPs. Notice that the only condition which varies is the size of each NP, and the larger the size the higher the consensus percentage indicating the low ecotoxicity of the Ni-NP. These results have a strong convergence with our explanation regarding the physicochemical interpretations of the perturbation terms, where we suggested that the size of any NP should be increased in order to decrease its

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Table 4. Consensus predictions performed using the QSAR-perturbation model

Nanoparticle	m_e	b_t	p_s	d_m	t_e	$ETOX_i(c_j)_{nw}$	%CCT[a]
Ni-30 nm	LC_{50} (μM)	*Danio rerio* (embryos)	spherical	dry	120	+1	84.71
Ni-60 nm	LC_{50} (μM)	*Danio rerio* (embryos)	spherical	dry	120	+1	89.41
Ni-100 nm	LC_{50} (μM)	*Danio rerio* (embryos)	spherical	dry	120	+1	96.47
CuO-30 nm	EC_{50} (μM)	*Pseudokirchneriella subcapitata*	N/A	dry	72	−1	87.06
CuO-30 nm	EC_{50} (μM)	*Pseudokirchneriella subcapitata*	spherical	dry	72	−1	97.65
CuO-30 nm	EC_{50} (μM)	*Pseudokirchneriella subcapitata*	pyramidal	dry	72	−1	76.47
CuO-30 nm	EC_{50} (μM)	*Pseudokirchneriella subcapitata*	irregular	dry	72	−1	76.47
CuO-30 nm	EC_{50} (μM)	*Pseudokirchneriella subcapitata*	elliptical	dry	72	−1	65.88
CuO-30 nm	EC_{50} (μM)	*Pseudokirchneriella subcapitata*	needle	dry	72	−1	57.65
CuO-30 nm	EC_{50} (μM)	*Pseudokirchneriella subcapitata*	strip	dry	72	−1	100.00

[a] Consensus percentage, *i.e.* the percentage of times that the QSAR-perturbation model correctly predicted the nanoparticle according to its observed value of $\boldsymbol{ETOX_i(c_j)_{nw}}$.

ecotoxic effect. On the other hand, predictions performed for the CuO-NP were also in agreement with the experimental evidence. In this case, the authors of the research did not report the shape of the CuO-NP (Aruoja et al., 2009). Therefore, we decided to predict the ecotoxicity of the CuO-NP by considering six of the shape labels understudy, namely: spherical, pyramidal, irregular, elliptical, needle, and strip. We also took into account the category where no NP shape has been reported (N/A). Our predictions indicate us that CuO-NP is toxic against *Pseudokirchneriella subcapitata*, for all the possible shapes considered by the QSAR-perturbation model (Table 4). Therefore, the most important factor associated with the ecotoxicity of the CuO-NP is not the shape but its composition. That comes from the fact that the CuO-NP has one very electronegative element (oxygen), and as commented above, the presence of electronegative atoms can increase the ecotoxic effect of NPs. Both these suggestions and the prediction results demonstrate that our QSAR-perturbation model is very sensitive to the changes in both physico-chemical properties associated with the composition, and different experimental elements, being thus a promising computational tool for the efficient prediction of ecotoxicity of NPs under diverse sets of experimental conditions.

CONCLUDING REMARKS AND RECOMMENDATIONS

Several researchers have emphasized the use of promising guidelines for the computational modeling of toxic effects of nanomaterials (Kahru & Ivask, 2013; Westerhoff & Nowack, 2013), and there are also some reviews and chapters directed towards the development of reliable nano-QSAR models in recent years (Fourches et al., 2010; Kar et al., 2014a; Puzyn et al., 2011; Toropov et al., 2012). It is genuinely true that such task is a great challenge that may lead to new and exciting directions for QSAR modeling techniques. However, there are some problems one should face, namely:

- In the process of building reliable QSAR models, the ecotoxicological profiles of nanomaterials should be clear along with the development of toxicology studies.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

- There is a strong need to supplement the existing set of molecular descriptors by novel "nano-descriptors" that can represent size, shape, and so on-dependent properties of nanomaterials.
- More sophisticated methods such as the present QSAR-perturbation theory should be followed whenever developing QSAR models to tackle nanomaterials' endpoints.
- Most likely the current criteria of evaluating the models' quality (*i.e.* the five OECD rules) will have to be re-evaluated and adapted to nanomaterials. This is due to the specific properties of chemicals occurring at the "nano" level (for instance, electronic properties change with changing size), and the very limited number of available data (Notice that one has to overcome the problems of the "classical" method of validation that is biased towards small, low molecular weight molecules.).
- Regarding composition, nanoparticles in biological media are covered by a stabilizing layer and/or a protein corona, so that the NP surface may not be in direct contact with cells, so a change in the toxicity profile is to be expected and should be taken into account.

FUTURE RESEARCH DIRECTIONS

In this chapter, we have developed the first unified QSAR-perturbation model, demonstrating its ability to predict ecotoxicity of NPs under diverse experimental conditions. In so doing, the next promising horizons regarding the application of QSAR-perturbation models are to be devoted to the integration of different ecotoxicity profiles, with other biological effects such as cytotoxicities, and pharmacological activities (antibacterial, antiviral, anticancer). This will ensure the design and application of safer nanoparticles in very important fields like nanomedicine. On the other hand, further studies aiming at deriving QSAR-perturbation models to predict synthesis of NPs can contribute to the creation of more sustainable processes and/or alternatives in nanochemistry, helping to control the release of NPs into the environment. Finally, we would like to point out that the use of complex network theory may well be of great interest in order to gain a more thorough knowledge about the ecotoxic effects of NPs. Towards that goal, the design and study of the dynamics of NP-NP complex networks may help to understand the evolution of the ecotoxic behavior of NPs over time. All these ideas will contribute towards further developing and establishing one discipline that has just emerged as a need to study the 'nanoworld' in a more rational way: *nanoinformatics*.

KEY TERMS AND DEFINITIONS

%CCT: Consensus percentage or percentage of times that the QSAR-perturbation model correctly predicts the NPs properties. This percentage is used to establish how promising is the QSAR model setup on the virtual screening of different NPs extracted from external sources (*i.e.* usually if it reaches %CCT greater than 50%).

ANN: Artificial neural network machine learning technique.

MAA: Moving average approach used in the QSAR-perturbation based models.

MNPs: Manufactured nanoparticles.

Nano-QSAR Model: Quantitative Structure–Activity Relationships model applied to target the properties of nanomaterials understudy.

Ontology: A set of factors that describe a specific experimental condition under which the properties of NPs have been measured.

Sensitivity of the Descriptors: Relative importance of the variables (descriptors) used in the final QSAR ANN-based model that allows estimating how those should be varied to trigger particular changes in the NPs' properties understudy.

This work was previously published in Quantitative Structure-Activity Relationships in Drug Design, Predictive Toxicology, and Risk Assessment edited by Kunal Roy, pages 506-534, copyright year 2015 by Medical Information Science Reference (an imprint of IGI Global).

Chapter 52
Stratagems of Nanotechnology Augmenting the Bioavailability and Therapeutic Efficacy of Traditional Medicine to Formulate Smart Herbal Drugs Combating

Anita Margret
Bishop Heber College, India

ABSTRACT

Mental illness is one of the most fundamental emotional states of conscious being which becomes unbalanced and leads to neurological disorders. It is a significant contributor to the global burden of disease and there is a strong desire to devise a remedy. Ayurveda represents a traditional medicine system of India that endorses antiquity than western medicine and relies on formulations rather than their active components. It has categorised a group of herbal medicines to improve mental abilities. Conversely, the mechanistic details of the therapy are not available in ayurvedic literature and there is a need to fortify this system with modern scientific analysis. The design of nanosystems encompasses promising characteristics in the field of drug delivery with a limited dosage thereby decreasing adverse effects. This chapter confers stratagems of devising polymeric nano herbal formulations as smart nano brain drugs to espouse mental health.

INTRODUCTION

The venture to maintain an optimal state of health includes both physical and mental wellbeing and a stable mind symbolizes an ideal physiology which is an imperative cause of existence. Mental health is an essential parameter that reflects the emotional, psychological and social wellbeing of an individual. Presently the populace stumble upon various emotional issues pertaining to their professional and

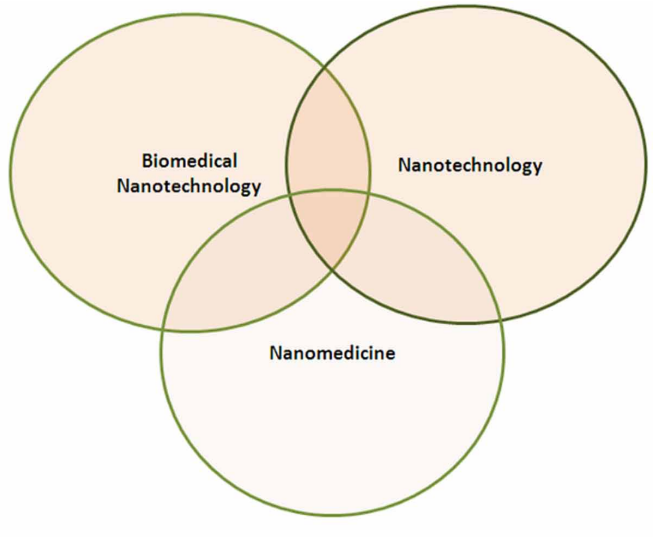
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

personal life that evokes stress in their day today life. The unbalanced state of conscious being leads to mental disorders that erode subsistence. Trapped with pessimistic thoughts they feel hopeless and helpless thereby desire suicide as their only redeemer. Mental illnesses are a sober condition which can affect a person's thinking, mood, and behaviour. There are various types of mental illness and mental health problems, such as:

- Anxiety disorders,
- Mood disorders,
- Post-traumatic stress disorder (PTSD),
- Obsessive compulsive disorder(OCD),
- Impulse control and addiction disorders,
- Personality disorders.

Though medical field has advanced technologies, the threat of mental ailments intrudes the normal survival rate. There is a sturdy necessitate to treat these distressing conditions and fetch a remedy to stir up the universal welfare. There are several, medications available to combat mental illness but are accompanied with severe adverse effects that would lead to other physiological ailments. The advancement in modern science has to resolve the instinct of studying the context, nonclinical elements and alternative therapies required for enhancing mental health. Therefore, there is a strong desire to elevate research in the field of neuroscience with the resourceful mechanisms revealed, by manoeuvring the innovative technologies. Drug delivery is the most essential feature in drug administration facility and the design of nanosystems makes the action more consistent and appropriate. Polymeric nano particles bind efficiently to the drug and disperse the drug proficiently into the system. This mechanism significantly reduces the side effects of the synthetic drugs. Nanoscience focuses on the approaches of drug delivery in a nano scale, which needs a minimum dosage of drug than the conventional medicinal use. Nanomedicine is the medical application of nanotechnology which is considered as the future medicine. Biomedical nanotechnology, nanobiotechnology, and nanomedicine are the areas used to evolve this hybrid field of research (Figure 1).

The size of nanomaterials is similar to that of most biological molecules and structures. Therefore, nanomaterials can be useful for both *in vivo* and *in vitro* biomedical research and applications. Nanotechnology has provided the possibility of delivering drugs to specific cells using nanoparticles.



It has the following possibilities of facilitating:

- Lowered overall drug consumption and side-effects,
- Reduces expenses,
- Targeted action and develops personalized medicine,
- To improve drug bioavailability.

Drug delivery is the most essential feature in drug administration facility and the design of Nanosystems makes the action more consistent and appropriate. Drug delivery is the most essential feature in drug administration facility and the design of nanosystems makes the action more consistent and appropriate. Polymer nano particles bind efficiently to the drug and disperse the drug proficiently into the system. The efficacy of many drugs is often limited by their potential to reach the site of therapeutic action. In most cases (conventional dosage forms), only a small amount of administered dose reaches the target

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 1. Venn diagram indicating the integration of various research fields as a hybrid

site, while the majority of the drug distributes throughout the rest of the body in accordance with its physicochemical and biochemical properties. Therefore, developing a drug delivery system that optimizes the pharmaceutical action of a drug while reducing its toxic side effects *in vivo* is a challenging task.

Biocompatibility is an essential feature for drug administration and polymeric nanoparticles represent a significant efficiency and effectiveness, with unique physiochemical characteristics. There are various advantage of using polymers as encapsulating agents in drug delivery where, the foremost is the augmentation of stability and exact dispersion of drugs. The polymeric nanoparticles have been devised with specificity, which channelizes them to deliver a higher concentration of pharmaceutical agent to a desired location. Polymeric nanocomposites represent a new alternative to conventional polymers which exhibits markedly improved properties such as:

- Increased modulus and strength,
- Outstanding barrier properties,
- Improved solvent and heat resistance,
- Decreased flammability.

Thus polymers can abet imminent drugs with smart formulations to facilitate drug delivery and improve the pharmaceutical index. Alternative medicine is the use of a nonconventional approach instead of standard synthetic drugs. Traditional system of medicine has a deep rooted contextual derived from ancient communities that endorses antiquity than western medicine. Ayurveda, the Indian traditional system of medicine, has categorized a group of herbal medicines to improve mental abilities and restore metal health effectively. The treaties mention a number of single and compound drug formulations of plant origin that are used in the treatment of psychiatric disorders which have a less adverse effect profile, and exhibit efficacy in treating physical ailments. However, an ambiguity is reflected in the interpretation and mode of action pursued by the drug formulations. The current scenario has realized the significance of Ayurveda, where biomedical and ayurvedic scientists are making attempts to combine

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

the best of different healing traditions to meet the challenge faced in healthcare requirements of modern era. Therefore, there is a robust requirement to promote ayurvedic medicine to reinstate mental illness with ingenious scientific technologies.

The considerable focus of this chapter is to reflect the advance strategies of nanotechnology on herbal medicine that can reduce adverse effects by improving the efficacy against mental illness.

The efficacy of many drugs is often limited by their potential to reach the site of therapeutic action. In conventional dosage system only a small amount of administered dose reaches the target site, while the majority of drug distributes throughout the body in accordance with its physicochemical and biochemical properties. Polymers synchronized with the drug facilitates its delivery precisely across the targeted sites precisely. India is sanctified with a profound herbal resources whose attributes needs to be fortified with novel technologies. The deliverables discussed provides insights to hoist the implication of ayurvedic medicine on par with the western medicine.

BACKGROUND

Mental ailment is a serious physiological condition that affects the wellbeing of individuals. Globally, there is a periodic increase in psychological disorders which is a threat to the society, and depression ascertains a menace among mental illness. The World Health Organization (WHO) has ranked depression the 4th leading cause of disability worldwide and projects that by 2020, it will be the second leading cause (Murray et al., 1996). It is one of the major concerns in current scenario where, people are stumbled and is considered as a threat that intrudes the normal subsistence. Further it has reported that only 12.3% of the global population with this infirmity accept this condition and go for treatment. (Who Fact sheet N0.369, 2015). It is essential to investigate this existing issue and need to pay attention over the mental health worldwide. Fortunately, there is a wide range of synthetic drugs to treat these ailments but are accompanied with side effects which makes the treatment appalling. Commonly, alternative medicines incorporate the practice of herbal remedies which are effective with a low potential of toxic effects. Indian traditional medicine has formulated rich medical expertise knowledge of treatise which was handwritten in Sanskrit language as pre-European information. But after the establishment of British rule western medicine was looked upon as the leading system of medicine. This might be one of the reasons due to which ayurveda could not stand parallel to the western medicine. An ambiguity is reflected in the interpretation and mode of action in the formulations and drugs (Perinchery et al., 2013). The ancient Ayurvedic literature available today does not elaborate the effects of any therapy in terms of our current understanding of biology or physiology. The mode of action and the mechanism involved is not mentioned comprehensibly in the written treatise (Valiathan 2006). Although, there has been an increased interest in traditional and herbal medicine systems in recent times, most studies have used specific extracts or ‘‘active principles’’ derived from herbal or other traditional drugs and formulations. However current scenario has realised the significance of ayurveda, where biomedical and ayurvedic scientists are making attempts to combine the best of different healing traditions to meet the challenge faced in healthcare requirements of modern era and nanotechnology is one such advanced field.

Drug delivery is the most essential feature in drug administration facility and the design of nanosystems makes the action more consistent and appropriate. Delivering drugs across the physiological barrier is one of the most promising applications of nanotechnology in clinical neuroscience. Nanoparticles could potentially carry out multiple tasks in a predefined sequence, which is very important in the delivery of

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

drugs across these barriers. Nanoscience is the study that involves the control of matter on an atomic and molecular scale which range usually below 100 nm. Initially nanomaterials were analyzed for its physical and electronic applications, but pharmaceutical appliance has been geared towards the area of drug delivery. Nanoparticles have the ability to defend the drugs from the degradation in the gastrointestinal tract, which channelizes the target delivery of drugs to various areas of the body. The oral bioavailability of drugs is profoundly increased due to absorptive endocytosis which is a cellular mechanism that sustains the drug for an extended time. This controls the release of drugs that minimizes the side-effects with increased effectiveness and safety that ultimately reducing health care costs. This technology also has the ability to enhance the performance of drugs that are unable to pass clinical trial phases. There is definite promise of nanodrugs to serve as drug delivery carrier of choice for the more challenging conventional drugs used for the treatment and management of various human ailments. Polymeric nano particles bind efficiently to the drug and disperse the drug proficiently into the system. The design of polymer-drug conjugates was propagated by Ringsdorf who used to deliver hydrophobic small molecules (Ringsdorf, 1975). The interpretation of his research described that, small molecule drugs, especially hydrophobic compounds, have a low aqueous solubility and a broad tissue distribution profile that may result in serious side effects. Consequently, conjugation of these compounds to hydrophilic, biocompatible polymers would significantly increase their aqueous solubility, modify their tissue distribution profile and enhance their plasma circulation half-life. The structural organization of a nanosystem is based on its composition and the presence of compartments within nanocapsules (Dong et al., 2013) leads to oily or aqueous cores surrounded by thin polymer membranes,(Arora et al.,2011) whereas, nanospheres provide a matrix-based organization of the polymeric chains.Nanoparticles have been prepared using several methods, including polymer polymerization(Chu, et al., 2013;Hu et al., 2011) ionic gelation or coacervation (emulsion solvent evaporation (Alshamsan, 2014), spontaneous emulsification or solvent diffusion, (Mainardes et al., 2012) nanoprecipitation, spray drying(Ali et al., 2014), supercritical fluid technology (Mazzarino et al., 2014), and (PRINT) particle replication in non-wetting templates(Galloway et al., 2013).Size is definitely a main advantage of these polymeric nanocomposites which enables them to penetrate capillaries (Brigger et al., 2002). Polymeric nanoparticles have been used brain drug targeting for neurodegenerative disorders such as Alzheimer's disease, to enhance penetration and distribution in and across the blood brain barrier (Medina et al., 2007). Nanoparticle based delivery methods are proved to be the best methods to transfer drugs across central nervous system (Jain, 2012). These strategies are proved to be the best methods to facilitate the delivery of drugs and biological therapeutics across the blood brain barrier (Gaillard et al., 2010). Due to their smaller size, nanoparticles penetrate into minute capillaries that distribute the drug after its delivery. Therefore, an efficient drug accumulation takes place at targeted sites in the body. However, to enhance the therapeutic action of drug its maximum absorption is required and polymers facilitate this aspect (Kreuter, 2014). The application of nanoscience in particular to drug delivery has extended immense accomplishments and has a hopeful elevation in the field of neuroscience. Subsequently, the chapter discusses the description and distinct features of nanotechnology in engendering smart herbal drugs to enhance mental health.

APPROACHES TO CONTEST THE INTIMIDATION OF MENTAL ILLNESS

Synthetic Drugs as a Redeemer of Mental Infirmity: A Blessing Transformed as Desecrate

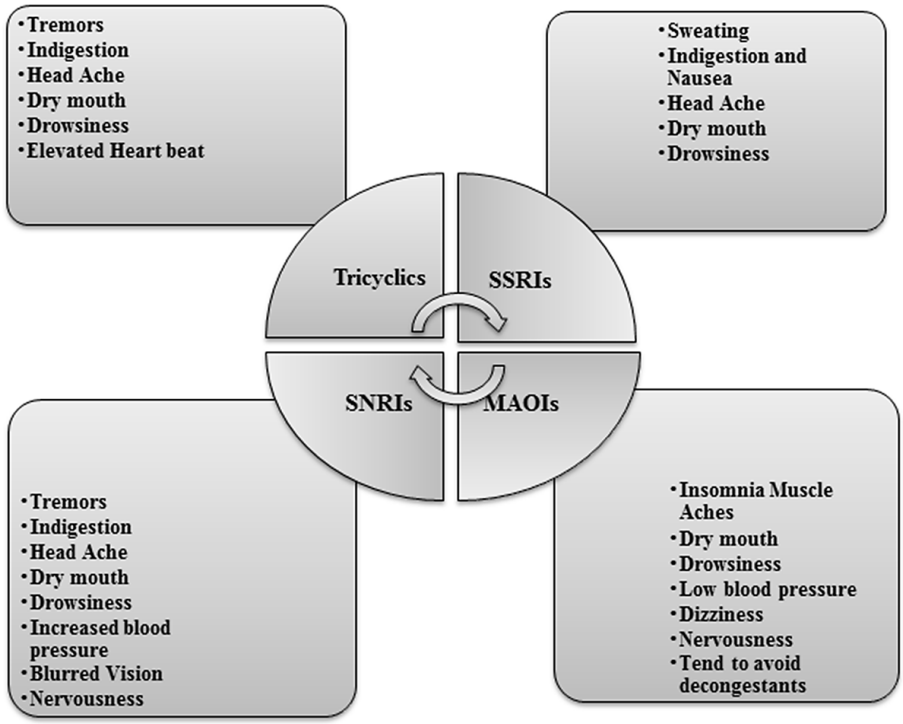
The preparatory phase for providing effective treatment against mental illness is to recognize the sort of problem and offer a proper diagnosis (NICE, 2010). There are fragmentary discussions regarding the effectiveness of the management of common mental health problems in general practice settings. Although evidence based clinical guidelines are available, initiation and adherence to effective treatment are usually poor (Richards, 2012). Untreated, depression can lead to serious complications that can lay life at risk. Fortunately, most clinical depression is treatable with the wide usage of antidepressant medications whose mode of action in the body occurs at the level of the synapse -the site in the nervous system where neurons communicate with each other or with other types of cells (e.g. muscle cell) by means of neurotransmitters. Some neurotransmitters (e.g. norepinephrine, serotonin and dopamine) are taken back into the nerve ending after release. This process is called uptake, reuptake or transport. This transport is a mechanism that prevents overstimulation of receptors in the receiving neuron. By blocking the (re-)uptake of these neurotransmitters, or inhibiting the mitochondrial enzyme monoamine oxidase, antidepressants alter the magnitude of the effects of neurotransmitter at these synapses (Richelson, 2001). The loss of sensitivity of the cell to the neurotransmitter is called desensitization, while the loss of the receptor protein from the cellular surface is called down-regulation. Though the specific mechanism of the therapeutic action of drugs remains unclear, it is known, that they adapt different mechanisms which can desensitize or down-regulate certain receptors for neurotransmitters by causing a local abundance of neurotransmitters. There are numerous synthetic drugs available to treat these psychological disturbances but are often prone to cause adverse effects, and the difficulty in tolerating these is the most common reason for discontinuing an effective medication.

The Major types of inhibitors are listed below:

- **Monoamine Oxidase Inhibitors:** MAOIs act by inhibiting the activity of the enzyme monoamine oxidase, thus preventing the breakdown of monoamine neurotransmitters and thereby increasing their availability. Well known examples of medicines in this class are phenelzine, isocarboxazid and trylcypromine. There are two isoforms of monoamine oxidase, MAO-A and MAO-B. MAO-A preferentially deaminates serotonin, melatonin, epinephrine, and norepinephrine. MAO-B preferentially deaminates phenylethylamine and trace amines. Dopamine is equally deaminated by both types. Due to the lethal dietary and drug interactions, monoamine oxidase inhibitors are usually reserved as a last line of treatment and used only when other classes of antidepressant drugs (for example selective serotonin reuptake inhibitors and tricyclic antidepressants) fail (Grady,2012).
- **Tricyclic Antidepressants:** TCAs were first discovered in the early 1950s and were subsequently registered later in the decade. The medicine is named after their chemical structure, which contains three rings of atoms. Examples of medicines from the TCA class are amitriptyline, imipramine and desipramine. The tetracyclic antidepressants, which contain four rings of atoms, are a closely related group of antidepressant compounds. The majority of the TCAs act primarily as serotonin-norepinephrine reuptake inhibitors (SNRIs) by blocking the serotonin transporter (SERT) and the norepinephrine transporter (NET), respectively, which results in an elevation of

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

the synaptic concentrations of these neurotransmitters. In addition to their reuptake inhibition, many TCAs also have high affinity as antagonists at several receptors, which may contribute to their therapeutic efficacy, as well as their side effects (Gillman, 2007).



- **Selective Serotonin Reuptake Inhibitors:** SSRIs were first developed in the 1970s with the aim of targeting a specific site of the neuron, the reuptake protein, while not influencing other parts of the neuron such as the receptors. SSRIs are believed to increase the extracellular level of the neurotransmitter serotonin by inhibiting its reuptake into the presynaptic cell, increasing the level of serotonin in the synaptic cleft available to bind to the postsynaptic receptor. They have varying degrees of selectivity for the other monoamine transporters, with the more specific SSRIs having only weak affinity for the noradrenaline and dopamine transporter. Examples of SSRIs are escitalopram, fluoxetine, sertraline, paroxetine and fluvoxamine (Royal Pharmaceutical Society of Great Britain 2010).
- **Serotonin and Noradrenaline Reuptake Inhibitors:** SNRIs were first introduced in 1994. This type of antidepressant acts by inhibiting the reuptake of the neurotransmitters serotonin and norepinephrine. In relation to major depressive disorder, norepinephrine is thought to be related to alertness and energy as well as anxiety, attention, and interest in life; while (a lack of) serotonin is thought to be related to anxiety, obsessions, and compulsions. The inhibition of the reuptake of these neurotransmitters results in an increase in their extracellular concentrations and, therefore, an increase in neurotransmission. Venlafaxine and milnacipran are examples of SNRIs (Royal Pharmaceutical Society of Great Britain 2010).
- **Noradrenergic and Specific Serotonergic Antidepressants:** NaSSAs are a class of psychiatric drugs used that act by antagonizing the α2-adrenergic receptor and certain serotonin receptors. Antidepressants mianserin and its successor mirtazapine are examples of medicines in this class. By blocking α2-adrenergic autoreceptors and heteroreceptors, NaSSAs enhance adrenergic and serotonergic neurotransmission in the brain involved in mood regulation. In addition, due to their blockade of certain serotonin receptors, serotonin transmission is not facilitated in unwanted areas. This specificity is what is referred to in the name of this class of medicines (Julien, 2004).

In spite of the novel development for pharmacotherapy against mental illness, it is unfortunate that this disorder goes undiagnosed and untreated in many patients. It has been shown that less than 50% of patients experience a clinical response to treatment with the foremost drug prescribed. Yet, the presently prescribed molecules provide some improvement in the clinical condition of patients, it is at a cost of having to bear the burden of their adverse effects (Tripathi 2008, Hardman et.al, 2007). Many patients are not able to tolerate available (Figure 2) medications due to its deleterious side effects.

Studies show that as many as 50% of subjects may discontinue antidepressant treatments within a six month period, reporting adverse effects as a main reason for discontinuation (Cipriani et al., 2009). Along with the classical theory of decrease in the neurotransmitter levels in the brain leading to the pathogenesis of clinical disorders, recent studies have also shown the involvement of oxidative stress in the phenomenon (Sarandolet.al, 2007, Ibrahim, et.al. 2007).

Figure 2. Signifies the common adverse effects caused by synthetic drugs

Alternative Herbal Remedies Formulated as Traditional Medicine to Combat Mental Illness: Plant Formulations as Potential Antidepressants

Although a number of synthetic drugs have been used as antidepressants they have adverse effects that compromise the treatment. These conditions create an opportunity for alternative treatment of depression by the use of medicinl plants or plant based antidepressant formulations. Several plants prove to contest depression but *Hypericum Perforatum* L. (St. John's Wort) is an established European medicine which is commercialized in large scale. The plant has profound medicinal properties and primarily, an extensive amount of clinical research shows that St. John's Wort extracts are effective in treating major depressive disorder. Botanical formulations are commercially available as herbal preparations over-the-counter in the forms of tea, tincture, tablet, and capsule usually containing its biologically active compounds such as hypericin (0.19 – 0.3%), hyperforin (1.3 – 3.9%) and flavonoids (calculated as rutin 4.8 – 11.4%.).The vital phytocompound Hypericin is a major psychoactive component of the plant is segregated with a phloroglucinol derivative compounds such as Hyperforin and Adhyperforin (Von Eggelkraut – Gottanka et al., 2002). A 300 mg - tablet of hypericum extract counterpart to about 15 mg hyperforin and clinical trials report a daily dose of 900 – 1500 mg (i.e., 0.3% hypericin) of the standardized extract (Biber et al., 1998). The European drug - monitoring study has reported that these commercial formulation associates certain adverse effects such as gastrointestinal irritation, allergic reactions, fatigue and restlessness. The blemish of this commercial herbal extract can be reinstated by the prominent ayurvedic medicinal plants.

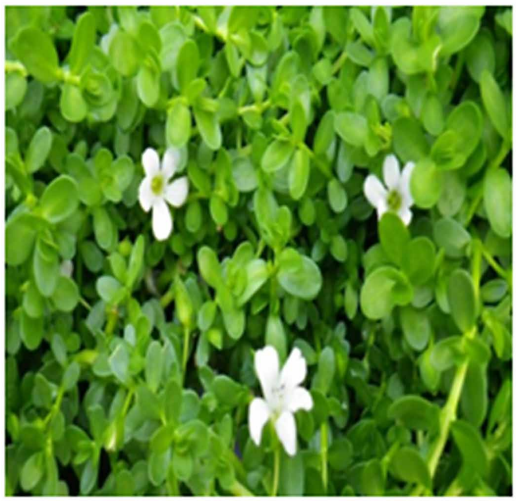
Indian Ayurvedic Medicine on Par with the Folk Medicine in Europe

Herbal medicine has the potential to decline the severity pertaining to the symptoms of mental illness and restore mental stability. There are various *ayurvedic* medicinal plants that have shown promise in reversing the neurological pathology. The vital phytochemical, biological, and cellular activities of these plants provides adequate baseline information that could be used in drug discovery campaigns and development processes.

- Medicinal plants as functional leads for mental illness classified as Medhya drugs:
  - **Ashwagandha (*Withania somnifera*):** Ashwagandha (*Withania somnifera*, family: *Solanaceae*) (Figure 3) is commonly known as "Indian Winter cherry" or "Indian Ginseng" which is widely spread in North western regions of India. It is one of the most important herb of *ayurveda* that has been used for ages as a Rasayana which is reputed to promote physical and mental health. The plant consists of vital phytochemical constituents that comprises of alkaloids (isopelletierine, anaferine, cuseohygrine, anahygrine), steroidal lactones (withanolides, withaferins) and saponins (Mishra, et al.,2000). Sitoindosides and acylsterylglucosides are considered as active ingredient of the herb that is established as anti-stress agents against acute models of experimental stress (Bhattacharya et al., 1987). As mentioned earlier in the text the plant belongs to a sub-group of Rasayanas known as Medhya rasayanas. Medhya is derived from Sanskrit language that refers to the mind and mental/intellectual capacity. The cognition intellectual effect of this ayurvedic drug enhances the learning skills in children, restores memory deficits during several circumstances such as head injury, protracted illness and old age (Singh and Udupa, 1993). Neuritic atrophy is a pathological condition that leads to synaptic loss which is the foremost cause of neurodegenerative diseases like Alzheimer's, Parkinson's, Huntington's and several other mental disorders. Numerous studies exhibit the

Figure 3. Pictorial representation of the medicinal plant Ashwagandha (Withania somnifera)



EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

realistic medication that can cease and reverse neuritic atrophy.Glyco withanolides withaferin- A and sitoindosides are the dynamic phyto compounds that have induced cognitive defects in Alzheimer's disease model (Bhattacharya et al., 1995).The furnished scientific details sustain the finale that Ashwagandha is a real potent herb that ingredients in regenerative tonic (Rasayana of *ayurveda*), due to its manifold pharmacological accomplishments like anti-stress and neuroprotective activity.

- **Brahmi (*Bacopa monnieri*)**: *Bacopa monnieri* (Brahmi) (Figure 4) belonging to the family *Schropulariaceae* is an ayurvedic herb which has a long primordial history of almost 3000 years and catalogued as an ingredient in medhya rasayana. The plant is habitat all over India particularly in wetlands and marshy tropical regions. The name of the plant is derived from Sanskrit language that reflects 'Brahma' who is considered as the god of creation according to Hindu religion. Brahmi has an alternative meaning "bringing knowledge of the supreme reality' that relates to brain which is the central organ of intellectual. In India this plant is utilized immensely as a revitalizing herb that fortifies the brain function and memory. The medicinal plant comprises of imperative phytocompounds among which saponins termed as "Bacosides" are considered to be a major bioactive marker that has therapeutic index (Deepak and Amit 2004). The whole plant extract of Brahmi has undergone various clinical trials that substantiate the reality to improve cognitive function in children and adults. A research conducted among school children by Sharma et al., 1987 improved their learning, memory and perception skills reaction without inducing significant side-effects. Brahmi has been commenced in the market as single or associated with other phytocompounds in treating attention deficient disorders. Pravina et al., 2007 devised a commercial formulation labeled as BacoMindR, which highlighted the non-noxious nature of the herbal extract reinforces ayurvedic medicine at the summit of healing mental illness. Hence there is a firm

requisite to elevate this herbal medicine with advent technologies that would stimulate it to be on par with the western medicines.

- **Shankhpushpi *Convolvulus pluricaulis*:** Shankhpushpi is a reputed drug constituted in medhya rasayana the name of the plant is derived from Sanskrit language that illustrates a plant with flowers shaped like a conch or shankha which is a sacred instrument used in ritual worships. According to the pharmacopoeia of India, *Convolvulus pluricaulis* (Convulvulaceae) (Figure 5a) as a whole plant rightfully claim the name of Shankapushpi but, Ayurvedic practitioners have used three other medicinal herbs such as *Canscora decussate* Schult. (Gentianaceae) (Figure 5b), *Evolvulus alsinoids* Linn. (Convulvulaceae) (Figure 5c), and (Figure 5d) *Clitoria ternatea* Linn. (Papilionaceae) (Nahata et al., 2008,2010) Indian Council of Medical Research(ICMR) has approved *C. pluricaulis as a herbal* drug with systematic potential as a brain drug, functioning as anxiolytic, tranquillizing, antidepressant, antistress, neurodegenerative, antiamensic, antioxidant agent. Phytochemical assays of the plant report to contain significant constituents like alkaloids, flavanoids, and coumarins (Sethiya et al., 2010).Though all the four plants are catalogued under the same class *Magnoliopsida*, *Clitoria ternatea* separates itself at the level of sub-class belonging to *Rosidae*, while the other three belong to *Asteridae*.

Figure 5. (a, b, c & d): Pictorial representation of the medicinal plants Convolvulus pluricaulis, Canscora decussate, Evolvulus alsinoides & Clitoria ternatea

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

- ***Clitoria ternatea*:** *Clitoria ternatea,* is distinct among other herbs and has the property of being a good brain drug (Sivaranjan 1994). The plant has a rich source of vital phytoconstituents such as tri terpenoids, flavonol, glycosides, anthocyanins and steroids which are therapeutically significant. Phytochemical screening has yielded tannins, resins, taraxerol and ternatins.

Interestingly, the floral petals of the plant yielded three flavonol glycosides - kaempferol 3-O-(2″-O-α-rhamnosyl-6″-O-malonyl)-β-glucoside, quercetin 3-O-(2″-O-α-rhamnosyl-6″-O-malonyl)-β-glucoside, and myricetin 3-O-(2″,6″-di-O-α-rhamnosyl)-β-glucoside (Ramaswami et al., 2011). Banerjee and Chakravarthi (1963) reported the isolation and identification of pentacyclic triterpenoids, taraxerol and taraxerone from the roots. Yadava and Verma (2003) isolated antimicrobial flavonol glycoside3,5,4_-trihydroxy-7-methoxyflavonol-3-O-_-d-xylopyranosyl-(1,3)-O-d-galactopyranosyl (1,6)-O-d-glucopyranoside from the ethyl acetate soluble fraction of the defatted seeds of the plants.

The GC/MS profile of root extract extricated a major compound 9,17-Octadecadienal, (Z)- o with a elevated retention time of 32.99.The in silico docking analysis furnished a minimum binding affinity energy values of -6.5 / -7.71 kcal/mol against both the isoforms of Monoamine oxidase(MAO) A and B there by establishing the plant as MAO-inhibitors (Anita Margret et al.,2015)The roots, seeds and leaves of plant have been widely used as a brain tonic and is believed to promote memory and intelligence (Mukherjee et al., 2007). The whole plant of *Clitoria ternatea* has been widely screened for its various pharmacological activities. The aqueous root extract of the plant affects the brain structures concernedwith learning and memory regions of brain namely hippocampus and amygdala that can restore permanent changes in the brain. It may also affect the biosynthesis of neurotransmitter viz. acetylcholine, which has been implicated in the process of learning and memory. On the other hand, *Clitoria ternatea* may also induce long-term potentiation (Rai et al., 2002) that not only promotes neurogenesis in the amygdala, but also stimulates the release of hormones or neuromodulators that modulate the activity of neurotransmitters and neuromodulators involved in learning and memory, thereby contributing to enhanced learning and memory. After detailed clinical trials in adults, aqueous root extract treatment of the plant may be envisaged as a memory enhancer and also might be useful in the treatment of neuronal degenerative disorders involving the amygdala (Rai et al., 2005). *Clitoria ternatea*, a traditional ayurvedic medicinal plant elevates itself as an efficient botanical medicine combating neurological ailments. It can be used as a lead drug for developing new phytoceuticals for the treatment of neurological disorders and may be used effectively as a memory enhancer.

Though pharmacotherapy of modern medicine is well developed with chemical units it faces several challenges among which, adverse effects, lethal dosage levels and ability to surpass physiological barriers have been highlighted. Consequently, research features a novel facet of shifting from mono therapy (single active compound) to multi therapy that involves a collection of synchronized active compounds. Traditional herbs head this revolution in embracing phytochemicals which possess highly beneficial medicinal properties. Interestingly this novel attempt contests the western medicine and remain a challenge to the therapeutics. The advent of newer technologies like nano science can elevate herbal formulations as smart drugs that can fetch natural remedy against depression and mental illness.

THE CONDUCT OF NANOTECHNOLOGY IN REFORMING THE MENACE OF MENTAL ILLNESS TO WELL-BEING

Nano particulate system is well devised to facilitate drug delivery that increases the therapeutic index of the drug. Nanoparticles are nanoscale sized polymeric particles which are made up of natural or artificial polymers that range in size between 10 and 1000nm (1 mm). Polymeric Nanoparticles have been shown to be promising carriers for central nervous system drug delivery due to their potential both in encapsulating drugs, and in delivering them across the blood-brain barrier without inflicting any damage to the barrier. The biodistribution of pharmaceuticals in a controlled manner and consequently protect them from excretion and metabolism. The capacity of the surfactants in the polymeric nanoparticles offer stability to the encased drugs and facilitates smart release and delivery. Studies have revealed ample number of mechanistic details pertaining to these particles such as site-targeted, controlled, and enhanced bioavailability of hydrophobic drugs (Panyam, et al., 2003).

Polymers Facilitating Bioavailability and Efficacy of Drugs

The efficacy of many drugs is often limited by their potential to reach the site of therapeutic action. In most cases only a small amount of administered dose reaches the target site, while the majority of the drug distributes throughout the rest of the body in accordance with its physicochemical and biological properties. Therefore, developing a drug delivery system that optimizes the pharmaceutical action of drug while reducing its toxic side effects *in vivo* is a challenging risk. One of the approaches is the use of colloidal drug carriers that can provide site specific or targeted drug delivery combined with optimal drug release profiles. There are several drug delivery systems among which three efficient organizations are listed below:

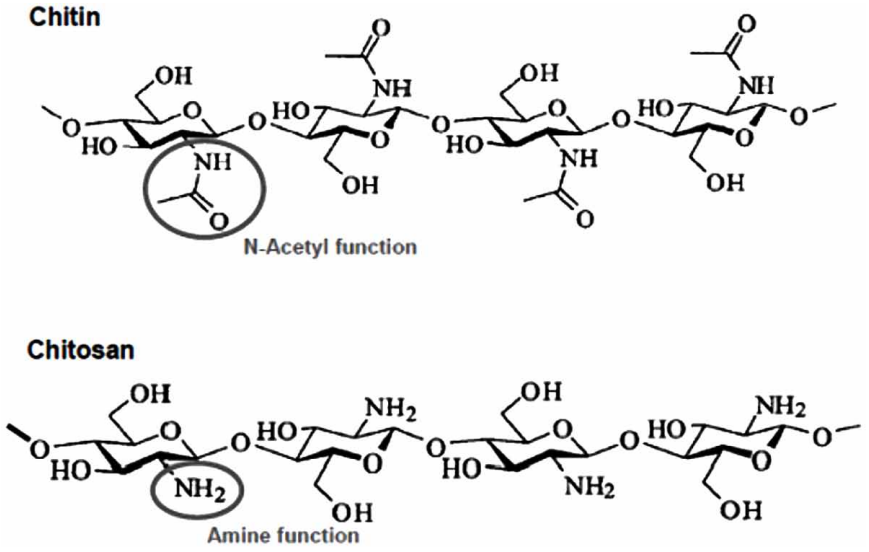
- **Liposomes:** They are spherically shaped vesicles composed of natural phospholipids. The properties of liposomes can be varied with composition, size, and surface charge of lipids and also the method used for preparation. Liposomes can carry both hydrophobic and hydrophillic molecules inside them. The surface of liposomes can also be modified by attaching polyethylene glycol (PEG) chain to the lipid bilayer (stealth liposomes) to enhance their circulation time in the blood. Drugs can be actively targeted by conjugating liposomes with antibodies or ligands.
- **Dendrimers:** They are hyper branched structures that comprise of an inner core, a series of branches and outer surface with functional groups. Due to their nanometer size range, ease of preparation and functionalization they are attractive drug delivery systems. Due to the presence of internal cavities it is possible to encapsulate therapeutic agents in the inner core. The properties of dendrimers can be controlled by the functional groups on outer surface. Drug can either be encapsulated in the interior of the dendrimers or attached to surface functional groups.
- **Polymeric Micelles:** They consist of amphiphillic block copolymers, which can self-assemble to form micelles in aqueous solution. They have a narrow size distribution in the nanometer range and core-shell structure, in which hydrophobic segments are separated from the hydrophillic exterior (Table 1). Drugs can be partitioned in the hydrophobic core of micelles and the outer hydrophillic layer forms a stable dispersion in aqueous media.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Table 1. Criteria for ideal polymeric carriers for nanoparticles and delivery systems

Polymeric Carriers	Nano Particle Delivery System
Easy to synthesize and characterize	Simple and inexpensive to manufacture and scale –up
Biocompatible	No heat high shear forces or organic solvents involved in the preparation process
Biodegradable	Reproducible and stable
Inexpensive	Applicable to a broad category of drugs, small molecules, proteins and polynucleotides
Non immunogenic	Ability to lyophilize
Non toxic	Non toxic
Water soluble	Stability after administration

Like liposome they can also be functionalized with PEG for stealth properties and with targeting ligands including antibodies to the micelle surface (Labhasetwar, 1993). Among these carriers, liposomes and nanoparticles have been the most extensively investigated. Liposomes present some technological limitations including poor reproducibility and stability, low drug entrapment efficiency. Polymeric nanoparticles which possesses a better reproducibility and stability profiles than liposomes have been proposed as alternative drug carriers that overcome many of these problems.



Chitosan: A Dextrous Biopolymer

Biopolymers are polymers produced by living organisms; in other words, they are polymeric biomolecules. Since they are polymers, biopolymers contain monomeric units that are covalently bonded to form larger structures. Chitosan is a natural polymer obtained by deacetylation of chitin. After cellulose chitin is the second most abundant polysaccharide in nature. It is biologically safe, non-toxic, biocompatible and biodegradable polysaccharide. Chitosan nanoparticles have gained more attention as drug delivery carriers because of their better stability, low toxicity, simple and mild preparation method and providing versatile routes of administration. Their sub-micron size is also suitable for mucosal routes of administration i.e. oral, nasal and ocular mucosa which is non-invasive route. Chitosan is a linear polysaccharide, composed of glucosamine and N-acetylglucosamine (Figure 6), produced by partial deacetylation of chitin by alkaline or enzymatic hydrolysis. Chitin is the major component of the exoskeleton of crustaceans, insects, cell wall of fungi and yeast.

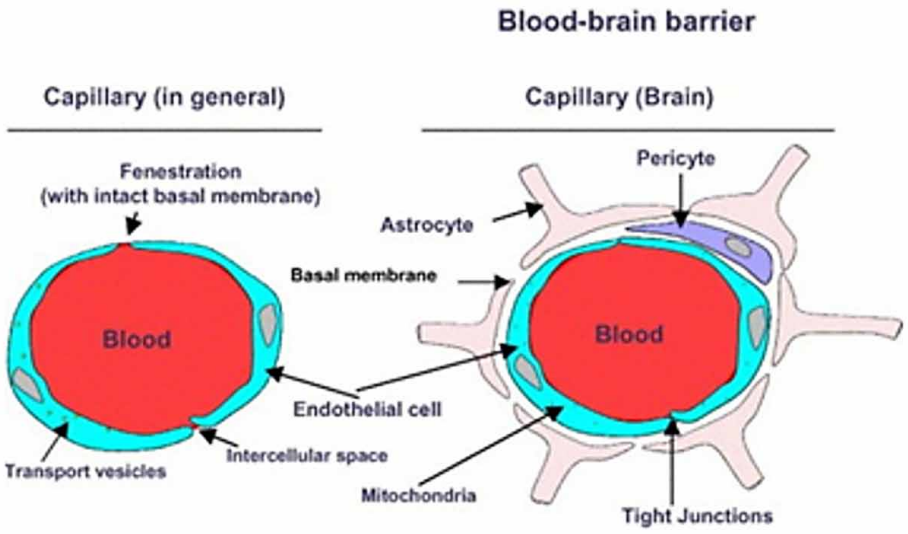
The most remarkable difference between chitin and chitosan is their solubility characteristics. There are few solvents for chitin and most of them are toxic and therefore inappropriate for pharmaceutical applications. Chitosan is insoluble at neutral and alkaline pH, but forms positively charged salts with inorganic and organic acids (e.g., glutaminic acid, hyaluronic acid, lactic acid, and acetic acid), whereas the positive charge of the protonated amine group promotes solubility in aqueous solutions. Chitosan is available in a wide range of different molecular weights (50 kDa-2000 kDa) and degrees of deacetylation (40%-98%). The most commonly used forms of chitosan salts are chitosan glutamate and chitosan hydrochloride. Chitosan features different conformations of the molecule for high and low deacetylated chitosan. At a high degree of deacetylation (highly charged) chitosan has extended conformation with a more flexible chain, whereas at low degree of deacetylation the molecule adopts a more coiled shape due to lower charge. The amino group in chitosan has a pKa value of ~6.5, thus, chitosan is positively

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 6. The chemical structures of Chitin and Chitosan

charged and soluble in acidic to neutral solutions. Chitosan with a relative low degree of deacetylation (40%) are soluble only at pH < 6.5 (Illum 2001).

Among water-soluble polymers available, chitosan is one of the most extensively studied. This is because chitosan possesses some ideal properties of polymeric carriers for nanoparticles such as biocompatible, biodegradable, nontoxic, and inexpensive. Furthermore, it possesses positively charge and exhibits absorption enhancing effect. These properties render chitosan a very attractive material as a drug delivery carrier. In the last two decades, chitosan nanoparticles (chitosan NP) have been extensively developed and explored for pharmaceutical applications.



Physiological Barriers Hindering Therapeutic Molecules to the Targeted Sites and the Polymers Facilitating the Brain Drug

The Blood Brain Barrier (BBB) is the protective barrier that separates the brain from the circulatory system, which blocks harmful compounds from entering the brain tissue. It is a capillary network of tightly woven endothelial cells lining the blood vessels in the brain, regulating transport of essential molecules and maintaining a stable environment. It is a highly sophisticated structural design of the human body which determines what fluids are permitted in and near the brain and which would prove harmful. Capillaries (Figure 7) which surround the connective tissue and neuroglia known as astrocytes "stand guard" and select the substances which are permissible.

Glucose, water, lipid soluble compounds, carbon dioxide, and oxygen pass through the Blood Brain Barrier without difficulty. Inorganic compounds may pass but will be permitted more slowly and more hesitantly. The concentration of ions within the brain needs to vary from the concentration within the bloodstream. Antibiotics, most toxins, proteins, lipids, urea, insulin, and creatine are prohibited from passing through the barrier. This is the body's natural defence mechanism against toxins penetrating the brain, and is how we protect ourselves from cerebral invasion. The problem is, however, when serious diseases of the brain manifest, it has proven nearly impossible to transcend the BBB with therapeutic

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 7. Morphological representation of the blood brain barrier

drugs in sufficient quantity to have an effect on the targeted malady without causing toxicity in the brain. The barrier provides such a protective shield to the brain that approximately 98% of small molecule drugs and 100% of large molecule drugs cannot cross it. This very tight regulation of the brain homeostasis results in the inability of some small and large therapeutic compounds to cross the blood–brain barrier (BBB). Therefore, various strategies are being developed to enhance the amount

Polymeric Nanoparticles as Drug Delivery Vehicles Encasing Brain Drug

Biodegradable polymers such as polylactic acid, polycaprolactone, poly(lactic-co-glycolic acid), the poly(fumaric-cosebacic) anhydride chitosan, and modified chitosan, as well as solid lipids, have revealed immense prospective in the delivery of proteins and peptidal drugs in nanao scale. Theses polymers channelize the drug *in vivo* is reported to mimic molecules that are easily surpassed through brain (example) polysorbate-coated nanoparticles are thought to mimic low density lipoprotein (LDL), allowing them to be transported across the capillary wall and into the brain by loading onthe LDL receptor (Kreuter, 2014) This mechanism adapted by the polymer improve the efficacy of the drug and allows it to pass through the Blood brain barrier. (Liu et al., 2012). It offers a sustained drug release at the targeted site after injection over a period of several days and weeks (. Nanoparticle based delivery methods are proved to be the best methods to transfer drugs across CNS (Jain, 2012). These strategies require the multifaceted attributes of nanoparticles which are combined and controlled to pass across the BBB. These are proved to be the best methods to facilitate the delivery of drugs and biological therapeutics for brain across the BBB. HAS (human serum albumin) is an illustrious example of a polymer that is used as nanoparticle and resists to the system by exhibiting no serious side effect. More exceptionally albumin functional groups can be utilized for surface modification of barrier that allows specific cell uptake (Vinogradov et al., 2002). It also acts like as a transforming growth factor in microbubble based drug delivery. (Kreuter, 2014). The efficacy of nanoparticulate drugs is, improved by these are coated biodegradable materials which make them more permeable to cross the blood brain barrier.

Smart Nanoparticulate Herbal Formulations to Contribute Mental Health and Stability

The herbal formulation throws in immense of optimism in human health, and has advanced periodically in this modern era. Deplorably the active constituents of the plants require certain amendments that would lead to an unblemished effect. The vital phyoconstituents constituents such as flavonoids, tannins, and terpenoids, are highly soluble in water, but have low absorption, due to which they are unable to cross the lipid membranes of the cells. An additional snag pertaining to the phytocompounds that limits its usage is the intense high molecular size, which poorly absorbed, resulting in loss of bioavailability and efficacy. Nanotechnology provides solution to these deficits and hence has been widely proposed to synchronize with herbal medicine. Some prospective features of nanostructures in elevating herbal medicine are:

- Reduced dosage,
- Lessen adverse effects,
- Increase bioavailability and absorption,
- Control drug release and metabolism,
- Increased endurance of the drug.

Size is a blessing in nanotechnology where the therapeutic agent is distributed into the miniature blood capillaries (smaller than 5 mm) without forming aggregates, and ensure that the particles are not agglomerated. Polymers as nanocarriers provide more surface area and have the potential to increase solubility, enhance bioavailability, improve controlled release and enable precision targeting of the entrapped compounds to a greater extent. As a consequence, the expenditure intensity decreases widely, since isolated phytocompounds are expensive. Further, polymers are efficient for both hydrophilic and hydrophobic herbal drugs and can be channelized through the lymphatic system, blood brain barrier and arterial walls. Several clinical trials and experimentation has been performed by encasing herbal formulation into polymers to combat human infirmity. A wide number of plants are being used to as nanoformulations using various suspension modes against human infirmity Table 2 shows the details of the nano system incorporated.

Various research works has substantiated smart herbal formulations as nano drugs extensively. The proportion of research related to neuro drugs is comparatively low. Yet, few studies establish the proficiency of herbal drugs as nano formulations. Ginkgo biloba L. (Ginkgoaceae) is prominent medicinal plant that has been widely marketed for its brain cell activation properties

techniques) It was demonstrated (Shinji et al., 2011, Williams et al., 2004) that extract of G. biloba containing nanoparticles increase the release of acetylcholine from cerebral cortical synapses there by stimulating the response of hippocampal pyramidal cell. Thus, the nanosized G. biloba extract is expected to activate the brain cell and restore the habitual symptoms of Alzheimer's dementia (like loss of memory, thinking, language, judgement and behavior).

Several conditions such as oxidative stress, mitochondrial dysfunction, infections, hypoxia, apoptosis, and others, play important roles in the development and prevalence of these diseases (Cacciatore et al., 2012). It has been reported that oxidative stress (OS) is implicated in the development of neurodegeneration, mainly by the presence and attack of reactive oxygen species (ROS) that oxidize and injury neural cell components, such as lipids, proteins and DNA, leading to the appearance and prevalence of Alzheimer´s or Parkinson´s diseases, aging and many others neural disorders (Uttara et al., 2009). In this

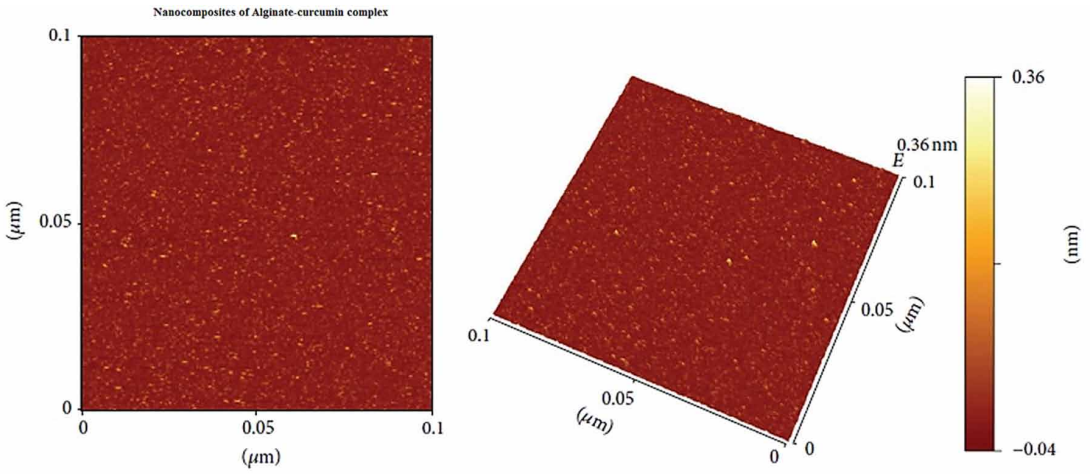
Table 2. List of potential Nano formulated medicinal plants targeting several human ailments

Name and Family of the Medicinal Plant	Nano System Employed	Purpose/Application	Reference
Panax ginseng(Araliaceae)	lipid-based systems	increase the absorption of the active components	Kesarwani and Gupta 2013
Artemisia arborescens L. (Asteraceae)	Liposomes	Facillitate the active compounds to penetrate the cytoplasmic viral barrier	Sinico C et al., 2005
Phytolacca decandra(Phytolaccaceae)	PLGA-encapsulate	lung cancer	Das et al 2012
Ocimum sanctum (Lamiaceae)	Sodium alginate chitosan nanoparticles(Cotton fabrics)	antimicrobial activity	Rajendran et al., 2013
Curcuma longa (Zingiberaceae)	copolymers of N-isopropylacrylamide, N-vinyl-2-pyrrolidone, and poly(ethylene glycol) monoacrylate.	pancreatic Cancer	Bisht et al 2007
Curcuma longa (Zingiberaceae)	PLGA	Prostate cancer	Mukerjee and Vishwanatha 2009
Magnolia officinalis (Magnoliaceae)	PEG/PLGA	anxiolytic, central nervous system depressant, and muscle relaxant activities	Zheng et al.,2010
Cuscuta chinensis Lam. (Convolvulaceae) nanoparticles	Eudragit (E) and PVA	Oxidation stress AND hepatoprotective effects	Yen et al., 2008
Camptotheca acuminata Decne (Cornaceae)	hydrophobically modified glycol chitosan (HGC)	Breast Cancer	Min et al., 2008
Ginkgo biloba (Ginkgoaceae)	polyvinyl alcohol (PVA)	anti-inflammatory, antitumor, antiviral, inhibitory of cataracts in diabetics, antihistamine (anti-allergic), cardiovascular, antioxidant, and hepatoprotective effects	Wu et al., 2008

way, flavonoids such as catechin, quercetin, rutin, have demonstrated that act as excellent free radical scavengers by rapid donation of a hydrogen atom to radicals (Seyoum et al., 2006). The work of Pool et al. (2012) was based in the development of polymeric nanoparticles (NPs) using Eudragit L30-D55 (Eud) polymers for the encapsulation, protection and target release within gastrointestinal tract of quercetin. In this study, the encapsulation of quercetin into Eud enhanced the protection of multi-lamellar vesicles of soybean phosphatidylcholine against lipid peroxidation of peroxyl and hydroxyl radicals. These results suggested that Eud NPs increased the lipid phase solubility of quercetin and also NPs act as protective agents against molecular oxygen, leading to a better free radical action that the free quercetin molecules used in the same experiments. Thus, these type or nanoparticulated systems might be suitable to across the BBB and deliver antioxidants to combat the OS in brain.

Studies have demonstrated that curcumin exert a net protective effect against oxidative damages initiated by free radicals, Despite, curcumin is a highly lipophilic compound and have the ability to cross the BBB, the poor bioavailability represent a limiting to its use in a functional product to combat neurological diseases. Accordingly, NPs decorated with appropriate ligands for curcuin brain delivery were developed lately (Mulik et al., 2010). These approaches were based in the preparation of curcumin-loaded PnBCA NPs decorated with ApoE3 ligand to exploit LDL-r- mediated transcytosis across the BBB and through SH-SY5Y cells. Results showed a reduction of Aβ1-42 related toxicity on cells treated with the function-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



alized nanospheres along with a reduction of reactive oxygen species formation than the free curcumin used in this study. Another work demonstrated that curcumin-loaded PLGA nanoparticles obtained by an emulsion-diffusion evaporation method increase the neuroprotective effect on human SK-N-SH cells (neuroblastoma cell line) against the OS effect by reducing the elevation of ROS and the consumption of gluthatione induced by H_2O_2. Also the uptake of the encapsulated curcumin into SK-N-SH cells was significantly improved than the free curcumin, which impact on the effects found them by researchers. Overall, this study demonstrated that the PLGA NPs have the capacity to protect human neuronal cells against oxidative damages, having a great potential to be used as bioactive compounds carriers in the application to treat several neurodegenerative disorders (Doggui et al., 2012). Further alginate-curcumin nanocomposites (Yasir Hasan Siddique et al., 2013) reduced the oxidative stress as well as apoptosis in the brain of Parkinsons Disease model drosophila flies (Figure 8).

FUTURE RESEARCH DIRECTIONS

Neurodegenerative diseases a are characterized by a progressive and irreversible damage in the brain, which are the fourth leading cause of death in the developed world that precedes heart diseases, cancer, and stroke (Plassman et al., 2007). The most common neurodegenerative diseases are Alzheimer's disease, Parkinson's disease, Lewy body dementia, fronto temporal dementia, amyotrophic lateral sclerosis, Huntington's disease, and prion diseases (Bertram y Tanzi, 2005). However, the most widely recognized are Alzheimer's disease and Parkinson's disease, which are among the principal debilitating conditions of the current century. Approximately 24 million people worldwide suffer from dementia, 60% of cases being due to Alzheimer's disease, which occurs in 1% of individuals aged 50 to 70 and dramatically increases to 50% for those over 70 years (Cacciatore et al., 2012).

Several pharmaceutical and bioactive compounds have been used to treat neurodegenerative diseases, however, most of these components do not reach the brain completely and are, instead, metabolized totally or partially by the liver with a difficulty in solubility. Therefore, there is a necessity for the development of new technologies that help to protect and maintain the integrity of the drugs until they are released

Figure 8. Microscopic examination of Alginate: Curcumin nanocomposites

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

at specific site of action in the brain (Nazem Mansoori, 2011). Nanosized drug delivery systems for herbal drugs can potentially enhance the biological activity and overcome problems associated with plant medicines (Pool et al., 2012;2013). However, significant challenges remain for implementation of clinically viable therapies in this field. Employing herbal drugs as nano formulations would aggravate the importance of ancient Ayurvedic medicine. The effectiveness of these potent phytocompounds as a synergetic effect with polymers can be further endorsed by performing clinical studies which would elevate the incredible competence of ayurvedic medicine on par with western medicine. The vital compounds present in the plant extract are further analysed towards the lysosomotrophic chronic effects along with the standard synthetic drugs by *in vitro* study using cell culture models. The regulation studies of the (neurotransmitters through receptors) β-Adrenoceptors and G protein would endorse the efficacy of the herbal drugs. Receptors stimulate the protein AC (Adenylate Cyclase) which there by induces CAMP (Secondary messenger) signalling the neurotransmitters which can authenticate the efficacy of drug released by the polymeric carriers. Experimental modes such as *in silico, in vitro* and *in vivo* studies with Cell lines and animal models can validate the therapeutic index of the herbal formulation. The cytotoxicity assay is the fore most parameter of in the process of drug development and in order to understand the *in vivo* mechanisms of ayurvedic nano formulations there is a need to propose good model system. This would propagate the therapeutic value of neurological diseases and disorders.

CONCLUSION

Herbal medicines are asserting importance in the current global scenario as the severity of pathogenesis is ascending. The advancement of modern science is elucidating the capacity several medicinal plant products. In order to compete with the rate of diseases and disorders there has to be an extensive rise in the therapeutic index. Multiple and synchronized therapy of combining the active ingredients of herbal extract would be an ideal stoppage solution. Polymeric nanocomposites augment the efficacy of these herbal formulations thereby causing less side effects. Nanosystems can deliver the active constituent at a sufficient concentration during the entire treatment period, directing it to the desired site of action which is failed by the conventional treatments. Brain drug delivery is a challenge as the rate of mental disorders are increasing hence there is stern constraint to exert more research to develop versatile drugs. An efficient herbal remedy without adverse effects is the need of the hour and smart herbal formulations can do this deed in a immaculately. This would rejuvenate the ancient riches present in the ayurvedic treatise.

Chapter 53
Toxic Effects of Engineered Nanoparticles on Living Cells

Manel Bouloudenine
Mohamed Chérif Messaâdia University, Algeria & Badji Mokhtar University, Algeria

Mohamed Bououdina
University of Bahrain, Bahrain

ABSTRACT

Measuring toxic effects of engineered nanoparticles on living cells would require a deep understanding of themselves by the mean of their composition, physical and chemical properties and exposure concentrations. Actually, high exposure concentrations are needed to generate quantifiable effects and to perceive accumulation above background. This chapter presents an overview on the assessment about the toxic effects of engineered nanoparticles on living cells. It consists of three main sections starting with a brief introduction, the current state of engineered nanoparticles in the environment, physical and chemical properties of some important engineered nanoparticles such as "Ag, Au, ZnO, TiO2" and the target organ toxicity of the engineered nanoparticles in several biological organisms.

INTRODUCTION

Because of their small-scale technology which means in scientific terms, 'Nano' where one nanometer is equivalent to one billionth of a meter, the nanoparticles (NPs) have the ability to interpose at a cellular level of living organs. They easily enter into the living cells, which may cause hostile effects on the environment and human health at their entry. Meanwhile, the potential development of nanotechnologies is expected to become new source of human or environmental risks through inhalation, ingestion, skin applications, or injection of engineered nanoparticles in factories, drugs or the use of customer foodstuffs.

In order to improve a natural development, new technologies always need an ecological balance between the benefit and risk. Understanding the toxic effects of nanoparticles on the environment is the biggest obstacle to the safe development of nanotechnology. A major challenge in understanding the environmental implications of nanotechnology lies in studying nanoparticles acceptance in organisms at environmentally truthful exposure concentrations.

Nevertheless, little is known about how NPs affect human health and the environment. This chapter provides recent information on harmful effects of NPs particularly including their toxicity on living cells.

The objectives of this chapter are to:

1. Investigate the current state of engineered nanoparticles in the environment.
2. Provide recent information about the main properties of some innovated nanoparticles.
3. Estimate whether this data are sufficient to facilitate their comprehensive and effective influence on living cells and human health.

BACKGROUND

During the last decade, the use of NPs has successfully increased in several areas such as drug delivery systems (Jin & Ye, 2007; Brannon-Peppas & Blanchette; 2012) food technology (Chaudhry et al., 2008; Tapia-Hernández et al., 2015), photovoltaic devices (Stratakis & Kymakis, 2013; Huang, De Valle, Kana Kana, Simmons-Potter, & Potter Jr, 2015), modern chemistry (Hosseinimotlagh, 2014), biomedicine (Pankhurst, Connolly, Jones, & Dobson, 2003; Canfarotta & Piletsky, 2014; Cabuzu, Cirja, Puiu, & Grumezescu, 2015) and cosmetics (Perugini et al., 2002; Wiechers & Musee, 2010; Bolzinger, Briançon, & Chevalier, 2011; Kathawala, Ng, & Joachim Loo, 2015).

However there is a crucial necessity to verify their harmlessn ss relative to human health and the environment. This important issue was raised in the last few years when many International Organizations (Asia Pacific Nanotechnology Forum, 2005), governmental bodies within the European Union (European commission, 2004), United States Institutions (IEEE, 2004; US National Institute of Environmental Health Sciences, 2004), learned institutions and societies (Institute of Nanotechnology, 2005; Australian Academy of Sciences, 2005; UK Royal Society & Royal Academy of Engineering, 2004) and scientists (G.Oberdörster, E. Oberdörster, & J. Oberdörster, 2005; Donaldson & Stone, 2003) reported several assessments on the current state of nanotechnology, and most attracted attention to this requirement for an exhaustive risk investigation. Nevertheless, the influence of these nanomaterials (NMs) on human and environmental health remained unclear (Maynard, 2006; Nel, 2006; Helmus, 2007).

Although a rich literature is now available, we are still surprisingly uncertain as to whether engineered nanoparticles affect the human health and the environment or not!.

The organism has several semi-open interfaces for exchange some elements with the environment. The same interfaces are the principal routes of exposure of nanoparticles such as inhalation, dermal absorption and ingestion. An increasing number of researches have appeared in the last decade with an interesting goal of understanding the interactions between different types of nanoparticles and living cells of organisms as functions of size, shape, and surface chemistry of the nanomaterial (Lewinski, Colvin, & Drezek, 2008; Prinz, 2015). Unfortunately, no simple conclusions have emerged from the available studies due to the variability of parameters such as the physical and chemical properties of the particle, cell type, dosing parameters, and the biochemical assays used. Moreover, the majority of the scientific reports that investigate the cellular impact of NMs are in vitro, with far less effort to understand the real situation in vivo (Fischer & Chan, 2007).

CURRENT STATE OF ENGINEERED NANOPARTICLES IN THE ENVIRONMENT

Sources of Free Nanoparticles

Free nanoparticles are formed over either the breaking down of larger particles or by controlled gathering processes.

Recently, engineered nanoparticles for innovative technologies and consumer products have become an intentional source of exposure. Actually, till now, it is unrevealed how significantly human exposure to these engineered nanoparticles has increased, is it in the workplace, or over the use of nanotechnology-based products.

There are two methods to the synthesis of nanoparticles and the fabrication of nanostructures; top-down and bottom-up approaches.

1. Top-Down Approach

The "Top-down" approach involves the breaking down of the bulk material into nano sized particles.

Many approaches are widely used in nanotechnology process such as:

1. **High Energy Wet Ball Milling:** This method is basically appropriate for making interconnected and integrated nanostructures such as in electronic circuits. By this route, nanocrystalline high-temperature phases can be obtained without going through extreme heat treatment for long times, which would promote grain growth and surface area loss (He et al., 2014).
2. **Heat-Up Method:** The synthesis of colloidal nanocrystals using a heat-up (non-injection) method is a reliable means to realize high quality NMs on large scale with little or no batch-to-batch variation (Vaughn, Bondi, & Schaak, 2010).
3. **Laser Ablation Synthesis in Solution (LASiS):** It is a green method that does not require chemicals or stabilizers, because NPs are directly obtained in water as a stable colloidal system (Amendola, Litti, & Meneghetti, 2013).

2. Bottom-Up Approach

The Bottom-up approach refers to the buildup of a material from the bottom: single atoms and molecules are assembled into larger nanostructures. This method is very powerful for creating identical structures with high atomic precision.

1. **High-Temperature Flame Process:** This method is basically applied in chemical product and engineering process to produce well-defined nanostructures with the desired phase without the need for post calcination (Poliak et al., 2015).
2. **Chemical Vapor Deposition (CVD):** It consists in activating a chemical reaction between the substrate surface and a gaseous precursor. Activation can be realized either with temperature or with plasma. CVD process is widely used to produce various types of carbon nanostructures (Xu et al., 2015).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

3. **Template Synthesis:** Any substance containing regular nanosized holes can be used as a template to synthesize NPs. Protein cages assembled from a defined number of subunits present a powerful example of such templates. Because of their extreme homogeneity "in size and structure", their interior cavities can serve as ideal template to encapsulate and synthesize well-defined NPs (Uchida, Qazi, Edwards, & Douglas, 2015).

How Engineered Nanoparticles Get into the Environment

The main factors determining human and environmental exposure to nanoparticles are their sources, the pathway they take from the source to the ecosystems and environment, and their fate and behavior during transport.

A number of potential sources of exposure for nanoparticles have been well-known. These involve the workplace, both deliberate and unintentional environmental statements, and straight application from users and medical products.

Nanoparticles exist in the environment naturally; nevertheless, natural nanoparticles are present at very low concentrations and have insignificant effect (Klaine et al., 2008). Recently, manufactured NPs have arisen and have been integrated into an increasable number of commercial products and human activities. The effort, both scientific and socioeconomic, to well understand the hazard posed by nanoparticles and to control their release into the environment has become very important. Although, in many cases, the statement of nanoparticles is compulsory, the main task should be to reduce those statements of nanoparticles that could pose a serious hazard in the environment and human health.

1. Human Activities

There are a number of human activities that discharge nanoparticles. These include burning fossil fuels, large scale mining, demolition, and automobile traffic. Traffic emissions and fossil fuel combustion typically produce ultrafine (nano) particles of soot or carbon black. Fossil fuel combustion (including natural gas burning) has also been exposed to produce more legally recognized types of carbon nanoparticles containing carbon nanotubes and fullerenes. Mining and metal factory operations have recently been presented to produce metal and metal oxide nanoparticles. One particularly harmful aspect of nanoparticle release from incineration reactions in which:

1. Airborne pollutants are difficult to comprise and can briskly extent to other ecosystems.
2. Airborne particle contaminants are being involved in many pulmonary conditions "including chronic frustrating pulmonary infection, pulmonary inflammation, and pulmonary fibrosis", because their reduced size makes it easy for them to pass deep into cellular lungs, where they may cause several damages in lung tissues.

2. Consumer Products

The other most expected source of nanomaterial pollutants is nanoparticle allowed consumer products. More than several thousand consumer products, including many items of clothing, personal care products, next-generation batteries, and sporting goods now contain NMs. In the next ten years, nanoparticles will likely be incorporated into many more sophisticated products, including pharmaceuticals and next-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

generation solar cells or batteries. While the inclusion of NMs in these products can enhance their performance, the breakdown of these products at the end of their useful life also provides several key points of entry for man-made nanoparticles into the environment. When nanoparticles are incorporated into products intended for domestic use (like anti-microbial fabrics or UV-blocking clothing), nanoparticles can end up in landfills or washed down the drain when clothes have been laundered. Nanoparticles that end up in drain water or in landfills can then enter the environment by many different routes.

3. Nanowastes and Living Cells

Once nanoparticles have been disposed of in household garbage or down the drain, their journey through the environment is just beginning. Nanoparticles that escape with water down the drain will eventually enter a wastewater treatment facility. Here, nanoparticle-contaminated water will undergo several purification processes, including mechanical filtering and settling treatments (designed to remove large particles [larger than a grain of sand]), followed by digestion with microbes, and ultimately chemical disinfection. Unfortunately, none of these treatment stages are specifically designed to eliminate nanoparticles from the waste stream. As a result, following waste water treatment, nanoparticles may remain in the purified water that is released back into the environment, or nanoparticles may remain trapped in the microbe-bearing sludge left over from the purification process. Often, the bio-sludge left over from wastewater purification is repurposed as fertilizer for farm land, which can potentially allow man-made nanoparticles to enter soils or small rivers. Alternatively, when nanoparticle-enabled products end up in a landfill, the original product can break down, allowing man-made nanoparticles to leach into soil in and around the landfill area, providing a route for man-made NMs to enter new environments via soils or even ground water sources.

Nanowastes are discharged from many different human activities, such as research and development, industrial production, transport and storage, and primarily after disposal of consumer products that contain NMs (Novack, 2007, 2012).

A little bit is known now about how nanoparticle contaminants may escape into the environment. Unfortunately, we still know far less about the specific environmental or human health hazards that some man-made nanoparticles may pose. Understanding the health implications of man-made nanoparticles is just one of many challenges still remaining if we want to understand the environmental behavior of these nanoparticles in great detail. For instance, we don't understand how the various components of a given environment (like available ions, minerals, local bacteria, and organic matter) may interact with different nanoparticles to change their size, shape, composition, and bioavailability. Furthermore, we are still unable to easily detect and monitor man-made nanoparticles that have been released into the environment. As a result, nanoparticles are difficult to track through real ecosystems and many different time-intensive assays are required to even determine whether humans or animals have been exposed to nanoparticles.

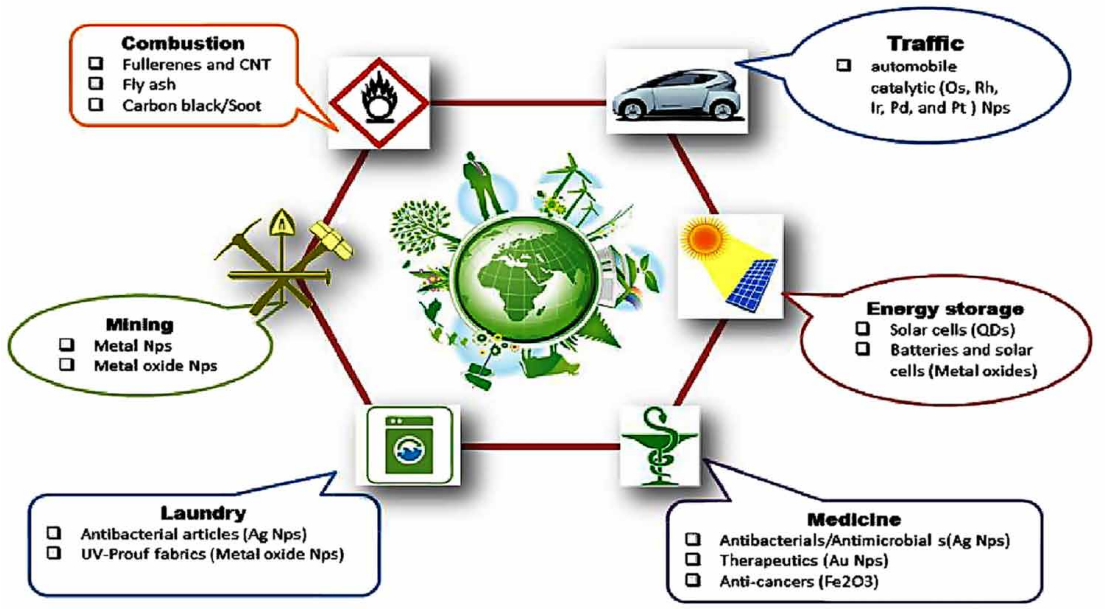
Nanotechnology is still a young field. While this means there are many things we still don't know about both the applications and implications of these new materials, this also gives us a new and unique opportunity to develop a chemical industry that could be truly sustainable from its inception. Hopefully, in the near future, we can overcome many of the barriers described above and help nanotechnology grow into a sustainable industry–one in which we can prevent environmental contamination by nanoparticles, rather than just clean up chemical waste after the fact. Look for the next post in this series soon, where

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

we discuss the specific issues of nanoscale titanium dioxide (a very common industrially produced nanoparticle) as an environmental contaminant.

Figure 1 presents an outline of the major possible paths through which fabricated nanoparticles may enter into human life and environment to potentially cause toxicity to living cells.

MAIN CHARACTERISTICS OF SOME INOVATED ENGINEERED NANOPARTICLES



When performing a toxicity study, characterization of the test substance is of crucial importance in order to understand the parameters that can be used to predict the hazard of NPs. The consequent changes in physicochemical, optical and reactive properties can all influence NPs toxicity.

Metallic Nanoparticles

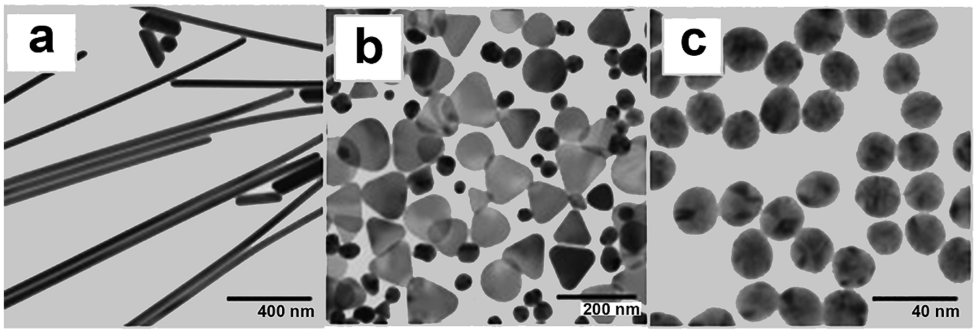
1. Silver Nanoparticles

Noble NMs have been synthesized using a variety of methods, including hard template, bio-reduction and solution phase synthesis. Among noble metal NMs, Silver nanoparticles have received considerable attention owing to their attractive physicochemical properties (*e.g.,* size and shape depending optical, electrical, and magnetic properties) which can be incorporated into antimicrobial applications, biosensor materials, composite fibers, cryogenic superconducting materials, cosmetic products, and electronic components. The surface plasmon resonance and large effective scattering cross section of individual Silver nanoparticles make them ideal candidates for molecular labeling where phenomena such as surface

Figure 1. Immersion of engineered nanoparticles (NPs) into human life and environment

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

enhanced Raman scattering (SERS) can be exploited. In addition, they exhibit strong toxicity in various chemical forms to a wide range of microorganism is well known and have shown to be a promising antimicrobial material.



Several physical and chemical methods have been used for synthesizing and stabilizing silver nanoparticles (Senapati, 2005; Klaus-Joerger, 2001). There are many consumer products and applications utilizing nanosilver in consumer products; nanosilver-related applications currently have the highest degree of commercialization. A wide range of nanosilver applications has emerged in consumer products ranging from disinfecting medical devices and home appliances to water treatments.

a. Shape and Sizes

Silver nanoparticles can be produced with various sizes and shapes depending on the fabrication method. Silver spheres, rods, wires and plates can be produced by varying the manufacturing method. Typically anisotropic shapes are formed in the presence of a stabilizing polymer that preferentially binds to one crystal face and results in one crystal direction growing faster than others. However, even "spherical" silver nanoparticles can have a range of shapes and sizes (Figure 2).

Superior physical and chemical properties were observed for the metal nanostructures with complex shapes. A typical example is the shape and size dependent optical properties exhibited by triangular silver nanoplates. Triangular plates show three surface plasmon resonance (SPR) bands corresponding to dipole and quadruple plasmon resonance, but only one SPR band is observed for spherical silver nanoparticles. A large number of aqueous and non-aqueous methods were reported in the past decade for the synthesis of silver nanoparticles having different size and shapes such as rods, prisms, cubes, wires and disks (Maillard, 2002; Gu, 2006; Bastys, 2006). For some photochemical syntheses, reaction times can be longer ranging from several hours to days. Stability of nanoparticles and use of environmental friendly chemicals are other considerations for real life applications. Recently a two-step seed mediated methods are reported for the synthesis of triangular silver nanoparticles, which involve the synthesis of spherical silver seeds and their growth into triangular nanoplates using polyvinylpyrrolidone (PVP) as a stabilizing agent (Ledwith, Whelan, & Kelly, 2007). Reliability of this procedure is highly dependent on the structure of silver seeds and a range of morphologies were observed in the final sol. Extreme care was required while storing the silver seeds.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

b. Surface Chemistry

It is important to remember that the surface of most nanoparticles is dynamic and is strongly influenced by the local environment. Different conditions will affect the particle in different ways. High salt environments will collapse the double layer and cause nanoparticle aggregation. Proteins and other biomolecules will often associate with and stabilize particles. When working with nanoparticles you must anticipate changes to the surface and plan accordingly. For example, when nanoparticles are to be added to solutions used in-vitro and in-vivo experiments, it is best to expose the particles to a low-salt solution that contains the protein components of the media and then add salt to bring the solution up to isotonic conditions. The protein binds to the particle surface and the suspension remains stable. If the nanoparticles are added directly to a high salt buffer, the particles may aggregate before protein stabilization can occur.

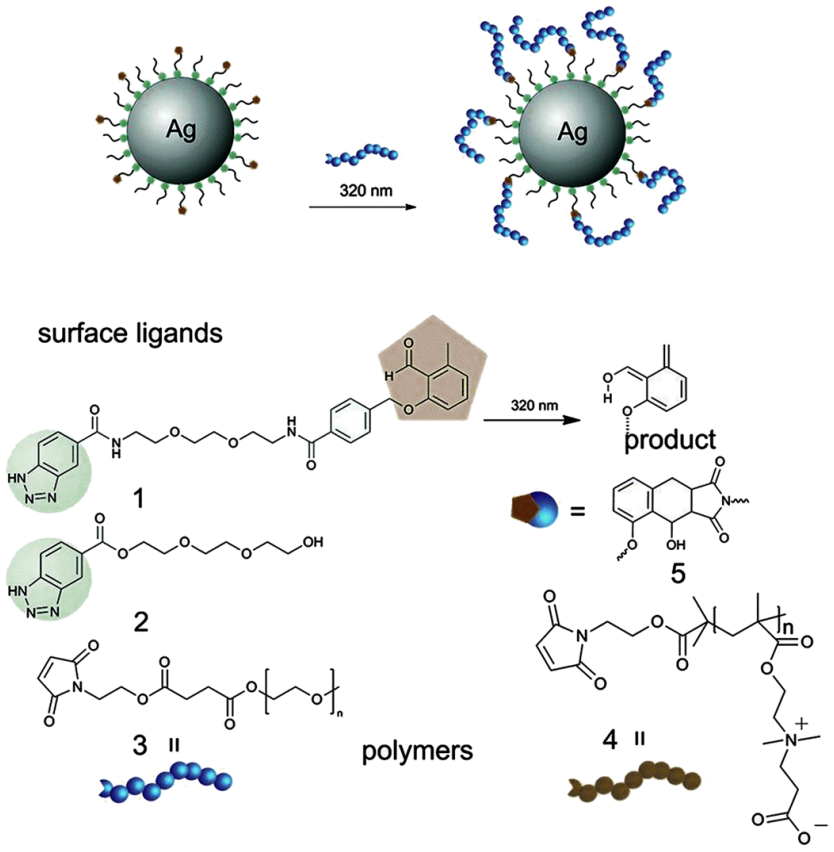
In solution, molecules associate with the nanoparticle surface and these surface bound molecules establish a double layer of charge that prevents nanoparticle aggregation.

Tannic acid is a multi-dentate capping ligand that can be displaced with many thiol containing molecules. Tannic acid is often used as a capping agent in applications where high particle concentrations are required.

Polyvinyl pyrollidone (PVP) is a polymer that binds strongly to the silver nanoparticle surface. It provides greater stability than citrate or tannic acid capping agents, but is more difficult to displace.

c. Surface Plasmon Resonance

There is increasing importance in developing the optical properties of silver nanoparticles as the functional component in various products and sensors. Silver nanoparticles are amazingly efficient at absorbing and scattering light and, unlike many dyes and pigments, have a color that depends upon the size and the shape of the particle. The strong interaction of the silver nanoparticles with light occurs because the conduction electrons on the metal surface undergo a collective oscillation when excited by light at specific wavelengths.



d. Surface Functionalization

Silver nanoparticles can be functionalized with a wide range of materials. Polymers such as polyvinyl pyrrolidone (PVP) and tannic acid are commonly used capping agents for silver nanoparticle materials applications, a zwitterionic polymer as well as polyethylene glycol are used to modify optical properties of Ag NPs (Stolzer et al., 2014). Silver nanoparticles used in biological applications are commonly coated with polyethylene glycol (PEG), bovine serum albumin (BSA), or numerous other proteins, peptides, and oligonucleotides. Particles can be functionalized with molecules that 'flip' the surface charge of the negatively charged silver nanoparticles to a positively charged surface. Particles can also be functionalized to provide reactive groups (for example, amine- or carboxy-terminated surfaces) for subsequent conjugation by the customer. Dielectric shells (for example, silica, aluminium oxide, and TiO_2) with a precisely controlled thickness can be used to encapsulate the particles, change the optical properties, or incorporate a fluorescent layer. Figure 3 illustrates the Light-induced modification of silver nanoparticles with functional polymers.

The approach of combining different mechanisms of antibacterial action by designing hybrid NMs provides a new paradigm in the fight against resistant bacteria.

Figure 3. Light-induced modification of silver nanoparticles with functional polymers
Source: (Stolzer et al., 2014)

The green synthesis of Ag-NPs using dextrose as reducing agent have recently revealed powerful characteristics in biomedical field. The as-synthesised Ag-NPs showed better efficacy than the antibiotics; ciproflaxin and imipenem, the minimum inhibition concentration (MIC) was 6 µg/mL against Pseudomonas aeruginosa (Mohan, et al., 2014).

It has been demonstrated that a material comprised of chitosan-stabilized Ag NPs is a very promising candidate to assemble voltammetric sensors for practical applications in the field of analytical chemistry and biomedicine (de Lima et al., 2014; Potara et al., 2011).

A facile method was developed to prepare a magnetic Ag nanocomposite. The 3-D nanofibrous structure of bacterial cellulose (BC) was homogenized with a ferric and ferrous mixture by a high speed blender. Magnetite NPs were precipitated and incorporated into BC nanostructure by adjusting the homogenate to alkaline pH. The magnetic Ag nanocomposite possesses a high antimicrobial activity against the model microbes Escherichia coli and Bacillus subtilis. It also has potential as a mild fermentation medium sterilizing agent that a freshly prepared LB medium shows no appreciable contamination after incubating with Ag nanocomposite for 4 h and removed by an external magnet (Sureshkumar et al., 2010).

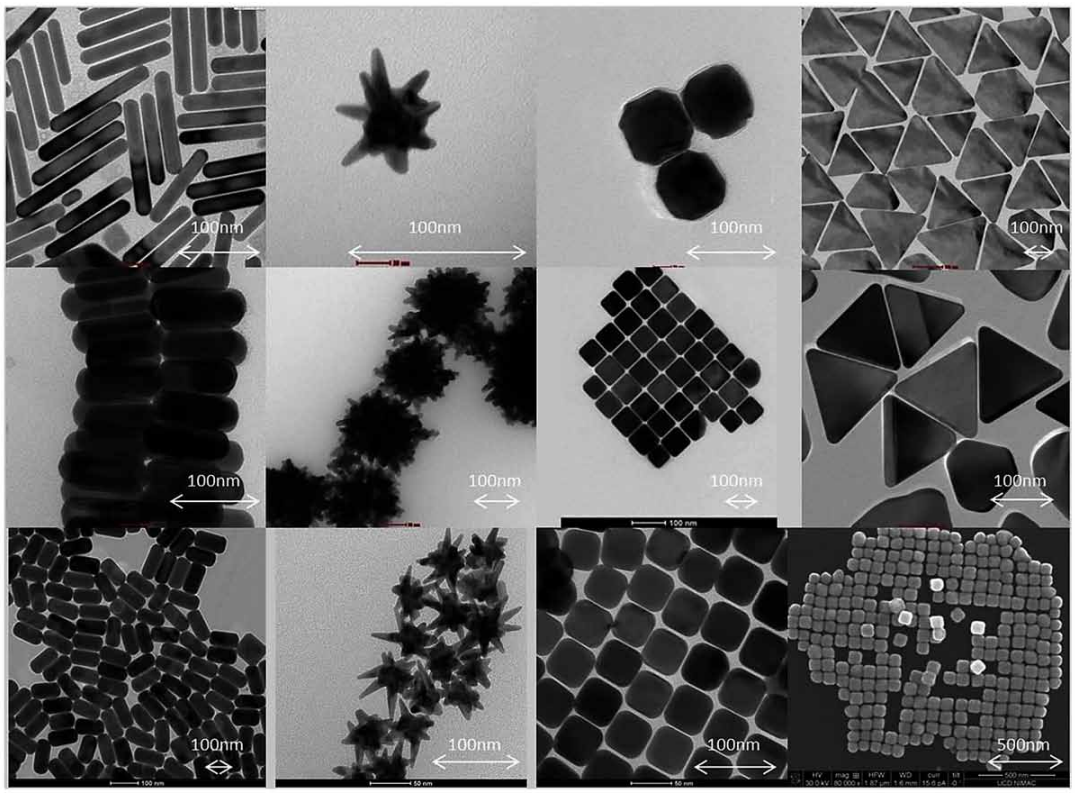
2. Gold Nanoparticles

The potential of gold nanoparticles (Au NPs) in therapeutic and diagnostic cancer applications is becoming increasingly recognized. These biologically compatible particles can be easily synthesized, tuned to different sizes, and functionalized by conjugation to various biologically useful materials. Efficient and specific delivery to tumor tissue can then be accomplished either by passive accumulation in leaky tumor vessels and tissue, or by directly targeting tumor-specific biomarkers.



Depending on the shape, size, and degree of aggregation and nature of the protecting organic shells on their surface, Au NPs can appear blue and other colors and emit bright resonance light of various wavelengths, which falls under visible region. Because of this property, Au NPs have been extensively used as probes for sensing/imaging a wide range of analysts/targets such as proteins, cells and nucleic acids.

a. Shape and Sizes

Gold Nano-particles come in a wide variety of shapes, including, sphere, rod, star and triangle, just to name some of them. Researchers are using several different shapes and sizes in this technology (Figure 4). It is still being determined what shape works best for killing cancerous cells.

However, although Gold Nano-Rods, Stars and Triangles behave similarly to the gold nano-Spheres, their shapes optimize their light scattering characteristics.

Figure 4. Library of nanoparticle shapes: TEM and SEM micrographs gold nanoparticles by Dr Željka Krpetić (CBNI, UCD)

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

In addition, Gold Nano-Rod have also been proven to enter a tumor more readily, than spheres.

Gold Nano-Particles can penetrate many cells throughout the body, they accumulating at tumor sites due to their EPR Effect "Enhanced Permeability and Retention Effect" (Maeda, 2010). It is the property by which certain sizes of molecules tend to accumulate in tumor tissue much more than they do in normal tissues.

b. Surface Plasmon Resonance (SPR)

Gold nanoparticles with unique optical properties may be useful as biosensors in living whole cells. They absorb and scatter light orders of magnitudes stronger than other materials (I. H. El-Sayed, Huang, & M. A. El-Sayed, 2005). The improved scattering property has been used in imaging and allows for detecting single cancer cell once nanoparticles are conjugated to cancer cell antibodies (I. H. El-Sayed, Xiaohua, & M.A. El-Sayed, 2006).The physical origin of the strong light absorption by noble metal nanoparticles is the coherent oscillation of the conduction band electrons (Surface Plasmon Resonance) induced by interaction with an electromagnetic field.

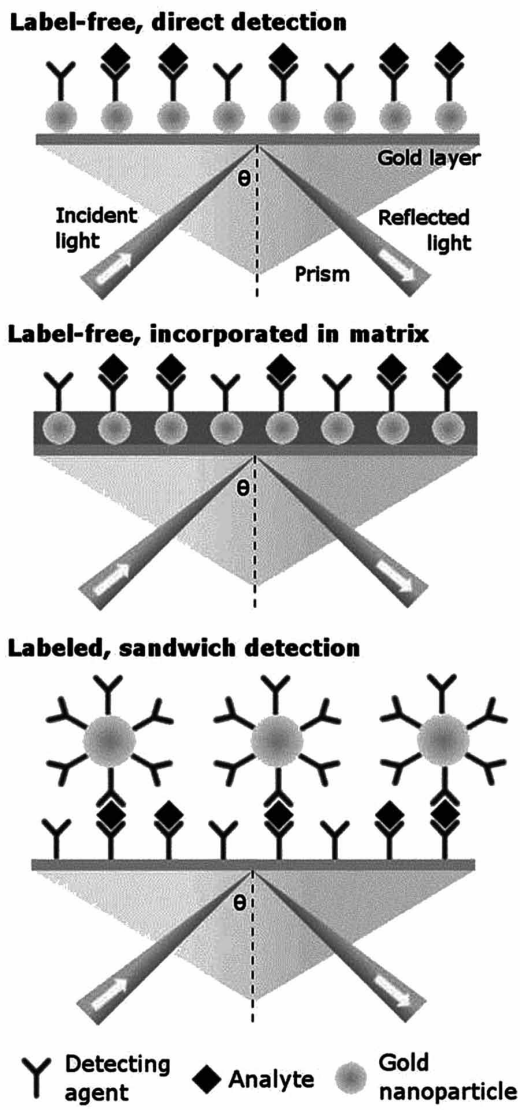
Recent methods to enhance SPR detection capabilities using gold nanoparticles are reviewed, as well as device fabrication and the results of incorporation (Bedford, Spadavecchia, Pradier, & Gu, 2012). As illustrated in Figure 5, SPR detection is a highly versatile method for the detection of biomolecules and, with the incorporation of Au NPs, shows promise in extending it to a number of new applications.

c. Functionalization of Gold Nanoparticles

Au NPs can be functionalized with a wide range of materials. The use of polymers such as cellulose, starch, alginate, dextran, and chitosan among others, gain great relevance not only due to their renewable nature and biodegradability, but also because a variety of formulations can be exploited depending on the envisaged functionality (Barhate, Gautam, Gairola, Jadhav, & Pokharkar, 2014; Chen, Cao, Quinlan, Berry,& Tam, 2015; Anh, Phu, Duy, Du, & Hien, 2010; Jang, Ryoo, Kostarelos, Han, & Min, 2013).

Metal Oxide Nanoparticles

1. Titanium Dioxide



Titanium dioxide (TiO_2) has become part of our everyday lives. It is found in various consumer goods and products of daily use such as cosmetics, paints, dyes and varnishes, textiles, paper and plastics, food and drugs, and even paving stones.

a. Shape and Sizes

Titania (TiO_2) is the most widely used photocatalyst (Fujishima, 2008; Henderson, 2011) for decomposition of organic pollutants because it is chemically stable and biologically benign. The band gap of TiO_2 is larger than 3 eV (~3.0 for rutile and ~3.2 for anatase), thus making pure TiO_2 primarily active for UV light. The most common commercial photocatalyst is the Degussa P-25, a powder consisting of both rutile and anatase crystallites (Ohno, Sarukawa, Tokieda,& Matsumura, 2001). The great versatility of titanium dioxide is owing to its various forms and sizes. Titanium dioxides may be used in the form of microscale pigments or as nano-objects. Their crystal structures may vary: Depending on the arrangement of TiO_2 atoms, one differentiates between rutile and anatase modifications.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 5. SPR detection capabilities using gold nanoparticles
Source: Bedford et al., 2012

b. Surface Chemistry

In a recent research, the effects of surface chemistry on the morphology and phase stability of titanium dioxide nanoparticles have been investigated using a thermodynamic model based on surface free energies and surface tensions obtained from first principles calculations. It has been found that surfaces representing acidic and alkaline conditions have a significant influence on both the shape of the nanocrystals and the anatase-to-rutile transition size (Bernard & Curtiss, 2005). The latter introduces the possibility of inducing phase transitions by changing the surface chemistry.

Surface modification such as coating, influences the activity of TiO_2 NPs. For example, diminished cytotoxicity was observed when the surface of TiO_2 NPs was modified by a grafting-to polymer technique combining catalytic chain transfer and thiolene click chemistry (Tedja et al., 2012).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

c. The Photocatalytic Activity

The photocatalytic activity for the degradation of phenol was improved under both visible and UV light by codoping. In 2009, Lai and Lee (Lai & Lee, 2009) revealed the ability and mechanism of photoexcited TiO_2 nanoparticles modified with folic acid to kill cells. Folic acid was bound to TiO_2 nanoparticles to provide cell targeting specificity. These nanoparticles exhibited higher cytotoxicity under photoexcitation. Mizukoshi et al. (Mizukoshi, Ohtsu, & Masahashi, 2009) prepared rutile TiO_2 by anodic oxidation in a sulfuric acid electrolyte. Sulfur doping played an important role in the response of the product to visible light by narrowing the band gap of TiO_2, allowing the photocatalyst to effectively bleach an aqueous solution of methylene blue under irradiation with visible light of >413 nm. Wang et al. (Wang, Ao, Wang, Hou, & Qian, 2010) synthesized TiO_2-coated magnetic silica that showed enhanced photocatalytic activity for the degradation of reactive brilliant red X-3B compared with Degussa P25 under both UV and visible light irradiation. Furthermore, the prepared composite photocatalyst had tunable magnetic properties.

2. Zinc Oxide

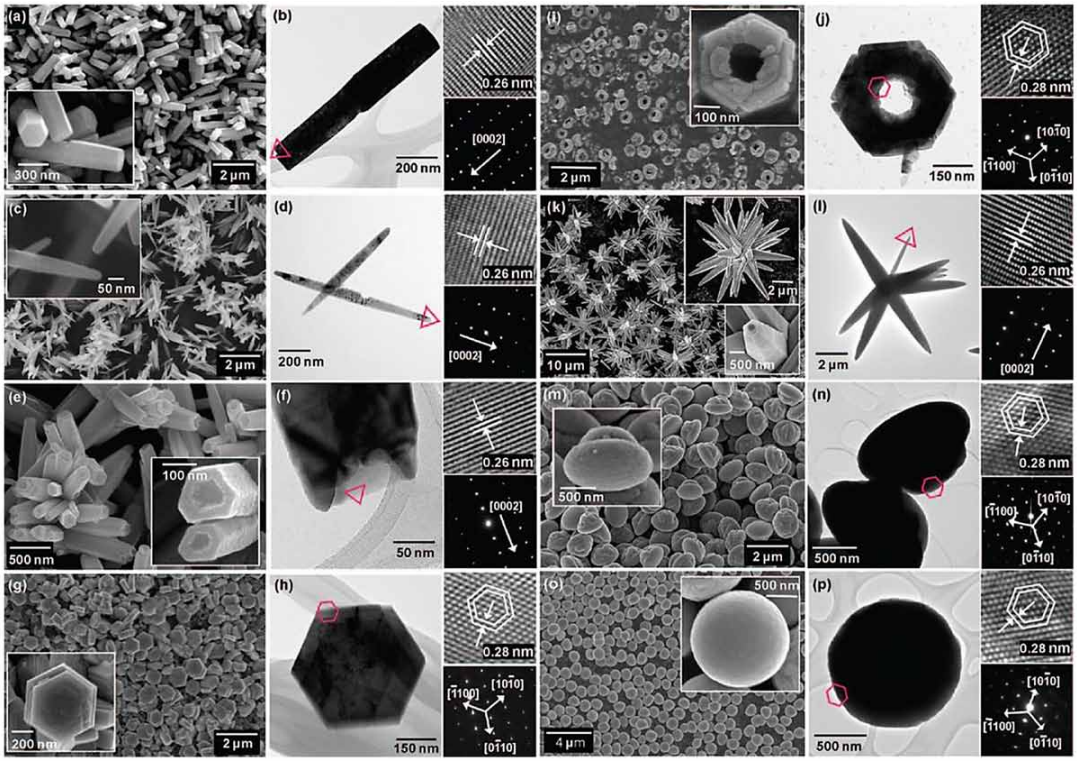
ZnO NPs have unique properties including small size and correspondingly large-specific surface area to volume ratio. ZnO has been increasingly employed in a variety of industrial applications including production of wave filters, UV detectors, catalysts, paint, transparent conductive film, cosmetics, gas sensor and catalytic processes, solar cells and microelectronics (Nel, 2006; Reijnders, 2006; Zhu, 2005), personal care products (toothpaste, beauty products, and sunscreens (Serpone, Dondi, & Albini, 2007), and textiles (Becheri, Dürr, Lo Nostro, & Baglioni, 2008). Increased applications in industry will increase chances of exposure of the nanoparticles to humans. Thus, zinc oxide nanoparticles are the subject of much research because of their high probability exposure to human and environment (Kahru & Dubourguier, 2010).

a. Shape and Sizes

The variety of structures of nanometric zinc oxide means that ZnO can be classified among new materials with potential applications in many fields of nanotechnology. ZnO provides one of the greatest collections of varied NPs microstructures among all known materials (Figure 6).

b. Surface Coatings of ZnO Nps

Surface coatings are added to ZnO nanoparticles for ease of handling and to modulate their properties. For example, coating facilitates their dispersability in the oil phase of sunscreen formulations, as well as improving the texture of the sunscreens on skin (Wang & Tooley, 2011).



From a nanotoxicological perspective, stable surface coatings have been reported to suppress the generation of reactive oxygen species (ROS) by ZnO nanoparticles (Yin, 2010, 2010) and may also decrease the propensity for ZnO nanoparticles to dissolve in biological environments.

c. Catalytic Activity

In recent years, in biological field, the potential utility of ZnO NPs in the treatment of cancer has been reported by many researchers. Owing to numerous advantages associated with this ecofriendly nature,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 6. Nanorods (a & b), nanoneedles (c & d), nanocandles (e & f), nanodisks (g & h), nanonuts (i & j), microstars (k & l), microUFOs (m & n), microballs (o & p)
Source: Cho et al., 2008

it has been explored as a powerful catalyst for several organic transformations (Moghaddam, 2009; Kumar, 2011; & Alinezhad, 2012) such as Mannich reaction, and the Knoevenagel condensation reaction, in the synthesis of coumarins, quinolines, polyhydroquinoline, 2,3-disubstituted quinalolin-4(1H)-ones, and benzimidazole.

3. Iron Oxide

Iron oxide NPs are the most popular magnetic NPs used in biomedical applications due to their low cost and unique magnetic properties. Magnetic iron oxide NPs have two main forms, magnetite (Fe_3O_4) and its oxidized form maghemite (γ-Fe_2O_3). They have attracted extensive interest due to their superparamagnetic behavior and their potential applications in many fields (drug delivery, diagnosis, therapy, and etc) and have been recently employed as supporting materials for enzymes, exhibiting striking characteristics, such as large surface area, mobility and high mass transference (Netto, Toma, & Andrade, 2013).

Applications of iron oxide NPs include terabit magnetic storage devices, catalysis, sensors, and high-sensitivity biomolecular magnetic resonance imaging (MRI) for medical diagnosis and therapeutics. These applications require coating of NPs by agents such as long-chain fatty acids, alkyl-substituted amines and diols.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

a. Shape and Size

Many successful challenges has been made to synthesis shaped and nanosized iron oxides using several mechanochemical and chemical methods (Wilcoxon & Provencio, 1999; Seip & Connor, 1999; Hyeon, Lee, Park, Chung, & Hyon, 2001; Jiang et al., 2004). By employing solvothermal techniques, various morphologies of iron oxides like nanorods, rings, cubes, spindles, hollow particles etc. have been prepared (Sun et al., 2004; Vayssieres et al., 2005; Huang, et al., 2011; Li et al., 2015.).

b. Functionalization of Iron oxide NPs

Magnetic iron oxide NPs with a bare surface tend to agglomerate because of strong magnetic attractions among the particles. Stabilizers such as carboxylates, inorganic compounds and polymeric compounds have functional groups to modify these particles and enhance its stability (Laurent et al., 2008; Zhang, He, & Gu, 2006). Among the various polymers, chitosan an alkaline product of chitin has been widely examined due to its hydrophilicity, biocompatibility and biodegradability (Unsoy, Yalcin, Khodadust, Gunduz, & Gunduz, 2012). Chemically chitosan is insoluble in water and behaves as a weak base making it inappropriate for biological and environmental applications. On the other hand, chitosan oligosaccharides, which can be produced by degradation of chitosan polymer chain, are water soluble making it suitable for biological and environmental applications (Mourya & Inamdar, 2008).

INTERACTION ETHICS OF NANOPARTICLES WITHIN LIVING CELLS

Some questions about the safety of such engineered NPs are very important and the most critical subject with this regard is the penetration of biological barriers allowing particle distribution throughout the living cells. Such translocation studies are technically challenging and many issues have been considered to obtain meaningful and comparable results.

A number of studies have demonstrated that NPs toxicity is extremely complex, and that their biological activity will depend on a variety of physicochemical properties such as particle shape and size, agglomeration state, crystal structure, chemical composition, surface area and surface properties.

Impact of Physicochemical Properties

The unusual physicochemical properties of engineered NPs are attributable to their small size (surface area and size distribution), chemical composition (purity, crystallinity, electronic properties, etc.), surface structure (surface reactivity, surface groups, inorganic or organic coatings, etc.), solubility, shape, and aggregation.

Although impressive from a physicochemical viewpoint, the novel properties of Nps raise concerns about hostile effects on living systems, which at the cellular level include structural arrangements that resemble NPs in terms of their function. Indeed, some studies suggest that Nps are not inherently benign and that they affect biological behaviors at the cellular, subcellular, and protein levels (Service, 2004; Colvin, 2003; Donaldson, 2001; Oberdörster, 2005; Ivask et al., 2015). Moreover, some nanoparticles readily travel throughout the body, deposit in target organs, penetrate cell membranes, and may trigger injurious responses (Barbasz, Oćwieja, & Barbasz, 2015).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

1. The Surface Effects

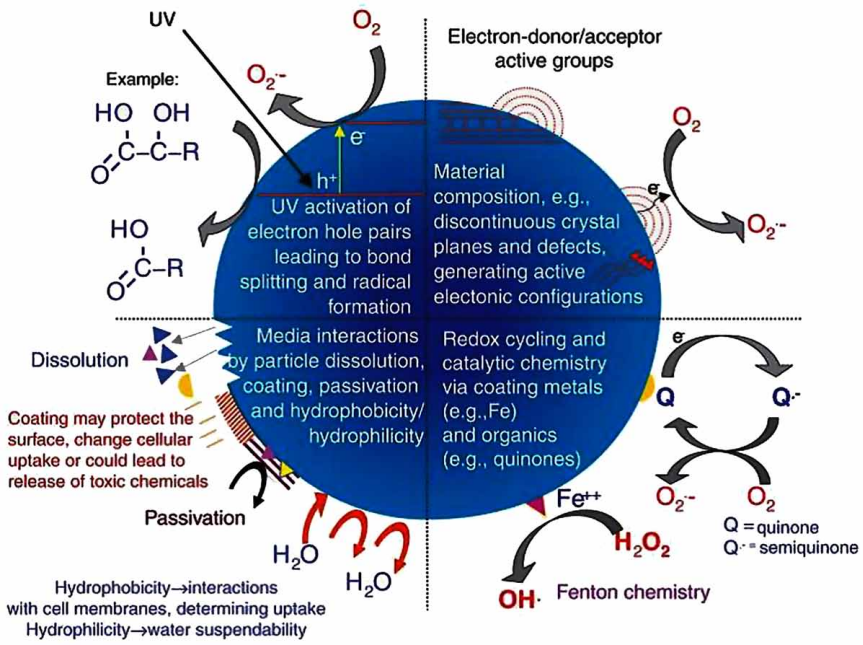
All NPs, upon exposure to tissues and fluids of the body, will immediately adsorb onto their surface some of the macromolecules that they encounter at their portal of entry. The specific features of this adsorption process will depend on the surface characteristics of the particles, including surface chemistry and surface energy, and may be modulated by intentional modification or functionalisation of the surfaces (Sperling & Parak, 2010). This is well demonstrated through the use of specific biomolecular linkers that are anchored on the surface of nanoparticles or within vesicles and liposomes (Nardin, Thoeni, Widmer, Winterhalter, & Meier, 2000). In this way the affinity of a NP can be shaped to fit to a particular protein, and thus target a specific biomolecular assembly on a membrane, or within a specific organelle or cell surface. Both the existence of passive surface layers and surface active agents compromise the risk evaluation of nanoparticles by mere chemical composition. In agreement with bulk surface chemistry, metallic nanoparticles are of considerable chemical reactivity and it is well established that metal NPs will often form passive surface layers on exposer to oxygen, just as do their bulk counterparts. (EE, International Handbook on Regulating Nanotechnologies, 2010).

2. Size, Shape, and Composition

The interaction of NPs with living cells is also affected by the characteristic dimensions. As noted above, NPs, of a few nm in size, may reach well inside biomolecules situation not possible for larger particles. It has been reported that inhaled nanoparticles reach the blood and may reach other target sites such as the liver, heart or blood cells (Oberdörster, 2002; MacNee, 2000; & Kreyling, 2000).

Nanoparticles may translocate through membranes. There is little evidence for an intact cellular or sub-cellular protection mechanism. For humans, inhalation is the most frequent route of access, and therefore the process of aggregation of NPs in the inhaled air has to be taken into account.

3. Solubility



In view of the active functionalization and the possible interaction of NPs with bio-molecular structures, it is important to consider the dose and dose rate of the particulate agent, its ability to spread within the body and ecosystem, the decay of number concentration and the erosion of individual particles. Many nanoparticles will have considerable solubility.

For these materials the interaction with living systems remains close enough to the bulk chemical agent to justify the use of well-established toxicological testing procedures and approaches. For biodegradable particles, the particle composition and degradation products will influence their biological effects. On the other hand, materials with very low solubility or degradability could accumulate within living cells and persist there for long durations. It is with nanoparticles of this character that the greatest concerns must arise, and attention will have to be paid to the comparison of the persistence of the particles and the time constants of the metabolic and cellular activities within the target host.

Figure 7 illustrates the importance of material composition, electronic structure, bonded surface species, surface coatings (active or passive), and solubility, including the contribution of surface species and coatings and interactions with other environmental factors (e.g., UV activation).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 7. Possible mechanisms by which nanomaterials interact with biological tissue
Source: Nel et al., 2006.

STUDIES SHOWING HARMFUL EFFECTS OF NANOPARTICLES ON LIVING CELLS

Uses of engineered Nps in sunscreens (e.g., TiO_2 and zinc oxide ZnO) and cosmetics and as bioimaging probes (e.g., superparamagnetic iron oxides) or tumor-specific photothermal therapy agents, antiangiogenic agents, and molecular reporters (Au NPs, Ag NPs) have not lead to reports of clinical toxicity in humans.

Nowadays, some answers related to fundamental aspects of the interactions of NPs with living cells, have been investigated. Studies reported in the literature have delivered only limited principles about the nano-bio interfaces and thus the biological behavior of NPs is yet far from being completely understood.

The in-vitro cytotoxicity findings and the potential for exposures to ZnO NPs from different sources via different routes of entry into the body have raised public health concerns.

However, although inhalation of ultrafine ZnO particles at relatively high dose (500 mg/m3) for 2 hours did not induce acute systemic effects in humans, inhalation of ZnO fumes in an occupational setting can cause metal fume fever (fatigue, chills, fever, myalgias, cough, dyspnea, leukocytosis, metallic taste, and salivation) (Beckett et al., 2005). Only a limited number of NPs have so far been shown to exert toxicity in tissue culture and animal experiments, usually at high doses (Service, 2004; Oberdörster, 2005).

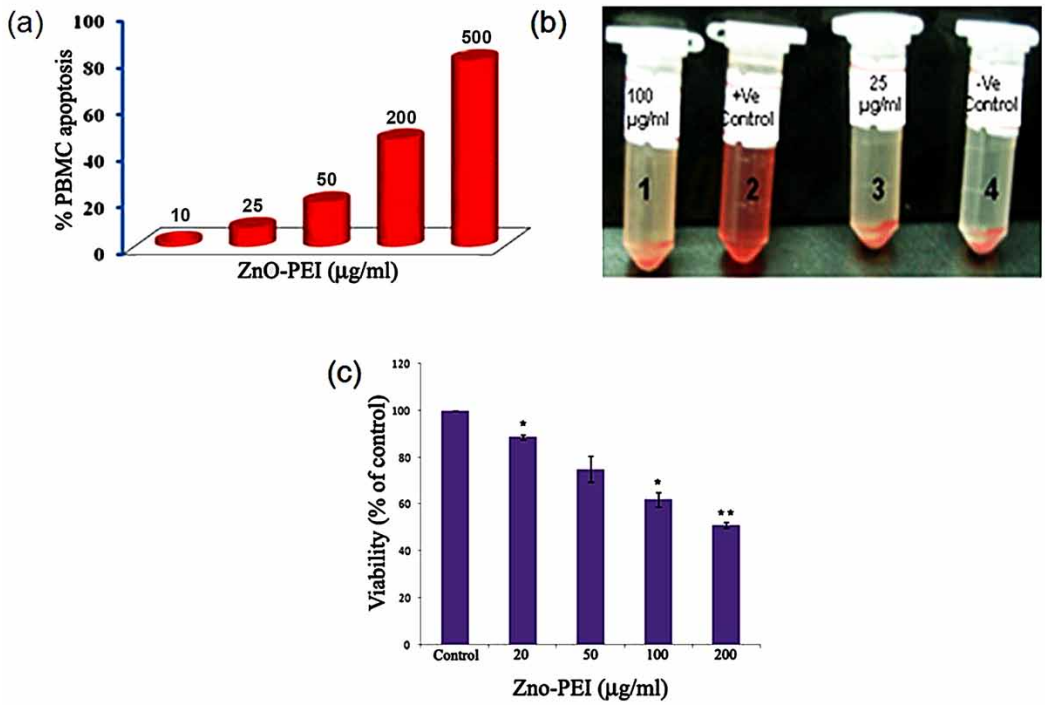
Although recent studies have shown the cytotoxic effects of these NPs, including oxidative stress, apoptosis and necrosis induction, genotoxicity, and others, irradiation-induced cytotoxicity has not been systematically studied. This was the aim of Yang & Ma study which focused on whether irradiation in the forms of visible light (approximately 400-600 nm), ultraviolet (UV) A (366 nm), and UVC (254 nm) would affect ZnO NPs-induced cytotoxicity. The results of their tests demonstrated that the cytotoxicity of 60 to 80 nm ZnO NPs to A549 cells is dosage, time, and wavelength dependent. Nuclear

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

decomposition by ZnO NPs, prior to membrane deformation, was found to be enhanced when exposed to irradiation. This study suggested that this phenomenon may be attributed to the irradiation-induced formation of positively charged sites on ZnO NPs, which enhances nuclear affinity and generation of reactive oxygen species (ROS). Finally, the data demonstrated that while ZnO NPs act preferentially toward nuclear regions, destructions of cell membrane and the cytosol have also been observed. The photocatalytic properties of ZnO NPs play a critical role during the early stages of cell death, and their effects were reduced through the use of an antioxidant, N-acetylcysteine. In conclusion, they released that both visible light and UV irradiations have been found to enhance the cytotoxic effect of ZnO NPs on A549 cell line. This finding supports the need for further in-vivo exposure studies relevant to actual conditions to confirm whether combined irradiation and ZnO NPs exposure could enhance the nanotoxicity of ZnO NPs (Yang & Ma, 2014).

On the other side, not much work is available on the bio-interaction of ZnO NPs with astrocytes, the major cells involved in brain homeostasis. Therefore, S. Sruthi and P.V. Mohanan have focused on the interaction of ZnO NPs with rat C6 glial cells. The results of their findings reveal that NPs are taken up by the astrocytes and induce time and dose dependent toxicological response which is indicated by NPs uptake studies and cell viability assays. Also the results of DCFH-DA (2',7'-dichlorofluorescein diacetate) assay showed that ZnO NPs induce strong oxidative stress in cells at 3 and 6 h. However, at 24 h the reactive oxygen species (ROS) detected in NPs treated groups were same as that of control. The mode of cell death induced by ZnO NPs was apoptosis as revealed by the nuclear condensation studies, live dead assay using acridine orange/ethidium bromide and apoptosis detection kit. This bio-test, which explores the interaction of ZnO NPs with astrocytes, concludes that the persistence of particle can continue to have a damaging effect on the astrocytes. Finally they concluded that the time of exposure and particle clearance by the system should be evaluated more thoroughly to prevent the health hazards due to nanoparticles (Sruthi & Mohanan, 2015).

Figure 8 reports toxic effect of polyethyleneimine (PEI) functionalized zinc oxide (ZnO) Nps against different human cells.



Titanium dioxide (TiO_2) is one of the most widely manufactured and consumed engineered and utilized NPs in numerous industries such as cosmetics, pharmaceuticals, water treatment and foods. Recent studies indicate that TiO_2 NPs have adverse effects on human health but there are limited studies that correlate the effects observed to specific biological pathways.

Intratracheal instillation of TiO_2 particles in rodents demonstrates that these nanoparticles induce bigger inflammatory responses than larger particles of an equivalent mass dose (Oberdörster, 2005). However, when the instilled dose is expressed as particle surface area, the inflammatory response fits the same dose-response curve (Colvin, 2003; Donaldson, 2002). This supports the concept that the surface area is the dose measurement that best predicts pulmonary toxicity (Oberdörster, 2005). In addition to the generation of pro-inflammatory effects, nanoparticles of various sizes and chemical composition are able to lodge in mitochondria (Oberdörster, 2005; Li, 2003). This can lead to disruption of the mitochondrial electron transduction chain, which leads to additional O_2^- production (Li, 2003). Further, ambient ultrafine particles perturb the mitochondrial permeability transition pore, which leads to the release of pro-apoptotic factors and programmed cell death (Li, 2003).

On the other hand, the toxicological effects of TiO_2 on liver which is the major accumulation site of TiO_2 NPs, directly through intentional ingestion or indirectly via NPs dissolution from food containers, have been concisely investigated. In the work reported by V. Natarajan et al., the concentration and phase dependent effect elicited by TiO_2 NPs on primary hepatocytes, has been investigated. Hepatocytes were

Source: Chakraborti et al., 2013

the most abundant cell type of the liver and perform numerous vital hepatic functions related to synthesis, catabolism and clearance. In this study, they exposed the primary hepatocytes to three different forms of commercially available TiO_2 NPs; Degussa P25, pure Anatase (50 nm) and pure Rutile (50 nm). TiO_2 exposure was resulted in a concentration dependent loss of cell viability and alteration in cell morphology. It was also observed an increase in production of Reactive Oxygen Species (ROS). Furthermore, liver-specific functions (urea and albumin synthesis) were also affected by TiO_2, P25 treated cells exhibiting the most significant loss in the functions. Currently, they were investigating the molecular mechanistic aspects of the observed change in cell phenotype, focusing primarily on the effect of oxidative stress and mitochondrial dysfunction induced by TiO_2 NPs (Natarajan et al., 2014).

Recently, increasing concern has been raised about the neurotoxicity of TiO_2 NPs. But the mechanisms underlying such toxic effects are still unknown. Z. Mao et al., have employed a human neuroblastoma cell line (SH-SY5Y) to study the effects of TiO_2 NPs on neurological systems. The results showed that TiO_2 NPs did not affect cell viability but induced noticeable morphological changes until 100 µg ml (-1). Immunofluorescence detection showed disorder, disruption, retraction, and decreased intensity of the microtubules after TiO_2 NPs treatment. Both α and β tubule expressions did not change in TiO_2 NPs treated group, but the percentage of soluble tubules was increased. A microtubule dynamic study in living cells indicated that TiO_2 NPs caused a lower growth rate and a higher shortening rate of microtubules as well as shortened lifetimes of de novo microtubules. TiO_2 NPs did not cause changes in the expression and phosphorylation state of tau proteins, but a tau-TiO_2 NPs interaction was observed. TiO_2 NPs

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

could interact with tubule heterodimers, microtubules and tau proteins, which led to the instability of microtubules, thus contributing to the neurotoxicity of TiO_2 NPs (Mao et al., 2015).

A. Katsumiti et al. have investigated the effects of a set of TiO_2 NPs on the viability of mussel hemocytes and gill cells using neutral red and thiazolyl tetrazolium bromide assays. For this, they have compared the cytotoxicity of TiO_2 NPs (0.1-100 mg Ti/L) produced by different methods: rutile NPs (60 nm) produced by milling and containing disodium laureth sulfosuccinate (DSLS), rutile NPs (10, 40 and 60 nm) produced by wet chemistry and anatase/rutile NPs (~100 nm) produced by plasma synthesis. The commercially available P25 anatase/rutile NPs (10-20 nm) were also checked in their essays tested. Exposures were performed in parallel with their respective bulk forms and the cytotoxicity of the additive DSLS was also tested. Z potential values in distilled water indicated different stabilities depending on the NPs type and all NPs tested formed agglomerates/aggregates in cell culture media. In general, TiO_2 NPs showed a relatively low and dose-dependent toxicity for both cell models with the two assays tested. NPs produced by milling showed the highest effects, probably due to the toxicity of DSLS. Size-dependent toxicity was found for NPs produced by wet chemistry (10 nm > 40 nm and 60 nm). All TiO_2 NPs tested were more toxic than bulk forms excepting for plasma produced ones, which were the least toxic TiO_2 tested. The mixture bulk anatase/rutile TiO_2 was more toxic than bulk rutile TiO_2. The authors concluded, that the toxicity of TiO_2 NPs varied with the mode of synthesis, crystalline structure and size of NPs and can also be influenced by the presence of additives in the suspensions (Katsumiti et al., 2014).

In the last decade, numerous in vitro studies have shown that Ag NPs have potential to induce toxicity in cells derived from a variety of organs. The use of Ag NPs in cosmetics and textiles has substantially increased the potential for human skin exposure. Recently, a study was carried out by using an artificial human skin exposure, which demonstrated that silver could be released from antibacterial fabric products into sweat (Kulthong, Srisung, Boonpavanitchakul, Kangwansupamonkon, & Maniratanachote, 2010). Ag nanoparticles are found to induce cell death and oxidative stress in human fibrosarcoma and skin carcinoma cells (Arora, Jain, Rajwade, & Paknikar, 2008) and it was demonstrated that Ag NPs could enter cells and cause DNA damage and apoptosis in fibroblasts and liver cells (Arora, Jain, Rajwade, & Paknikar, 2009).

W. Liu et al. investigated the cytotoxicities of three types of Ag NPs; SNP-5, SNP-20 and SNP-50 with different sizes (approximately 5, 20 and 50 nm) using four human cell models (A549, SGC-7901, HepG2 and MCF-7). Endpoints included cell morphology, cell viability, cellular membrane integrity, oxidative stress and cell cycle progression. Observable deleterious effects on the cell morphologies and membrane integrity were induced by SNP-5 and SNP-20. SNPs elevated the ROS levels in cells and arrested the cells at Ag phase. Apoptosis occurred for 4-9% of the exposed cells. All these cellular responses as well as EC50 values were found to be size-dependent for the tested SNPs. Ultrastructural observations confirmed the presence of Ag NPs inside cells. Elemental analysis of Ag in cells by ICP-MS showed that smaller NPs enter cells more easily than larger ones, which may be the cause of higher toxic effects (Liu et al., 2010).

C. Arulvasu et al., (2014) revealed the toxic effect of Ag NPs in Artemia nauplii and evaluated the mortality rate, the hatching percentage, and the genotoxic effect in Artemia nauplii/cysts. The AgNPs were commercially purchased and characterized using field emission scanning electron microscope with energy dispersive X-ray spectroscopy. NPs were spherical in nature and with size range of 30-40 nm. In their assessment, Artemia nauplii (II instar) were treated using Ag NPs of various nanomolar concentrations and LC50 value (10 nM) and mortality rate (24 and 48 hours) was evaluated. This study

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

showed that as the concentration of Ag NPs increased, the mortality rate, aggregation in gut region, apoptotic cells, and DNA damage increased in nauplii, whereas the percentage of hatching in Artemia cysts decreased. Thus this study revealed that the nanomolar concentrations of Ag NPs have toxic effect on both Artemia nauplii and cysts (C. Arulvasu, et al., 2014).

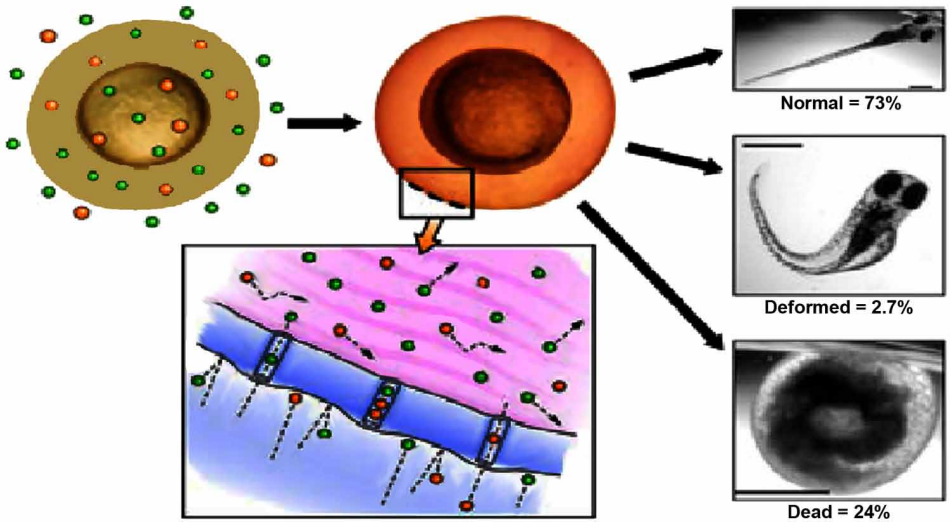
The toxic risk of Ag NPs usage, liver, as a detoxifying organ, is particularly important. This was the purpose study reported by I. V.Vrček et al. The authors explored the toxicity mechanisms of nano and ionic forms of Ag on human hepatoblastoma (HepG2) cells. The results showed that Ag ions and citrate-coated Ag NPs reduced cell viability in a dose-dependent manner. The IC50 values of Ag ions and citrate-coated Ag NPs were 0.5 and 50 mg L−1, respectively. The LDH leakage and inhibition of albumin synthesis, along with decreased ALT activity, indicated that treatment with either Ag NPs or Ag ions resulted in membrane damage and reduced the cell function of human liver cells. Evaluation of oxidative stress markers demonstrating depletion of GSH, increased ROS production, and increased SOD activity, indicated that oxidative stress might contribute to the toxicity effects of nano and ionic forms of Ag. The observed toxic effect of Ag NPs on HepG2 cells was substantially weaker than that caused by ionic Ag (Vrčekstudy et al., 2014).

Ag NPs are expected to end up in the aquatic environment. Mussels have been proposed by Katsumiti et al., (2015) as marine model species to evaluate NPs toxicity in-vitro. In this work, the mechanisms of toxicity of Ag NPs were studied on mussel hemocytes and gill cells, in comparison to ionic and bulk Ag. The cytotoxicity of commercial and maltose stabilized Ag NPs was screened in parallel with the ionic and bulk forms at a wide range of concentrations in isolated mussel hemocytes and gill cells using cell viability assays. Maltose-stabilized Ag NPs showed size-dependent cytotoxicity, smaller (20 nm) NPs being more toxic than larger (40 and 100 nm) NPs. Maltose alone provoked minor effects on cell viability. Ionic Ag was the most cytotoxic Ag form tested whereas bulk Ag showed similar cytotoxicity to the commercial Ag NPs. The main mechanisms of action of Ag NPs involved oxidative stress and genotoxicity in the two cell types, activation of lysosomal AcP activity, disruption of actin cytoskeleton and stimulation of phagocytosis in hemocytes and increase of MXR transport activity and inhibition of Na-K-ATPase in gill cells. Similar effects were observed after exposure to ionic and bulk Ag in the two cell types, although generally effects were more marked for the ionic form. In conclusion, results suggest that most of the observed responses were due at least in part to dissolved Ag (Katsumiti et al., 2015).

With the advance in materials science and the need to diversify market applications, Ag NPs are widely modified by different surface coatings. However, how these surface functionalization's influence the effects of Ag NPs on living cells and human health is still largely unknown. Pang et al., (2015) have evaluated the uptake, toxicity and pharmacokinetics of Ag NPs coated with citrate, polyethylene glycol, polyvinyl pyrolidone and ranched polyethyleneimine (Citrate Ag NPs, PEG Ag NPs, PVP Ag NPs and BPEI Ag NPs, respectively). It was demonstrated that the toxicity of Ag NPs depends on the intracellular localization that was highly dependent on the surface charge. BPEI Ag NPs (ζ potential = +46.5 mV) induced the highest cytotoxicity and DNA fragmentation in Hepa1c1c7. In addition, it showed the highest damage to the nucleus of liver cells in the exposed mice, which is associated with a high accumulation in liver tissues. The PEG Ag NPs (ζ potential = -16.2 mV) showed cytotoxicity, a long blood circulation, as well as bioaccumulation in spleen (34.33 μg/g), which suggest better biocompatibility compared to the other chemically modified Ag NPs. Moreover, the adsorption ability with bovine serum albumin revealed that the PEG surface of Ag NPs has an optimal biological inertia and can effectively resist opsonization or non-specific binding to protein in mice. The overall results of this assessment indicated that the biodistribution of Ag NPs was significantly dependent on surface chemistry: BPEI Ag NPs >

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Citrate Ag NPs = PVP Ag NPs > PEG Ag NPs. The authors finally concluded that this toxicological data could be useful in supporting the development of safe Ag NPs for consumer products and drug delivery applications (Pang et al., 2015).



Several research groups have investigated the cellular toxicity of Au NPs with regard to particle shape, size, and surface group. Rotello et al. have investigated the toxicity of 2 nm Au NPs functionalized with both cationic and anionic surface groups in three different cell types. The results suggested that cationic particles are generally toxic at much lower concentrations than anionic particles, which can be related to the electrostatic interaction between the cationic NPs and the negatively charged cell membranes (Goodman, McCusker, Yilmaz & Rotello, 2004). Chithrani group have examined the uptake of Au NPs of various shapes and sizes into HeLa cells, a well-known line of human cervical cancer cells (Chithrani, Ghazani, & Chan, 2006).

Au NPs are materials with unique optical properties that have made them very attractive for numerous biomedical applications. With the increasing discovery of techniques to synthesize novel NPs such as star-shaped Au nanostars for biomedical applications, the safety and performance of these new NMs must be systematically assessed before their practical use. In the study conducted by Pelagie Marlene Favi et al., Au nanostars (AuNSTs) with multi-branched surface structures were synthesized and their influence on the cytotoxicity of human skin fibroblasts and rat fat pad endothelial cells (RFPECs) were assessed and compared to gold nanospheres (AuNSPs) with un-branched surfaces. The results indicated that AuNSPs with diameters of approximately 61.46 nm showed greater toxicity with fibroblast cells and RFPECs compared to the synthesized AuNSTs with diameters of approximately 33.69 nm. AuNSPs were lethal at concentrations of 40 μg/mL for both cell lines, while AuNSTs were less toxic at higher concentrations (400 μg/mL). The calculated IC50 (50% inhibitory concentration) values of Au NSPs exposed to fibroblast cells were greater at 1 and 4 days of culture (26.4 and 27.7 μg/mL, respectively) compared to the RFPECs (13.6 and 13.8 μg/mL, respectively), indicating that AuNSPs have a greater toxicity to endothelial cells. It was proposed that the possible factors that could be promoting the reduced toxicity effects of AuNSTs to fibroblast cells and RFPECs, compared to AuNSPs may be size, surface chemistry, and shape of the Au NPs. The reduced cell toxicity observed with AuNSTs suggests that the latter may be a very promising material for use in biomedical applications (Favi et al., 2015).

Combining computational tools to experimental approaches helps to precisely probe the nano-bio interface and allows the development of predictive and descriptive relationships between the structure and the activity of NMs. In this regard Bigdeli group has statistically established a nano-quantitative structure-activity relationship (nano-QSAR) model, using Partial Least Squares Regression (PLSR) model. Also, variable importance on PLS projections (VIP) has been used to find the most responsible factors on NPs exocytosis. Physicochemical properties of a set of different sized Au NPs with different surface coatings were greatly correlated to their exocytosis in macrophages. The results of this study suggest that among the pool of physicochemical properties defined as nano-descriptors, charge density and surface charge seem to be the paramount factors leading to higher exocytosis values. Furthermore, charge accumulation and circularity of NPs are in the next level of priority among other nano-descriptors. The regression based nano-QSAR model reported in this work is satisfactory in both statistical quality and interpretability. The authors concluded finally that the results could serve as a quantitative framework for better understanding the mechanisms that govern the interactions at the nano-bio interface (Bigdeli et al., 2015). Figure 9 presents an illustration of the accumulation mechanism of Gold NPs in the embryos of zebrafish.

Superparamagnetic iron oxide NPs (IONPs) have attracted a great interest for use in several biomedical fields. In general, they are considered biocompatible, however little is known about their effects on the human nervous system. C. Costa et al. evaluated the cytotoxicity of two IONPs (magnetite), coated with silica and oleic acid, previously determining the possible interference of the IONPs with the methodological procedures to assure the reliability of the results obtained. Human neuroblastoma SHSY5Y and glioblastoma A172 cells were exposed to different concentrations of IONPs (5-300 µg ml(-1)), prepared in complete and serum-free cell culture medium for three exposure times (3, 6 and 24 h). Cytotoxicity was evaluated by means of MTT, neutral red uptake and alamar blue assays. Characterizations of the main physical-chemical properties of IONPs were also performed. The results of this assessment have demonstrated that both Fe_2O_3 NPs could significantly alter absorbance readings. To reduce these interferences, protocols were modified by introducing additional washing steps and cell-free systems. Significant decreases in cell viability were observed for both cell lines in specific conditions by all assays. In general, oleic acid-coated IONPs were less cytotoxic than silica-coated IONPs; besides, a serum-protective effect was observed for both IONPs studied and cell lines. These results contribute to increase the knowledge of the potential harmful effects of IONPs on the human nervous system (Costa et al., 2015).

Ge group has evaluated the cytotoxicity effect of dimercaptosuccinic acid-coated iron oxide (DMSA-Fe_2O_3) using cultured human aortic endothelial cells (HAECs). Their results showed that DMSA- Fe_2O_3 in the culture medium could be absorbed into HAECs, and dispersed in the cytoplasm. The cytotoxicity effect of DMSA- Fe_2O_3 on HAECs was dose-dependent, and the concentrations no more than 0.02 mg/ml had little toxic effect which were revealed by tetrazolium dye assay. Meanwhile, the cell injury biomarker, lactate dehydrogenase, was not significantly higher than that from control cells (without DMSA- Fe_2O_3). However, the endocrine function for endothelin-1 and prostacyclin I-2, as well as the urea transporter function, was altered even without obvious evidence of cell injury in this context. It was also shown by real-time PCR analysis that DMSA- Fe_2O_3 exposure was resulted in differential effects on the expressions of pro- and anti-apoptosis genes of HAECs. It was noted that DMSA- Fe_2O_3 exposure could activate the

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

expression of genes related to oxidative stress and adhesion molecules, which suggested that inflammatory response might be evoked. Moreover, it was demonstrated by in-vitro endothelial tube formation that even a small amount of DMSA- Fe_2O_3 (0.01 and 0.02 mg/ml) could inhibit angiogenesis by the HAECs. Altogether, the results indicate that DMSA- Fe_2O_3 have some cytotoxicity that may cause side effects on normal endothelial cells (Ge et al., 2013).

Zavisova et al., (2014) have studied the toxicity of magnetite NPs modified with bioavailable materials such as dextran, bovine serum albumin, polyethylene glycol, and polyvinylpyrrolidone in normal and cancer cells. The size distribution and magnetic properties of the modified magnetic NPs were characterized by different techniques. Transmission electron microscopy showed a nearly spherical shape of the magnetite core with diameters ranging from 4 to 11 nm. Dynamic light scattering was employed to monitor the hydrodynamic size and colloidal stability of magnetic NPs: Z-average hydrodynamic diameter was between 53 and 69 nm and zeta potential in the range from −35 to −48 mV. Saturation magnetization of the modified NPs was 55-64 emu/g Fe_3O_4. The authors found that the prepared biocompatible NPs had no significant toxic effect on Chinese hamster lung fibroblast cell line V79, however they substantially affected mouse melanoma B16 cell line (Zavisova et al., 2014).

CONCLUSION

With growing public awareness about the potential harmful effects of novel technologies, the world today is viewed with more doubt than before. Thus, scientists aiming to introduce new technology must be more assured of the benignity of their contribution.

Understanding the toxic effects of NPs on the environment and human health is the biggest obstacle to the safe development of nanotechnology. However, little is known about their toxic mechanisms. The main important question is whether the indefinite hazard of engineered NPs particularly their environmental impact are compensating their recognized benefits for human daily life.

To fully understand and predict possible health effects following exposure to NPs, information about their physicochemical properties and NPs -living cell interactions are indispensable.

In this chapter, we have tried to collect, present and summarize recent studies from the literature on the effect of engineered NPs on living cells which may ultimately establish exposure standards and recommended handling practices to avert significant human health risks in the future. Better understanding these effects is essential to establish satisfactory regulatory policies on the safe use of NPs by human.

Currently successful application of NPs for therapeutic objects needs their effective uptake by the living cell. Hence, studying of the interaction between NPs and cell membrane for effective cellular uptake seems to be vigorous and imperative. Transferring of lipids, proteins, glucose, and other biomaterials into living cells is possible from two major exocytic and endocytic pathways. The penetration ability of NPs into the living cell must be considered in manufacturing nanotechnology of these particles. Enormous in vivo and in vitro experiments in the field of nanotechnology have confirmed the effect of physiochemistry properties in state of NPs /living cell interactions. Thus, the parameters directly related to physicochemical characteristics (e.g., size and shape) and biopersistence, or to specific interaction with biomolecules through their surface properties (e.g., surface chemistry and reactivity) or release of toxic ions have to be optimized through the preparation process or during the bio-tests for improving therapeutic effects of nanocarriers.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Besides, living cells exposed to NPs may undertake repairable oxidative stress and DNA damage or be induced into apoptosis. Exposure to NPs may cause the cells to alter their reproduction or differentiation or their cell-cell signaling with neighboring cells in a tissue. NPs are usually more toxic to some cell subpopulations than others, and toxicity often varies with cell cycle. All of these facts dictate that any nanotoxicity assay must be applied at the single-living cell level and try whenever viable to include one or many of other factors. Thus, focusing on one type of quantitative measure of nanotoxicity, is very promising to obtain more focused information about interaction between NPs and living cells.

Finally, it is our trust and recommendation that every nanoparticle-based product must be subjected to appropriate nanotoxicity tests and associated assessments before being used.

Chapter 54
Cyanobacterial Toxins in Water Sources and Their Impacts on Human Health

Zakaria Mohamed
Sohag University, Egypt

ABSTRACT

Cyanobacteria are a group of phytoplankton of marine and freshwaters. The accelerated eutrophication of water sources by agricultural and industrial run-off has increased the occurrence and intensity of cyanobacterial blooms. They are of particular concern because of their production for potent hepato-, neuro-, and dermatoxins, being hazardous to human health. Dissemination of knowledge about cyanobacteria and their cyanotoxins assists water supply authorities in developing monitoring and management plans, and provides the public with appropriate information to avoid exposure to these toxins. This chapter provides a broad overview and up-to-date information on cyanobacteria and their toxins in terms of their occurrence, chemical and toxicological characteristics, fate in the environment, guideline limits, and effective treatment techniques to remove these toxins from drinking water. Future research directions were also suggested to fill knowledge and research gaps, and advance the abilities of utilities and water treatment plant designers to deal with these toxins.

INTRODUCTION

Cyanobacteria are ancient prokaryotic microorganisms that have been in existence for at least 2.7 billion years and the first organisms to have released oxygen into the primitive atmosphere (Zanchett & Oliveira-Filho, 2013). Cyanobacteria were formerly regarded as blue-green algae because of the presence of chlorophyll a and performing oxygen-evolving photosynthesis in a manner very similar to algae. They occupy a broad range of habitats including freshwater, marine, terrestrial and even extreme niches such as hot springs. In aquatic ecosystems, cyanobacteria constitute the most important compartment in the food web, as they are one of the main primary producers of organic matter and serve as a food source for aquatic organisms. However, cyanobacteria become a problem only when they increase to excessive numbers forming water blooms under eutrophication conditions (high nutrient concentrations) along

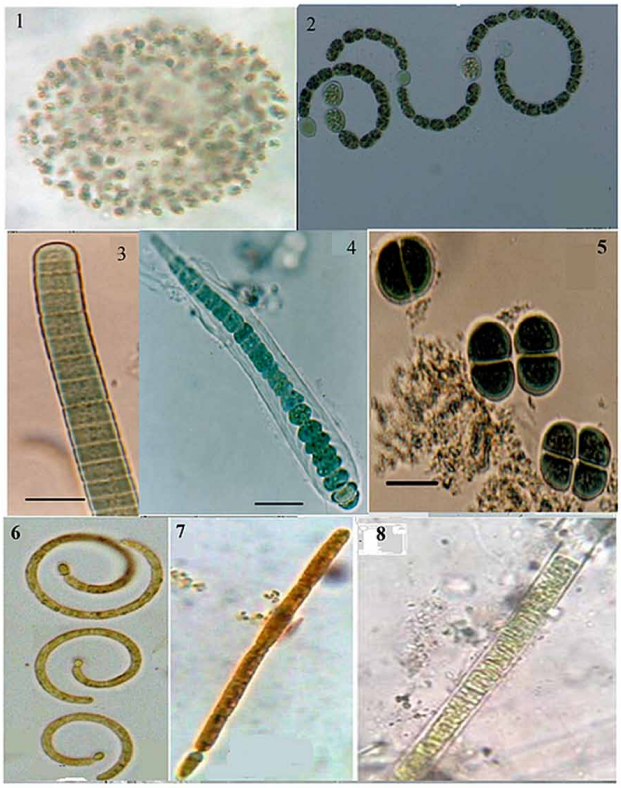
with suitable light and temperature. These blooms can also consume all of the oxygen in the water when they die and decompose, leaving a dead zone (hypoxia) where fish and other animals cannot survive (Diaz & Rosenberg, 2008). The hypoxic dead zone is typically found in the central basin of Lake Erie for decades (Zhu, Michalak, Beletsk, Rao, & Richards, 2015). Additionally, because many species of cyanobacteria are capable of producing potent toxins called cyanotoxins, these blooms are harmful and may lead to many negative environmental impacts such as mortality of domestic and wild animals, and unsustainability of the overall ecosystem. Cyanotoxins vary in their chemical structure and mode of toxicity in human including hepatotoxins, neurotoxins, and irritants and gastrointestinal toxins (Codd, Morrison, & Metcalf, 2005). These cyanotoxins may lead to a wide array of biological impacts on aquatic organisms, including: allelopathic effects on other phytoplankton (Suikkanen, Fistarol, & Granéli, 2004); suppression of zooplankton grazing, leading to reduced growth and reproductive rates and changes in dominance, toxic effects on fish and accumulation of toxins in tissues of invertebrates (Lehtiniemi et al., 2002) and fish (Mohamed, Carmichael, & Hussein, 2003). Furthermore, cyanotoxins are known to affect a number of processes in plants, and their presence in water used for irrigation may have considerable impact on the growth and development of crop plants (Wiegand & Pflugmacher, 2005). The exposure of edible crop and vegetable plants to cyanotoxins is also a concern for human health, as the toxins can accumulate in plant tissues and might be transferred into the food chain (Mohamed & Al-Shehri, 2010). Cyanotoxins are not easily removed by conventional treatment techniques as they are resistant to heat and most physico-chemical factors. Consequently, the presence of such potent toxins in water sources poses a risk to human health upon exposure to them. Additionally, *In vitro* and *in vivo* studies conducted by Zhou, Yu, & Chen (2002) and Svircev, Krstic, Miladinov-Mikov, Baltic, & Vidovic (2009) provided evidences that chronic exposures to low concentrations of the cyanotoxins contribute to the increased the risk for primary liver in China and Serbia and colon cancer development (Zegura, Volcic, Lah, & Filipic, 2008), as microcystin is mutagenic tumor promoter and inhibit DNA repair (Zegura, Straser, & Filipic, 2011). This chapter provides information on cyanotoxins and their human health risks in water sources because many water suppliers may have little understanding of how to manage them, particularly in rural communities and developing countries. This chapter covers six parts: section 1 introduces the occurrence of toxin-producing cyanobacteria in different water sources; section 2 presents the environmental factors promoting cyanobacterial blooms; section3 describes the human health impacts of cyanotoxins; section 4 presents the exposure routes to cyanotoxins; section 5 highlights management strategies and guideline levels of cyanobacteria and their cyanotoxins in the water sources; and finally section 6 sheds some light on the sustainability of cyanotoxins in the aquatic environment.

BACKGROUND ON OCCURRENCE OF TOXIN-PRODUCING CYANOBACTERIA



Cyanobacteria can be found in diverse environments including freshwater bodies, oceans and estuaries, extreme environments such as cold and hot springs, and Antarctic lakes (Taton et al., 2006; Mohamed, 2008). The ability of cyanobacteria to tolerate huge changes in salinity and temperature and survive low light intensity gives them an extremely large competitive advantage in these environments (Funari & Testai, 2008). Cyanobacteria can multiply rapidly in surface waters and form blooms when favorable conditions prevail, such as high temperature, intense light, high pH, and increased availability of nutrients, especially phosphorous and nitrogen, artificially released by anthropogenic activities (Funari & Testai, 2008). Blooms will persist in waters with temperatures between 15 and 30°C and pH levels

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

between 6 and 9, with maximum growth rates occurring at temperatures in excess of 25°C (Robarts & Zohary, 1987). Most, if not all, bloom-forming cyanobacteria in freshwater bodies are planktonic such as *Microcystis* spp., *Cylindrospermopsis raciborskii*, *Planktothrix rubescens*, *P. agardhii*, *Gloeotrichia* spp., *Anabaena* spp, *Aphanizomenon* spp. (Figure 1). Planktonic cyanobacteria can also be found in marine environments including *Trichodesmium* and *Nodularia*, which produce heavy toxic blooms during summer months (Charpy, Casareto, Langlade, & Suzuki, 2012).

In addition to planktonic cyanobacteria, benthic cyanobacteria can proliferate at the bottom of lakes, rivers and coastal waters forming dense mats near the shore. The presence of benthic cyanobacterial mats in water sources is of public concern as many studies reported that benthic cyanobacteria could produce hepatotoxins and neurotoxins (Catherine et al., 2013). Despite they have been linked to numerous animal deaths worldwide, there is a little information regarding the distribution, toxin production and species composition of toxic benthic cyanobacterial communities, compared to planktonic species. Cyanotoxins have been assigned for many benthic cyanobacterial species in both marine and freshwater ecosystems (Zanchett & Oliveira-Filho, 2013; Mohamed & Al-Shehri, 2015, Table 1). Toxic benthic species of cyanobacterial mats have been found in hot springs, a habitat characterized by harshness and extreme conditions. As most hot springs are accessible to the public worldwide, as recreational places for citizens and tourists and some are also used as cooking resources by rural communities, human exposure

Figure 1. Most common toxic cyanobacterial species: (1) Microcystis aeruginosa; (2) Anabaena sp.; (3) Oscillatoria sp.; (4) Calothrix sp.; (5) Chroococcus sp.; (6, 7) Cylindrospermopsis raciborskii; (8) Lyngbya majuscula.

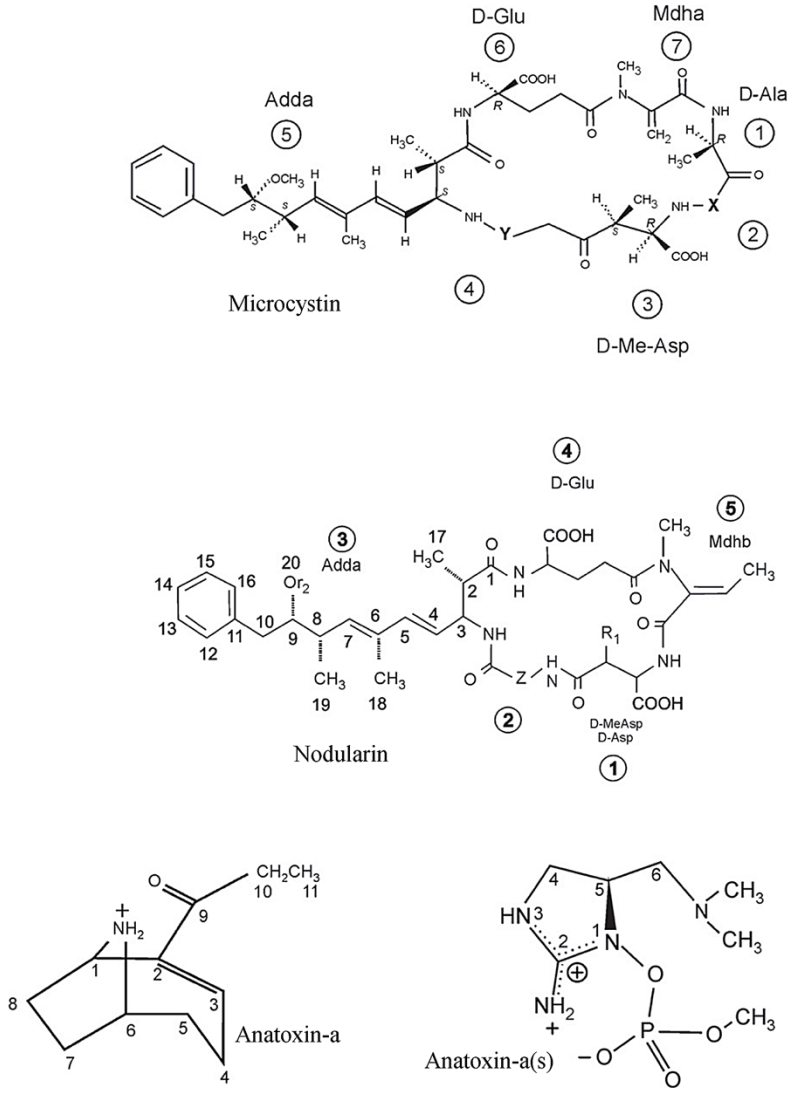
Table 1. Continued

Cyanotoxin	Chemical Nature	Producer	*I.P. LD_{50} (µg/kg b.w)	Target Organ	Mode of Action	Genotoxicity/ Carcinogenicity
Dermatotoxins						
Aplysiatoxins Debromoaplysiatoxin	Alkaloid	*Lyngbya, Oscillatoria, Planktothrix*	**107-117**	Skin	potent tumor promoters, acting through potentiation of protein kinase C (PKC)	Tumor promoter
Lyngbyatoxins	Alkaloid	*Lyngbya majuscula*	**300**	Skin, gastro-intestinal tract	potent tumor promoters, acting through potentiation of protein kinase C (PKC)	Tumor promoter
Gastrointestinal irritant toxins						
Lipopolysaccharide endotoxins	Lipopolysacch-aride	All cyanobacteria	**40-190**	Skin/ gastro-intestinal tract	Inflammatory agents,, gastroenteritis	Possible pro-carcinogenic

*I.P. LD50 = Intraperitoneal median lethal dose in microgram per kilogram of animal body weight



can easily occur (Mohamed, 2008). Toxin production has also been reported for epiphytic cyanobacteria on macrophytes in the aquatic environment, and caused the avian vacuolar myelinopathy (Wilde et al., 2014). These aquatic macrophytes provide ideal substrate for attachment of epiphytic toxic cyanobacteria, which may pose toxicological risk to marine organisms upon feeding on such toxic cyanobacteria or by the exposure to their potent cyanotoxins. Furthermore the invertebrates feeding on toxic cyanobacteria can act as vectors transferring cyanobacterial toxins to organisms at higher trophic levels in the food web. This leads to a potential poisoning of human populations that eat contaminated seafood from these areas. Therefore, epiphytic cyanobacteria should be considered when evaluating risk of harmful algae in fresh and marine water bodies in order to prevent possible adverse effects of their occurrence.

Depending on the human organ affected, the known cyanotoxins are categorized into hepatotoxins, neurotoxins, dermatotoxins, and gastrointestinal irritant toxins (Codd et al., 205; Figure 2, 3).

The hepatotoxins produced by cyanobacteria include cyclic peptides with 7 amino acids, microcystins (MCs) or with five amino acids, nodularin (NOD), and the alkaloid cylindrospermopsin (CYN). The cyanobacterial neurotoxins include the alkaloid anatoxins (ANTXs) and saxitoxins (STXs) and the non-protein amino acid β-methylamino-L-alanine (BMAA). Dermatotoxins produced by cyanobacteria include the indole alkaloid lyngbyatoxins (LTXs) and the bromophenol aplysiatoxins (APTXs) (Rzymski & Poniedziałek, 2012). The gastrointestinal irritant cyanotoxins are a structural constituent of the outer layer of gram negative prokaryotes including enteric bacteria and cyanobacteria, and composed of lipopolysaccharide (LPS) (Jann & Jann, 1984).

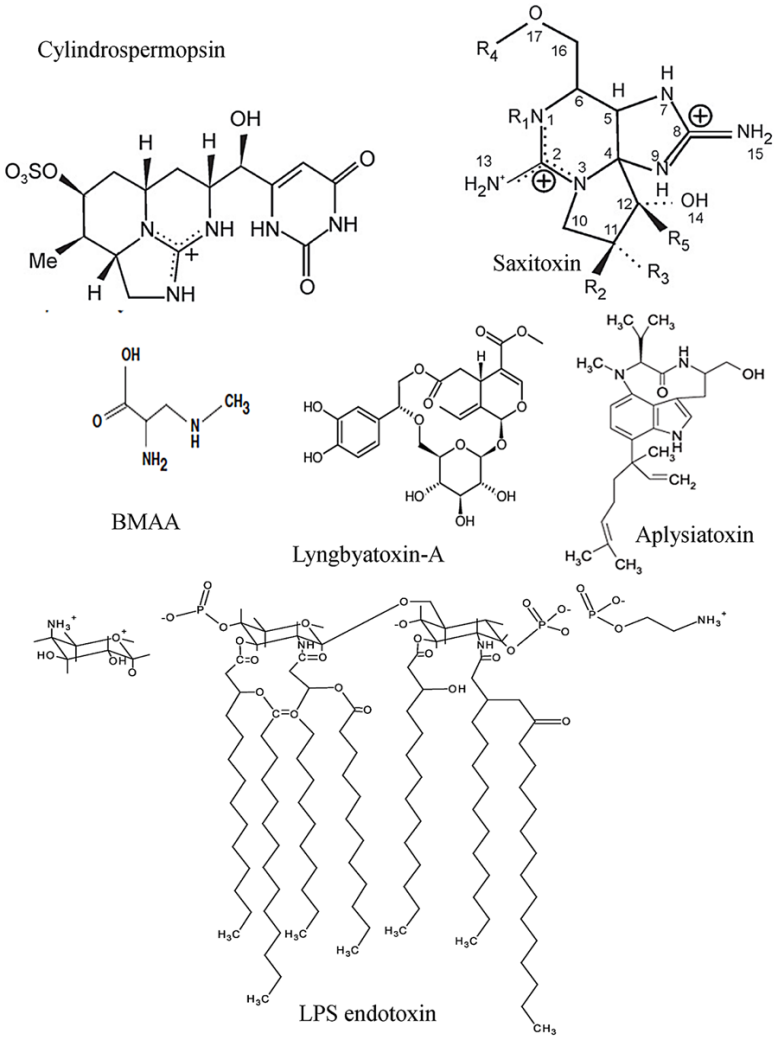
Figure 2. Chemical structure of some cyanotoxins produced by cyanobacteria



ENVIRONMENTAL FACTORS PROMOTING CYANOBACTERIAL BLOOMS

The growth and toxin production of cyanobacteria can be influenced by some environmental factors such as temperature, light intensity, pH, nutrients, and environmental pollutants (Neilan, Pearson, Muenchhoff, Moffitt, & Dittmann, 2013). However, the empirical modeling has shown that phosphorus, nitrogen and temperature are the most important drivers for cyanobacterial proliferation and harmful bloom formation (Beaulieu, Pick, & Gregory-Eaves, 2013). Over-enrichment of freshwater and marine ecosystems by nitrogen (N) and phosphorus (P) from anthropogenic activities (urban, agricultural, and industrial) promotes cyanobacterial growth and harmful bloom formation (Paerl, Hall, & Calandrino, 2011). However, it seems that the cyanobacterial growth depends largely on N:P ratio rather than concentrations of absolute N and P in the aquatic environment. Cyanobacteria successfully proliferate and form blooms

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 3. Chemical structure of some cyanotoxins produced by cyanobacteria

at high P concentrations and low N:P ratio. Lakes with cyanobacteria dominance have total nitrogen: total phosphorus (TN:TP) ratio <29:1 by mass, and lakes without such dominance have TN:TP>29:1 (Smith,1983). Eutrophic and hypertrophic lakes are usually characterized by lower N:P ratio, and thus dominated by cyanobacteria (Liu, Lu, & Chen, 2011). In addition to nutrients, high temperatures of surface water (> 20 ºC) favor cyanobacterial growth and bloom formation (Pearl & Paul, 2012). This implies that climate change, in particular global warming may promote the growth and the dominance of harmful cyanobacterial blooms (Paerl et al., 2011). This may occur through a variety of mechanisms including: warming of surface water, which exhibits optimal growth of cyanobacteria and lengthens the period of stratification leading to long-time buoyancy of cyanobacteria; intense precipitation and heavy rainfall increase enrichment of water bodies with land-derived nutrients through enhanced erosion surface runoff and groundwater discharge; and high evaporation leading to rising in salinity of freshwaters systems, which allows for the expansion of salinity-tolerant cyanobacteria into brackish waters, and causes

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

leakage of cells of non-tolerant cyanobacteria and the release of their cyanotoxins (Paerl et al., 2011). Besides their effects on cyanobacterial growth, some environmental factors such as nutrient concentration, light intensity, and temperature could also affect cyanotoxins production (Paerl & Paul, 2012; Holland & Kinnear, 2013). These effects vary among environmental parameters and types of cyanotoxins. For instance, anatoxins production was found to increase with nutrient limitation, light, temperature, and not related with cell growth, but microcystin production is associated with growth rate (Boopathi & Ki, 2014). Furthermore, environmental factors could regulate cyanotoxin production at molecular level (Neilan et al., 2013; Boopathi & Ki, 2014), as many strains have the capability to turn certain genes on or off depending upon environmental conditions (Merel et al., 2013). This means that strains with and without the genetic potential for cyanotoxin production may co-occur in natural systems at the same time.

HUMAN HEALTH IMPACTS OF CYANOTOXINS

Cyanotoxins vary widely in their chemical nature and structure, toxicity, mode of action and organ affected (Codd et al., 2005). Most of the hepatotoxins, MCs and NOD are water-soluble and stable molecules (Sivonen & Jones1999), bind to and inhibit protein phosphatases 1 and 2A (MacKintosh, Beattie, Klumpp, Cohen, & Codd, 1990), leading to the accumulation of phosphorylated proteins in the liver, cell necrosis, massive hemorrhage and death, depending on the dose. Human intoxication by MCs has been demonstrated by many authors in different countries. For instance, over 50 dialysis patients died after exposure to dialysate prepared from microcystin-contaminated drinking water derived from surface sources in Brazil (Carmichael et al., 2001). Lévesque et al. (2014) documented a relationship between gastrointestinal symptoms and contact of residents who receive their water from a plant equipped with a full treatment system whose source is highly contaminated by cyanobacteria and microcystins in Canada. High incidence of primary liver cancer was associated with the consumption drinking water contaminated with cyanobacterial toxins in China (Svircev et al., 2009). However, no human intoxication of NOD has been reported so far, and no guidelines have been proposed for drinking water due to the lack of suitable toxicological data. The alkaloid hepatotoxin, CYN is highly polar compound and mainly impacts the liver via the irreversible inhibition of protein synthesis with LD_{50} of 2100 µg/kg in mice, 24 h after i.p. injection (van Apeldoorn, van Egmond, Speijers, & Bakker, 2007). However, CYN exposure can also lead to fetal toxicity and tumor initiation (Falconer & Humpage, 2001). The hepatotoxicity of CYN to human has been shown in Australian and Brazilian (Carmichael et al., 2001; Griffiths & Saker, 2003). In addition to acute toxicity, cyanobacterial hepatotoxins may also bring genotoxicity and carcinogenicity upon exposure to low toxin levels (Table 1). This should be taken into consideration in toxicity assessment, especially in case of the toxins of long persistence in water, such as MCs. As MCs and NOD are inhibitors of protein phosphatases, they may affect activity of DNA-dependent protein kinase that is the key enzyme involved in the non-homologous end joining (NHEJ) of radiation induced DNA strand breaks (Lankoff, Wojcik, Fessard, & Meriluoto, 2006). This means that MCs are genotoxic and can act as tumor initiators. Genotoxicity of cyanobacterial extract and MCs has been studied *in vitro* and *in vivo* in different mammalian test systems (Zegura et al., 2011). Most studies have reported that the genotoxic activity of MCs is mediated by induction of reactive oxygen species (ROS) formation, leading to the formation of DNA strand breaks and mutagenic oxidative DNA lesions. MCs have also been shown to inhibit DNA repair pathways, which is a very important factor involved in carcinogenesis (Douglas, Moorhead, Ye, & Lees-Miller, 2001). NOD also can induce oxidative DNA

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

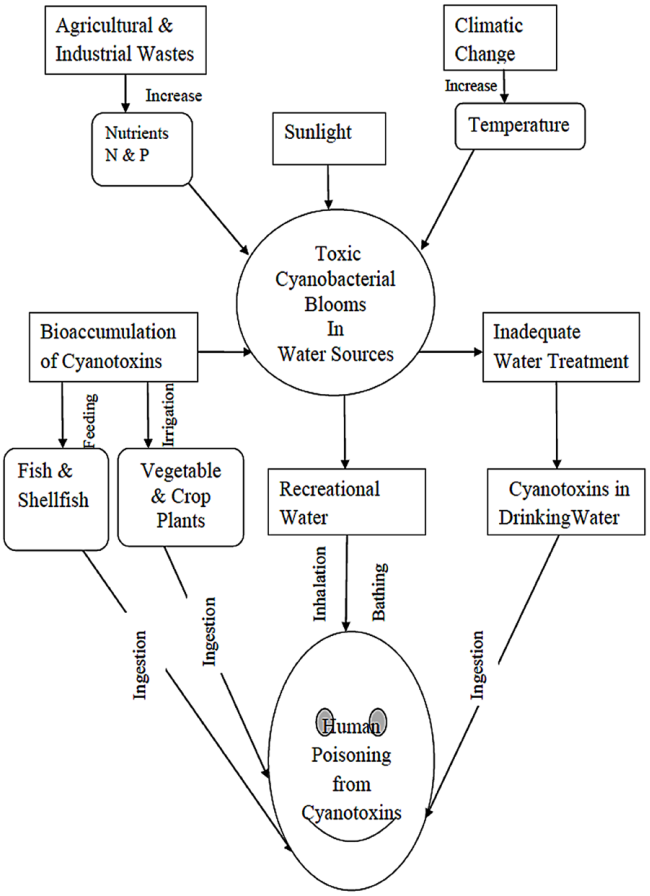
damage and apoptosis in HepG2 cells, leading to genetic alterations and carcinogenesis (Lankoff et al. 2006). CYN induced micronuclei formation in human liver-derived HepG2 cells along with nuclear bud and nucleoplasmic bridge formation, with the cytokinesis block micronucleus assay after 24 h exposure to 0.05 and 0.5 μg CYN ml^{-1} (Straser, Filipič, & Žegura, 2011). It can also induce DNA strand breaks in human HepG2 cell line (Straser et al., 2011), and in human peripheral blood lymphocytes (Zegura et al., 2011) after exposure to lower CYN concentrations. Furthermore, the carcinogenic potential of CYN was investigated *in vitro* using Syrian hamster embryo (SHE) assay at very low concentrations (Maire et al., 2010). However, evidence of carcinogenic potential of CYN *in vivo* is limited, with only one study reporting tumors in 5 mice out of 53 who were orally dosed with cell-free extracts of cylindrospermopsin producing *C. raciborskii* (Falconer & Humpage 2001).

Cyanobacterial neurotoxins affect the nervous systems in different mechanisms. ANTX-a binds to acetylcholine receptors and remains available to overstimulate muscle, being degraded by acetylcholinesterase (Osswald, Rellán, Gago, &Vasconcelos, 2007). Consequently, death can occur by respiratory arrest when muscles involved in breathing activity are affected. ANTX-a is very toxic with LD_{50} of 375 μg/kg leading to death within 24 hours after i.p. injection in mice (Table 1). Anatoxin-a (S) inhibits acetylcholinesterase and induces muscular paralysis with potential death by respiratory arrest (Molica et al., 2005). It is a highly toxic with LD_{50} of 20 μg kg^{-1} body weight (mouse ip) (Table 1). ANTXs have caused poisoning for various animals e.g. sheep, birds dogs and cattle (Krienitz et al., 2003; Wood et al., 2007), but no human poisonings have yet been reported. STXs block sodium ion channels in nerve axon membrane and induce nerve dysfunction, paralysis then death due to respiratory failure (van Apeldoorn et al., 2007). The LD_{50} of the most toxic variant in mice is 10 μg/kg after i.p. injection (Table 1). Cases of human poisoning were mostly associated with consumption of STX-positive shellfish (van Apeldoorn et al., 2007). However, no intoxication through drinking water has been documented so far. BMAA is structurally similar to glutamate and binds to glutamate receptors, causing toxicity to neurons *in vitro* at concentrations as low as 10–30 nM (Lobner, Piana, Salous, & Peoples, 2007). BMAA has been linked to neurodegenerative diseases such as Alzheimer's disease, Parkinson's disease, and Amyotrophic Lateral Sclerosis (ALS) (Pablo et al., 2009). The implication of BMAA in these diseases was supported by the detection of this toxin in the brains of Chamorro patients with ALS/PDC (Pablo et al. 2009), and in brains from North American ALS, Parkinson's disease, and Alzheimer's disease (Murch, Cox, Banack, Steele, & Sacks, 2004). Recently, Banack et al. (2015) have demonstrated the presence of BMAA in aquatic food web and in aerosol samples from a lake adjacent to an area of previously documented high ALS incidence. This indicates that BMAA toxin may transfer through aquatic organisms and reaches to human via food intake. Despite the acute toxic effects of cyanobacterial neurotoxins have been studied extensively, there is nearly no information regarding the genotoxicity or carcinogenicity of these toxins to human. However, some *in vitro* studies reported the possible genotoxic effects of ANTX-a, and STXs (Sieroslawska & Rymuszka, 2010; da silva et al., 2014). No data are available yet for the genotoxicity and carcinogenicity of BMAA toxin.

LTXs are slightly lipophilic, penetration through human skin after 1 h of exposure to 26 μg cm^{-2}. They are potent skin irritants and cause a condition known as Swimmer's Itch off Oahu, Hawaii. They exert this activity through potent activation of protein kinase C (PKC). Direct contact with APTXs contaminated water caused acute skin irritation, rashes and blisters (Osborne, Webb, & Shaw, 2001). LTXs and APTXs can also be carried by wind in an aerosolized form and cause a health risk for people not exposed to water (Rzymski & Poniedziałek, 2012). LTXs can also accumulate in tissues of aquatic organisms upon feeding on *L. majuscula* being a source of food as sea turtles *Chelonia mydas* (Ysaumoto,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

1998). Consumption of such products, as well as ingestion of water containing lyngbyatoxin leads to inflammation of the esophagus and digestive tract (Ysaumoto, 1998). APTXs and LTXs are also potent tumor promoters through the activation of protein kinase C (van Apeldoorn et al., 2007).



Cyanobacterial LPS endotoxins are heat stable and toxic to mammals. LPS endotoxins exposure has been associated with local effects due to direct contact, such as skin or eye irritation, gastrointestinal problems or allergic reactions (Rzymski and Poniedziałek, 2012). No genotoxic effects have been assigned yet with cyanobacterial lipopolysaccahride endotoxins.

EXPOSURE ROUTES TO CYANOTOXINS

Generally, humans may be exposed to cyanotoxins through different routes: drinking water, recreational water and food consumption (Figure 4).

Humans are exposed to cyanotoxins through drinking water, depending on their concentrations in raw surface water and the effectiveness of treatment methods for removing cyanobacteria and cyanotoxins. However, rural communities in developing countries using untreated surface waters will be exposed to

Figure 4. Schematic representation for bloom formation and possible exposure routes to cyanotoxins

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

both cell-bound and dissolved cyanotoxins. Depending on cyanotoxin levels in drinking water, both acute/short-term and chronic effects in humans may occur (Chorus & Bartram, 1999). Cyanotoxin concentrations in surface waters vary in a very wide range of values, from trace to several milligrams per liter, being strongly influenced by the occurrence and amount of biomass (Funari & Testai, 2008). For instance, MC concentrations of 10–350μg L^{-1} have been reported in surface waters in Germany (Fastner et al., 1999), but much higher levels (up to 25,000μg L^{-1}) were recorded elsewhere (Sivonen & Jones, 1999). Total CYN and anatoxin-a(s) concentrations up to 12.1 and 3300μg L^{-1} have been determined in surface waters (Sivonen & Jones, 1999; Rucker et al., 2007). STXs have been detected in high concentrations in Australia (2,040–3,400 μg g^{-1}) (Negri, Jones, Blackburn, Oshima, & Onodera, 1997). Recreational activities can also represent a source of exposure to cyanobacteria and their cyanotoxins through direct contact, inhalation, and/or ingestion (Funari & Testai, 2008).

Besides their presence in drinking water, cyanotoxins may accumulate in some aquatic organisms such as fish, bivalves, snails, and other macroinvertebrates, via ingestion of cyanobacteria cells or via the transdermal route for dissolved toxins (Li, Chung, Kim, & Lee, 2004). Crop and vegetable plants can also accumulate cyanotoxins in their edible parts such as leaves, roots, fruits, when surface water bodies containing cyanobacteria are used for irrigation (Mohamed & Al-Shehri, 2009). Cyanotoxin accumulation in such food organisms and edible vegetable plants may pose a risk to human health, upon consumption of such contaminated food. Therefore, Information on cyanotoxin concentrations accumulated in these animals and plants is very important for risk assessment and derivation of safe guideline levels. In this respect, significant levels of MCs have been detected in aquatic organisms at maximum concentrations of 370, 2700 and 16 000 µg kg^{-1} have been reported in the edible parts of fish, crustaceans, and mussels, respectively (Table 2). CYN can also accumulate in edible tissues of aquatic organisms, including invertebrates and vertebrates at concentrations ranging from 0.8-103 ng/g (Berry, Jaja-Chimedza, Davalos-Lind, & Lind, 2012; Table 2). Bioaccumulation of cyanobacterial neurotoxins (ANX-a, STXs, BMAA) has also been reported in marine and freshwater seafood animals at considerable concentrations (Sephton, Haya, Martin, Legresley, & Page, 2007; Mondo et al., 2012; Table 2).

The available data on the accumulation of cyanotoxins in crop and vegetable plants revealed that MCs are, by far, the most commonly reported (Table 3). MCs were detected in several plants destined for human and animal consumption such as ryegrass (*Lolium perenne*), clover (*Trifolium repens*), rape (*Brassica napa*), lettuce (*Latuca. sativa*), radish (*Raphanus sativus*), arugula (*Eruca sativa*), dill (*Anethum graveolens*), parsley (*Petroselinum hortense*), cabbage (*Brassica oleracea*) and fruits of *S. lycopersicum* and *C. annuum plants* (Crush, Briggs, Sprossen, & Nichols, 2008; Mohamed & Al Shehri, 2009; Romero-Oliva, Contardo-Jara, Block, & Pflugmacher, 2014). MCs concentrations accumulated in these plants ranged from 70 to 1450 ng g^{-1} (Table 3), which may exceed the WHO limit proposed for this toxin (µg L^{-1}) (WHO, 1998) depending on the amount consumed. MCs were also detected in water chestnut and rice grains but at low concentrations ((Xiao et al., 2009; Chen, Han, Wang, Zhang, & Shi, 2012). For other cyanotoxins, there is only one study on CYN accumulation (maximum, 49 µg g^{-1}) in the leafy components of some cruciferous vegetables (e.g. *Brassica* spp., *Sinapsis alba*) (Kittler et al., 2012), but no available data on the accumulation of ANTXs, STXs, LTXs and LPS toxins in vegetable or crop plants.

SOLUTIONS AND RECOMMENDATIONS: MANAGEMENT STRAEGIES AND GUIDELINE LEVELS

Water suppliers and authorities in different countries have developed monitoring and management strategies to mitigate problems presented by cyanobacteria and their cyanotoxins in drinking and recre-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

ational waters (Chorus, 2012). Generally, the management of cyanobacterial blooms and cyanotoxins in surface water includes three levels: bloom prevention, management of the source water or reservoir, and treatment to remove cyanobacteria or their toxins. The best approach for prevention of cyanobacterial bloom formation is decreasing the inputs of nutrients in agricultural and industrial wastes into surface water (Paerl et al., 2011). The concentration of these nutrients, particularly nitrogen and phosphorus is a key factor in promoting bloom formation and eutrophication of surface waters worldwide (Merel et al., 2013). Bloom monitoring and management in the source water is another option to reduce the levels of cyanobacteria and their cyantoxins. For drinking water sources, the most common monitoring and management action is the development of an Alert Levels Framework (ALF). These alert levels are defined by the determination of cyanobacterial cell numbers, cell biovolume or chlorophyll-a concentration. Although some countries have developed their own ALFs, most countries adopted the ALF released by WHO (Chorus & Bartram, 1999). The WHO alert level framework consists of three levels to be followed when cyanobacteria are detected in the water source during routine monitoring. During vigilance level (low cyanobacterial cells), regular surveillance and monitoring occurs weekly. Alert level 1 is activated, when greater than 2000 cyanobacteria cells mL^{-1} or 1 μg/L chlorophyll a is detected. At this alert level, an increase in monitoring frequency (daily), toxin analysis and consultation with health authorities occurs. Alert Level 2 is triggered when cyanobacterial cell concentration are more than 100,000 cells mL^{-1} or 50 μg L^{-1} chlorophyll a, and toxin level is higher than 0.8 μg L^{-1}. At this level the WHO suggests that an alternative water supply may be needed. But other alert level frameworks such as the ALF of South Africa (Du Preez &Van Baalen, 2006) suggested treatment optimizations, continuous monitoring of cyanobacteria and cyanotoxins, mouse test bioassay, and response committee meetings at alert level 2. The sequence can then move to a higher alert level, Alert level 3 when mouse bioassay is positive and toxin concentration is higher than 2.5 μg L^{-1}. The main actions at alert level 3 are the daily monitoring of cyanobacteria and cyanotoxins, optimization of treatment process, and communication with governmental departments. Finally, alternative drinking water should be supplied when the microcystin concentration in the drinking water is between 2.5 and 5 μg L^{-1} for eight consecutive days or exceeds 5 μg L^{-1} for two consecutive days.

For managing cyanobacteria in recreational water, WHO (2003) suggested 3 guideline levels: low level of 20 000 cyanobacterial cells ml^{-1} (10 μg L^{-1} chlorophyll-a, with dominance of cyanobacteria and MC < 10 μg L^{-1}) which corresponds to a low probability of adverse effects; moderate level of level of 100 000 cyanobacterial cells ml^{-1} (50 μg L^{-1} chlorophyll-a, with cyanobacteria dominance and MC =10-20 μg L^{-1}) which corresponds to a moderate probability of adverse effects ; and high level of more than 100,000 of total cyanobacterial cells mL^{-1} OR > 50 μg L^{-1} chlorophyll-*a* with dominance of cyanobacteria and MC > 20 μg L^{-1}) which corresponds to highest risk of adverse effects and immediate action should be taken to prevent totally swimming and other water contact activities.

In addition to alert level frameworks for managing toxic cyanobacteria, some countries established guidelines values for the presence of cyanotoxins in drinking water supplies for human health protection (Table 4). These guideline values were derived from the available toxicological data of these toxins based on animal studies, particularly, the identification of an acute NOEL, which is the highest dose at which no effects are observed. For instance, WHO (1998) established a provisional guideline of 1 μg L^{-1} for MC- LR in drinking water (WHO 1998) using a subchronic NOEL of 40μg/kg bw/day obtained upon orally administration of mice with MC-LR (Fawell, Hart, James, & Parr, 1993). Guideline levels for other cyanotoxins were also released by authorities in different countries including Australia, Canada and New Zealand (Table4).

Table 4. Guideline values estimated for cyanotoxins in drinking and recreational waters

Cyanotoxin	Drinking Water ($\mu g\ L^{-1}$)	Recreational Water ($\mu g\ L^{-1}$)
Cyanobacterial cells (Australia)	6500 cells ml^{-1}	(WHO) 20000 cells ml^{-1}
MCs (WHO)	1	20 (Canada)
NOD (NewZealand)	1	ND
CYN (Australia)	1	4.5 (Washington)
ANTX-a (NewZealand)	6	1 (Washington)
ANTX-a(s) (NewZealand)	1	ND
STX (NewZealand)	3	7.5 (Washington)
MMBA	ND	ND
Aplysiatoxins	ND	ND
Lyngbyatoxins	ND	ND
LPS	ND	ND

ND, Not determined; the word in parentheses refers to the country who derived the guideline
(Adapted from Chorus, 2012)

For cyanotoxins in food, some countries calculated guideline values (GV) for the maximum tolerable concentration of most common cyanotoxins in aquatic animals and edible plants by using NOEL from the available literature data and on the basis of assumptions for body weight (bw), the amount of food ingested (C) and a factor for the relative allocation of toxin intake to that food (Allocation Factor, AF) (Ibelings & Chorus, 2007). However, it is not prudent to generalize and use these guidelines worldwide, as the major factors contributing to human exposure to cyanotoxins through food consumption are variable. For instance, it has been found that different species of fish accumulate different amounts of cyanotoxins, and the same fish species can accumulate higher amount of toxins when they are found in heavy toxic cyanobacterial blooms. Additionally, the tolerable daily intake (TDI) of these toxins depends on the relative of importance of food as a source of exposure and the amount consumed. Finally, the allocation factor (AF) depends also on the share of this food in the diet of a given country population. Therefore, different countries are advised to derive their own guideline values of cyanotoxins in edible food (animals or plants) according to the local conditions.

Cyanotoxin Removal and Treatment Efficiency

As prevention of cyanobacterial bloom formation in drinking water resources is a long term solution, drinking water treatment option should be adopted by companies and authorities to protect consumers from exposure to such potent cyanotoxins. Drinking water treatment plants usually apply different processes to remove both cyanobacterial cells and dissolved cyanotoxins (Pantelic, Svircev, Simeunovic, Vidovic, &Trajkovic, 2013; Table 5). The effectiveness of a water treatment system differs according to many factors including the types and properties of cyanotoxins (e.i. hydrophobicity/ hydrophilicity and intracellular/extracellular), and species of cyanobacteria dominated in the source water (Westrick, Szlag, Southwell, & Sinclair, 2010). Applying the wrong treatment process at a specific treatment stage could lyse cells and result in the release rather than removal of cyanotoxins. Generally a treatment system removing intact cells without lysis and toxin release is the most efficient treatment approach (Westrick et al., 2010). There are conventional and advanced oxidation treatment options available for the removal of cyanobacteria and their cyanotoxins during drinking water treatment. Conventional technologies in-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Table 5. Effectiveness of most common treatment methods for removal of intact cyanobacteria cells and dissolved toxins (Adapted from Pantelic et al. 2013)

Treatment Method	Cells/ Intracellular Toxins	Extracellular Toxins	Remarks
Pre-treatment oxidation	Cell lysis	Not effective	Enhance coagulation, but lead to toxin release
coagulation/ sedimentation	>90%	Not effective	Efficient for cell removal but may lead to cyanotoxin release.
Slow sand filtration	< 86%	Low effective	Effective for cell removal, but its removal for dissolved toxins depends on bacteria found on the filter, sometimes lead to toxin release
Rapid sand filtration	low	Not effective	Not effective for cell removal or extracellular toxins, and may lead to toxin release
UV Radiation	Cell lysis	Effective	Able to degrade MCs, ANTX-a, and CYN, but at impractically high doses.
Chlorination	Cell lysis	Effective	Effective for oxidation MCs, CYN and STXs, free chlorine is >0.5 mg L^{-1} after >30 min at pH < 8 and low DOC, but not effective for ANTX-a oxidation
Ozonation	Cell lysis	Effective (> 98%)	Effective for degradation of MCs, ANTX-a, CYN and STXs. Effectiveness decreases at lower temperatures and high organic matter., may lead to cell lysis and toxin release
Potassium Permanganate	Cell lysis	Effective (95%)	Effective for oxidizing MCs and ANTX-a, but in absence of the whole cells.
Activated Carbon	>60%	Effective (85-95%)	Powdered activated carbon of wood origin is the most effective type for removal of MCs, ANTX-a and CYN. Granular activated carbon is effective for MCs but less effective for ANTX-a and CYN
Membranes	>96%	Effective.	Micro- and ultrafiltration are effective in removing intact cyanobacterial cells. Dissolved toxins MCs, CYN, NOD, ANTX-a are removed by nanofiltration and reverse osmosis. Membranes may be clogged leading to cell lysis and toxin release

clude coagulation, sand filtration, chlorination and activated carbon adsorption; and advanced oxidation technologies are ozonation, UV photolysis, Fenton oxidation and sonolysis (Xagoraraki, 2007). In this section, we will shed the light on the effectiveness and drawbacks of most common technologies used for removing both cyanobacterial cells and cyanotoxins (Table 5).

Pre-Oxidation

The pre-oxidation process by chlorine or ozone aims to improve and enhance the efficiency of next treatment steps, particularly coagulation. Although pre-oxidation may reduce taste, odor compounds, zebra mussels and other contaminants, it damages the membrane of cyanobacteria and induces cell lysis leading to the release of intracellular toxins (Miao & Tao, 2009). Furthermore, pre-oxidation result in the production of harmful by-products e.g. trihalomethanes (Merel et al., 2013). Therefore pre-oxidation should be avoided when a bloom occurs in drinking water resources.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Coagulation–Flocculation–Sedimentation

Coagulation is the aggregation of cells using chemicals (i.e. ferric chloride or aluminum sulfate) into larger particles flocs) subsequently removed by sedimentation. This is the first step in conventional drinking water treatment. This process is only efficient for eliminating cyanobacterial cells from water, but dissolved cyanotoxins (i.e. extracelllar toxins) are not efficiently removed by this method (Teixeira & Rosa, 2007). Efficiency of coagulation process is dependent on pH values and chemical doses (Mouchet & Bonnelye, 1998). The presence of natural organic matter (NOM) in surface waters may result in lower cyanobacterial removal efficiencies (Ma &Liu, 2002). Coagulation can remove up to 90% of cyanobacterial cells and intracellular MCs (Xagoraraki, 2007). But, sludge containing toxic cyanobacterial cells can break down rapidly (within 24 h) and release dissolved MCs into the aqueous phase toxin (Drikas, Chow, House, & Burch, 2001). Therefore, sludge should be quickly removed from the treatment process.

Sand Filtration

Rapid sand filtration is usually used after coagulation to remove the particles. Rapid filtration is not effective method for removal of cyanobacterial cells and extracellular cyanotoxins (Ho et al., 2006). Conversely, slow sand filtration and riverbank filtration were shown to remove both cyanobacteria and their toxins (85% to 99%) during water treatment (Mohamed, El-Sharouny, & Ali, 2007). However, this process requires regular and careful backwashing of the filters to avoid lysis of cyanobacterial cells and release of cyanotoxins into the water (Chorus & Bartram, 1999). Moreover, microorganisms growing on the upper layer of sand filters efficiently degrade cyanotoxins (Edwards, Graham, Fowler, & Lawton, 2008). Biodegradation has now been suggested as a promising alternative for the removal of cyanotoxins in drinking water treatment (Merel et al., 2013).

Membrane Filtration

Membrane filtration processes can efficiently remove cyanobacteria and their toxins, depending on the membrane employed (i.e. microfiltration (0.1–10 μm), ultrafiltration (1–100 nm), nanofiltration (1 nm) and reverse osmosis (0.1 nm). Microfiltration and ultrafiltration membranes were effective for cell removal, but they may not be able to retain dissolved cyanotoxins, particularly toxins with small molecular weight (Westrick et al., 2010). As any filtration technique, microfiltration and ultrafiltration membranes may be clogged, and cell lysis and toxin release will occur. On the other hand, extracellular cynaotoxins such as MCs, CYN, NOD, ANTA-a have been shown to be removed by nanofiltration and reverse osmosis at a range of 90-100% (Pantelic et al., 2013). However, use of membrane filtration is expensive and filtered water may need subsequent re-mineralization due to the high retention potential of nanofiltration and reverse osmosis.

Activated Carbon

Activated carbon is usually used in two forms in drinking water treatment: powdered (PAC) to perform adsorption simultaneously with clarification, or granulated (GAC) to perform adsorption in percolation units (Westrick et al., 2010). Activated carbon adsorption was found to be effective in removing extracellular MCs, CYL, ANTX-a and STXs from drinking water (Pantelic et al., 2013; Table 5). The removal

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

of cyanotoxins by activated carbon mostly depends on the kind of adsorbent employed and the type of cyanotoxin (Newcombe & Nicholson, 2004). For instance, MCs can be efficiently adsorbed on mesporous adsorbents (pore diameter = 2–50 nm), but other cyanotoxins such as STXs are well adsorbed on microporous instead of mesoporous carbon, being smaller than MCs (Newcombe & Nicholson, 2004). PAC is effective in cyanotoxin retention providing up to 85% removal of extracellular MCs and about to 98% removal of extracellular ANTX-a (Alvarez, Rose, & Bellamy, 2010). GAC was found to remove up to 95% of extracellular MCs and ANTX-a (Xagoraraki, 2007), but it takes place slowly and needs more than 12 h exposure for complete removal of MCs (Lee, Kim, Cho, Kim, & Kim, 2004). Although its effectiveness for cyanotoxin removal, activated carbon is not always a very efficient method, due to its short lifetime of adsorption and the need to be changed frequently, increasing the treatment costs (Haider, Naithani, Viswanathan, & Kakkar, 2003).

Chemical Inactivation and Degradation of Cyanotoxins

Some advanced oxidation technologies such as oxidants, catalysts and radiation have been adopted for the destruction of cyanotoxins. The efficiency of the oxidative agent in cyanotoxins oxidation depends on the type of toxins present, the concentration of released toxins, the water quality and the contact time (Zamyadi et al., 2010). UV irradiation is effective in destroying MCs, ANTX-a and CYL from drinking water (He et al., 2012; Table 5). However, this degradation occurs at higher doses (1,530 and 20,000 mJ/cm2) than practicable required (10 and 40 mJ cm^{-2}) for disinfection, making it a not viable treatment for these cyanotoxins (Westrick et al., 2010). Chlorination has been shown as an effective mechanism for the cyanotoxins MCs and NOD as well as CYL and STXs (Merel, Clément, & Thomas, 2010). However, Inactivation of cyanotoxins by chlorine is usually pH-dependent because the pKa of hypochlorous acid is 7.6. For instance, chlorination is efficient for inactivation of MCs at pH <8.0, and CYN at pH 6-9, (Merel et al., 2010). SXTs inactivation by chlorination has improved from 20% to 98% when pH increases from 4 to 9 (Nicholson et al., 2003).The inactivation of ANTX-a by chlorine is not effective (Rodriguez et al., 2007). Ozonation is very effective for destruction of intracellular and extracellular cyanotoxins. Ozone can degrade MCs, even at extremely high concentrations of the toxin (Miao et al., 2010) at pH <7, but not effective at pH7 (Alvarez et al., 2010). Inactivation of ANTX-a and CYN by ozone is pH-dependent and is effective at pH 7-10, and pH 4-10, respectively (Westrick et al., 2010). Both chlorination and ozonation of cyanotoxins may be affected by the presence of organic matter. Additionally, oxidant dose or the residual oxidant level required for complete toxin oxidation is a key factor for water quality and treatment issues. KMnO4 is effective in oxidizing microcystin and anatoxin-a (from pH 6 to 8), but is not very reactive with CYN or STXs (Pantelic et al. 2013). Although The use of permanganate does not release intracellular cyanotoxins (Ho, Tanis-Plant, Kayal, Slyman, & Newcombe, 2009), it leads to the formation of particulate manganese dioxide in solution which can cause potential problems in treated drinking water (Lahti et al., 2001).

SUSTAINABLITY OF CYANOTOXINS IN THE AQUATIC ENVIROMENT

Cyanotoxins are produced within cyanobacterial cells (i.e. intracellular), and released into the ambient environment during cell senescence, death and lysis (Chorus &Bartram, 1999). The release of cyanotoxins from the cells is enhanced by chemical treatment for eradication of cyanobacteria, particularly

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

pre-chlorination and algicide application (Jones & Orr, 1994). Once released into the water, cyanotoxins can persist for a relatively long period before being removed through various processes naturally occurring in the environment such as photochemical degradation by UV, adsorption in particles in suspension or onto sediments, and biodegradation (Corbel, Mougin, & Bouaicha, 2014). However, cyanotoxins differ greatly in their chemical stabilities in the environment. MCs and NOD, being cyclic peptides are extremely stable and persistent to chemical breakdown. These toxins can persist in the aquatic environment for weeks (Edwards et al., 2008) and sometimes several months (Harada, Tsuji, Watanabe, & Kondo, 1996). The photodegradation of MCs in full sunlight occurs slowly and is enhanced by the by the presence of cell pigments (Welker & Steinberg, 2000). It can last for 2- 6 weeks, depending on the pigment concentration. The photodegradation of MCs and NOD is high in the presence of humic substance (Thirumavalavan, Hu, & Lee, 2012), and low in deep and muddy waters of lakes due to low radiation penetration (Wormer, Huerta-Fontela, Cires, Carrasco, & Quesada, 2010). CYN is also relatively stable in the dark, but it is rapidly degraded under sunlight and in the presence of cell pigments (Chiswell et al., 1999). ANTX-a is stable in the dark, but it undergoes rapid photochemical degradation ($t_{1/2}$ = 1-2 h) in sunlight under alkaline conditions, even in the absence of cell pigments (Smith & Sutton, 1993) in the laboratory. STXs undergo slow chemical degradation in the dark at room temperature with a half-life of 1-3 months (Chorus & Bartram, 1999). Cyanotoxins can also be removed by adsorption on suspended particles or sediments in aquatic environment (Corbel et al., 2014). Some studies reported that about 20% of toxins can be adsorbed on sediments (Lahti, Kilponen, & Kivimaeki, 1996). Moreover, it was suggested that the removal of cyanotoxins by this process is not only due to adsorption but also to biodegradation by bacteria present in sediments (Lahti et al., 1996). Therefore, sediments may play a crucial role in cyanotoxin biodegradation by supplying toxin-degrading bacteria to the water column (Chen et al., 2010).

Many studies reported the degradation of MCs by different species of aquatic bacteria e.g. *Sphingomonas, Paucibacter, Burkholderia* sp., *Methylobacillus, Arthrobacter, Bacillus*, and *Lactobacillus (*Kormas & Lymperopoulou, 2013). MC degradation is regulated by *mlr* gene cluster consisting of four genes (*mlrA, mlrB, mlrC*, and *mlrD)* which codes for at least three intracellular enzymes (Bourne, Riddles, Jones, Smith, & Blakeley, 2001). This gene cluster was identified and sequenced in all MC-degrading bacteria. MC removal by biodegradation can be >90% within 2–10 days depending on the water body, initial MC concentration and water temperature (Park et al., 2001). Some MC-degrading bacteria can also degrade NOD, because of the similar mode of action of mlrA that opens the ring of its cyclic structure at the Adda-Arg peptide bond (Ho, Sawade, & Newcombe, 2012). Biodegradation has also been reported for the alkaloid heptaotoxin, CYN, by indigenous microorganisms (Smith, Boyer, & Zimba, 2008) and isolated *Bacillus* strain (Mohamed & Al-Amri, 2012). Regarding to cyanobacterial neurotoxins, there is scarcity of literature regarding their biodegradation compared to heptotoxins, despite of their increasing occurrence in surface waters. Kayal, Newcombe, & Ho (2008) revealed bacterial degradation of STXs during passage through bioactive treatment plant, but this led to structural modification of the predominant C-toxins variants to more toxic variants (G-toxins). ANTX-a biodegradation was assigned for *Pseudomonas* sp strain isolated from *Anabaena* culture, with a rate of 6–30 mg mL^{-1} per 3 d (Kiviranta, Sivonen, Luukkainen, Lahti, & Niemela, 1991). To date, no published data exist on the biodegradation of other cyanotoxins including ANTX-a(s), BMAA, LTXs and LPS endotoxins.

FUTURE RESEARCH DIRECTIONS

From inspection of the available literature on cyanotoxins, some other specific issues have received very limited attention or not explored yet. Some of which are listed in this section to be addressed in the future.

Regarding the risk assessment of cyanotoxin to human health, the available toxicological data are limited to MCs, but scant for other cyanotoxins. For example, there is no toxicological data for BMAA toxin and its relationships with neurodegenerative illnesses, though it has been investigated in free-living and symbiotic cyanobacteria in most ecosystems. For the accumulation of cyanotoxins in crop plants irrigated with contaminated water, most studies have evidenced the accumulation of MCs in some plants in laboratory experiments. Therefore, more studies on the presence of MCs and other cyanotoxins are needed, especially in real crop conditions, to evaluate the risks for humans more accurately. Since cyanobacterial blooms contain a mixture of different kinds of cyanotoxins, combined exposure and interaction between different cyanotoxins can occur. Hence, further research is needed on possible additive, synergistic or antagonistic effects of these cyanotoxins. As removal of cyanobacteria and cyanotoxins from water bodies by physical or chemical treatment may lead to cell lysis and toxin release causing a great problem for the aquatic ecosystem, more efficient and cost effective technology needs to be developed. For instance, the efficiency of aquatic macrophytes might be tested for cyanotoxin elimination from raw water before entering drinking water treatment plants.

CONCLUSION

Cyanobacteria are a group of primary producers, present naturally in marine and freshwater environments. However, eutrophication (i.e. high nutrient concentrations) of water bodies along with high temperatures and intense sunlight provide optimum conditions for the growth and proliferation of cyanobacteria and bloom formation. The presence of cyanobacteria are of particular concern for human health, because their ability to produce potent cyanotoxins, which affect human in different ways including hepatotoxicity, neurotoxicity, dermatotoxicity, genotoxicity, and carcinogenicity. These cyanotoxins are synthesized and remain within the cells and only release into the ambient water upon cell lysis during senescence or chemical treatment. Consequently, they can be found in inadequately treated drinking water, accumulate in seafood and fish upon feeding on toxic cyanobacteria, and accumulate in vegetable and crop plants irrigated with contaminated waters. This definitely poses human health at a risk upon consumption of drinking water and/or food products contaminated with cyanotoxins. In response to such health hazards of cyanotoxins, WHO and other agencies in some countries have estimated guideline values for these toxins. These guideline limits could be used during monitoring of cyanobacteria and their toxins in drinking and recreational waters in other countries. Nevertheless, each country has to derive its own guideline value for the presence of cyanotoxins in food products (i.e. fish, seafood & edible plants), as these guidelines differ among countries according to local conditions. For example, the amount of food ingested and the frequency of food consumption (i.e. food preference) affect on the value of allocation factor (AF) for the relative allocation of toxin intake to that food. Once cyanobacterial blooms are detected in the water, water source has to be monitored and managed to prevent or reduce the growth of these organisms. The best way to prevent bloom formation is decreasing the input of agricultural and industrial wastes into the water bodies. Eradication of cyanobacterial bloom by algaecides should be avoided because of the subsequent release of toxins. On the other hand, to protect consumer's health,

cyanobacteria and their cyanotoxins have to be removed during drinking water treatment processes by efficient and effective techniques. In this respect, water operators and companies have to increase and update their knowledge about the effective methods used for removal of cyanobacteria and cyanotoxins in drinking water treatment plants. This is because some conventional treatment methods are effective for removing cyanobacterial cells rather than cyanotoxins. Some methods can lead to breakdown of cyanobacterial cells and release of cyanotoxins into water. Other methods are efficient for removing one type of toxins, but cannot simultaneously remove all cyanotoxins.

KEY TERMS AND DEFINITIONS

Bloom: A large population or extremely high cell densities of phytoplankton (20,000 to 100,000 cells per milliliter) found on the water surface.

Cyanobacteria: Cyanobacteria are gram negative bacteria with a prokaryotic cell structure containing chlorophyll-*a*, and phycobilin pigments. Cyanobacteria were previously called blue-green algae.

Cyanotoxins: Secondary metabolites produced cyanobacteria including dermatoxins, hepatotoxins, and neurotoxins. They have a serious impact on plant, animal and human health.

Dermatoxins: The toxins that affect the skin and membrane tissues.

Extracellular Toxins: The toxins released from the cells into the ambient environment upon cell lysis.

Hepatotoxins: The toxins that affect the liver.

Intracellular Toxins: The toxins produced and remained within the cells.

Neurotoxins: The toxins that affect the central nervous system.

Chapter 55
Pharmaceuticals and Personal Care Products as Emerging Water Contaminants

Julie Becker
University of the Sciences, USA

Alexandros Stefanakis
University of Brighton, UK

ABSTRACT

With the advent of better detection, more micro-contaminants are being found in water. Many of these micro-contaminants come from medical therapies and personal care products. These chemicals are comprised of a wide-range of substances including pharmaceuticals, dietary supplements, veterinary drugs, fragrances, hair care products, body lotions, oral care, and cosmetics. Many of these products enhance our quality of life and in some cases, provide life-saving therapies. But, they come with an environmental cost. Scientific research has found sub-therapeutic levels of many of these chemicals in our waterways and in our finished drinking water, causing concern about the potential environmental and public health impacts associated with very low, chronic exposure. As tailored therapies and personal care products are developed, it is crucial to consider how to control emerging contaminants from medical therapies and personal care products. Specific actions and policies can be implemented now by adopting upstream approaches to prevent waste and decrease environmental exposures.

INTRODUCTION

The 1950's adage, *better living through chemistry*, still resonates today through our use of pharmaceuticals and personal care products. America is the prescription nation, with more than four billion prescriptions dispensed annually, and with the average citizen using not only prescribed medications, but over-the-counter drugs, homeopathic treatments, and herbal remedies as well (Lindsley, 2015). The average female consumer uses at least 12 personal care products, while males use at least six products (Leonard, 2010). Humans are not alone in their use of pharmaceuticals. The increased use of pharmaceu-

ticals among animals, especially antibiotics, is well documented. And the use of all of these chemicals comes with an environmental cost: much of what we use ends up in our water and little can be removed through water treatment processes.

The purpose of this chapter is to:

1. Describe how pharmaceuticals, and personal care products (PPCP) as well as some medical therapies end up in various water sources, and identify some pharmacological, chemical, and toxicological properties of PPCP.
2. Identify how medical therapies and PPCP are detected and evaluated in various water sources, and identify some of the issues associated with determining levels of exposure and risks associated with exposure.
3. Define the problems associated with emerging contaminants (EC) from medical therapies and personal care products (PCP), using two general categories of EC (antibacterials and endocrine-disruptors) and two specific examples (Iodine 131 and nanotechnology) to illustrate these problems, by:
    a. Identifying the chemicals associated with the medical therapy or PCP and their potential and actual human health hazards;
    b. Characterizing potential policy implications as a result of these examples.
4. Examine the life-cycle of emerging contaminants from design through disposal to consider the following questions:
    a. How can the design and production of these contaminants be improved to decrease bioactivity, increase absorption, reduce waste, and lesson their carbon footprint?
    b. What incentives may be helpful in the development of new products and/or the redesign of existing products that utilize green chemistry and decrease the impact upon the environment?
    c. What production methods would decrease chemical waste, use less or least harmful materials, and reduce the carbon footprint?
    d. How can policies and practices be changed to reduce the waste and decrease pollution from emerging contaminants?
5. Explore potential recommendations to decrease the effects of emerging contaminants and future contaminants based upon existing research and some new areas for consideration.

With thousands of pharmaceuticals and chemicals that make up different PPCP, there is no way a chapter like this can be all-inclusive. By discussing key components of emerging contaminants in water, this chapter is an exploration of what needs to be considered now and in the future to mitigate exposure and safeguard our drinking water.

BACKGROUND

Pharmaceuticals and medical therapies not only save lives by preventing and treating diseases, but also by enhancing the quality of life for those with chronic diseases. Personal care products also improve our daily living by providing products that ease discomfort, improve our perceptions of appearance, and make

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

us feel good about ourselves. Both pharmaceuticals and personal care products (PPCP) contain chemicals that are biologically active, toxic, and hormone-disrupting. Both are found in drinking water sources and wastewater effluents worldwide. Their presence in water has been documented and publicly reported by government experts, academic researchers, and the media for nearly two decades. While this is not a new discovery, the level of detection at trace amounts of non-therapeutic levels of pharmaceuticals or non-harmful levels of personal care products has changed and created a heightened awareness due to media coverage (Donn, Mendoza, & Pritchard, 2008; Donn, et al., 2009). Detection of trace amounts of chemicals will continue to improve, documenting the effects of low-level, chronic exposures of PPCP, linking these exposures to biological harm for aquatic and human life.

Pharmaceuticals enter the environment as a result of human activity: 1) unintentionally through human excretion; 2) intentionally through flushing unwanted, unused, or expired medications (Daughton & Ruhoy, 2008); 3) design and large-scale production of medications through wastewater effluent (Fick, et al., 2009); 4) animal excretion through large-scale livestock and aquaculture farming practices (Gunnarsson, et al., 2009; Jones, Voulvoulis, & Lester, 2002).Currently there is no single method to remove pharmaceuticals from wastewater, and the majority of water treatment plants cannot address removal of trace amounts (Bolonga, Ismail, Salim, & Matsuur, 2009).

The route of entry for personal care products into various water sources is a little different. Instead of excretion, most personal care products enter the water exclusively through human interventions like showering, hand washing, cleaning, or laundry (Grassi, Rizzo, & Farina, 2013). However, through the application of a personal care product, the skin may absorb some chemicals that are then excreted through the body in trace amounts into the sewage system.

When metabolized by humans or animals, many PPCP undergo structural changes resulting in metabolites, which may differ in pharmacological, chemical, and toxicological properties from the original products (Ortiz de Garcia, et al., 2013; Boxall, et al., 2012). The methods of administration may also impact how PPCP are metabolized. For example, if a substance is ingested versus administered dermally, it will have an effect on how it gets metabolized. Two key factors affect the metabolism: its pharmacodynamics and pharmacokinetics. Pharmacodynamics describe what influences the drug has on the body including therapeutically, side effects, concentrations, and mechanism of drug interactions. The influence the being has on the drug is pharmacokinetics, and considers areas such as absorption, distribution, metabolism, elimination, and the time it takes to process the chemical (Khetan & Collins, 2007). Since pharmaceuticals are made up of chemicals, and personal care products are also made up of chemicals, similar principles may be applied to these products as well.

Europeans have taken a different approach to PPCP. For example, since the 1990s, guidelines for human and veterinary medicinal products have existed. These guidelines provide a framework to predict environmental concentrations, assess the effects of pharmaceuticals in the environment, and provide some baseline ecotoxicity data (Koschorreck & Hickmann, 2008). Although it is not in wide use throughout Europe, other countries are considering various aspects of these guidelines. Commonly used chemicals found in PCP have been discontinued or banned in Europe, including phthalates and parabens. Manufacturers who sell in multiple international markets already have found ways to reformulate products to exclude banned substances for the European market. Extending the discontinuation of these products to all personal care products might be a consideration in the future.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

DETECTION AND EVALUATION

PPCP were first detected in water systems through aquatic life during a national survey of organic wastewater contaminants in U.S. waterways conducted by the U.S. Geological Survey (USGS) in 1999-2000 (Kolpin, et al., 2002). This survey found the following in very low concentrations: human and veterinary drugs (including antibiotics), natural and synthetic hormones, detergent metabolites, plasticizers, insecticides, and fire retardants. These substances were found in residential, industrial, and agricultural wastewater, sampled from 139 streams representing 30 states, with half the streams containing one or more of these chemicals (Kolpin, et al., 2002). Subsequently, other studies have been done that demonstrate the pervasiveness of these chemicals and other emerging contaminants that influence water quality. As detection technology improves, more contaminants from PPCP will be found at lower concentrations but at sufficiently high enough levels to harm aquatic organisms (Ferrari, Paxeus, Lo Giudice, Pollio, & Garric, 2003).

While there is little evidence that PPCP exposure affects human health, evaluating this exposure is very difficult for several reasons. First, most of the detectable levels of PPCP are at sub-therapeutic concentrations. Second, PPCP are not detected as single compounds but as part of a group of environmental contaminants, and it is difficult to tease out what is causing the problem, and/or the chemicals may mix to form other contaminants. Next, very little is known about the efficacy or health effects of low-level, chronic, non-therapeutic exposure to PPCP. Lastly, the environmental persistence of PPCP varies widely (Löffler, Römbke, Meller, & Ternes, 2005; Scheytt, Mersmann, Leidig, Pekdeger, & Heberer, 2004; Scheytt, Mersmann, & Herberer, 2006; Tixier, Singer, Oellers, & Müller, 2003). Some of the most widely prescribed drugs or frequently used personal care products may not show up in drinking water because their persistence in the environment is relatively short, and therefore may be undetected.

ANTIBACTERIALS AND ENDOCRINE-DISRUPTING DRUGS

Chemicals of Concern and Health Effects

Two key contaminants in water are of particular concern: antibacterials and endocrine-disrupting drugs. Half the antibiotics used in livestock are in the same classes as those used in humans, raising concerns about contributing to growing antibiotic resistance (World Health Organization, 2002; Centers for Disease Control and Prevention, 2009). Specific antibiotics have been used historically in the feed or drinking water of livestock such as poultry, hogs, and cattle to decrease the amount food that is used and for the animals to gain weight quickly. Many of these antibiotics also are used to treat human infections, creating genuine concern about bacteria, which become resistant to antimicrobial drugs. Once resistance occurs, a drug is no longer effective in treating various infections or illnesses.

Endocrine-disrupting pharmaceuticals are excreted as waste by-products from the use of birth-control pills (ethinylestradiol), menopause treatments, thyroid replacements, and cancer therapies. Ethinylestradiol is extremely potent at very low concentrations and bioaccumulates within an organism; a concentration of 0.1 ng/L is sufficient to induce production of the female egg protein vitellogenin in male rainbow trout (Purdom & Randall, 1998; Larsson, et al.,1999).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Policy Implications

The Food and Drug Administration (FDA) has encouraged eliminating the use of these antibiotics for growth production (FDA, 2009; Pew Trusts, 2014), but FDA's guidance policy still permits about a quarter of antibiotics to be used for growth purposes or to treat bacteria. By not banning the use of antibiotics in the feed of farm animals altogether, antibiotic resistance will continue to be an ongoing problem that will hinder the ability of medical personnel to provide adequate treatments for infections and illnesses.

The policy implications for limiting or banning endocrine disrupters are not as easy to assess. Since many PPCP contain chemicals that act as endocrine disrupters in the environment, eliminating these chemicals will prove to be much harder. In some cases, which chemicals act as endocrine disrupters in the environment are known and in other cases they are unknown. For example, certain pharmaceuticals, like thyroid medications, are endocrine disrupters, so a mitigation strategy is needed to reduce the chemical and biologic activities associated with the drug once it enters the environment. But in some PCP, it is unclear which chemicals act like endocrine disrupters, but the effect is similar on aquatic life. Additional research should be required to prove if PPCP may act like an endocrine disrupter and then other alternatives should be considered for reformulation when possible.

IODINE 131

Chemical of Concern and Health Effects

Medical treatments are another source of emerging contaminants in water. For example, Iodine 131(^{131}I) is a frequently used radioactive isotope that can be found in human and veterinary medical treatments, released from nuclear power plants (unplanned releases or from their laundry facilities), or as a tracer into the environment as part of hydraulic fracturing fluid to determine the location of fissures created in this process.

Most commonly, ^{131}I is used frequently for the treatment of thyroid cancer in humans and animals, primarily cats. Yet the major health effect caused by over exposure to ^{131}I is thyroid cancer. Low dose therapy of ^{131}I is also used to treat an overactive thyroid. Health care providers know that this type of medical treatment must be keenly balanced in order to provide treatment not harm, and therefore exposure to ^{131}I treatment is strictly monitored (Institute of Medicine Committee on Thyroid Screening Related to I-131 Exposure, 1999).

When patients are treated with ^{131}I, they are told to drink a great deal of fluids to flush their system. As a result, patients excrete waste directly into the sewage collection systems, which pass through the wastewater treatment facilities. The radioactive half-life for ^{131}I is eight days but patients do not store their bodily waste until the half-life is completed. While ^{131}I does decrease in activity over time, it is introduced to surface waters through wastewater plant effluents. The extent to which ^{131}I is present in detectable concentrations is unknown. The U.S. national environmental radiation monitoring program, RadNet, is not designed to help water departments assess the amount of ^{131}I in drinking water. While drinking water utilities participate in the RadNet program, it is hard to assess the amount of ^{131}I that occurs in water due to how sampling occurs and the locations of the samples (source water, finished water, and tap), corresponding to different ages of water and therefore different levels of dilution and decay of ^{131}I. Since the half-life is relatively short, if targeted monitoring is not occurring on a very regular basis,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

water utilities may miss an increase in detectable ^{131}I in source water used for drinking. The majority of utilities do not monitor for ^{131}I on a regular basis, so the chances of missing that elevation are highly likely. Additionally, some analytic methods do not account for radioiodine in all the chemical forms that may be present in environmental samples, leading to difficulty in evaluating this exposure in drinking water throughout the United States.

Policy Implications

In 2011, an earthquake and tsunami caused the Japanese Fukushima Daichi Nuclear Plant to emit large amounts of radiation into the atmosphere and water near the plant. As a result of these emissions, U.S. water departments increased monitoring for radioactive iodine. One water department noticed an uptick in ^{131}I. After extensive monitoring and intergovernmental/non-profit cooperation, all parties concluded that the likely source of ^{131}I in this location's source waters is not from the Diachi Nuclear Plant melt down. Rather, it is from patients receiving medical treatments (most likely for thyroid cancer), since this region has a large number of medical facilities that treat patients for thyroid cancer. More intensive monitoring would help other water departments identify detectable ^{131}I in drinking source water, especially in areas where people are treated for thyroid cancer. Since this kind of monitoring for ^{131}I had not been done before, and most water departments would not voluntarily increase the targeted monitoring for this contaminant, it would be hard to determine if this was a one-time anomaly or is more common than previously suggested. In addition to more monitoring, the need to develop analytic techniques for more sensitive and less expensive ways to detect ^{131}I should be considered, as well as better equipment that can remove and process ^{131}I in drinking water through the wastewater treatment process.

With this kind of medical treatment emerging as a contaminant to water, the need to engage the healthcare community and patients will become necessary and essential. Outreach to the healthcare community and their patients needs to be done with the realization that medical practitioners work within their regulations, as well as time and economic constraints.

NANOTECHNOLOGY

Chemical of Concern and Health Effects

Another example of an emerging contaminant comes from personal care products. A large number of personal care products contain nanotechnology. Nanotechnology is the manipulation of atoms and molecules on a subminute scale – "80,000 times smaller than the width of a human hair," (Silpa, Jose, Sumod, & Sabitha, 2012). Nanotechnology is being incorporated by cosmetic manufacturers as ingredients for UV protection, moisturizing, increased and more intense cosmetic colors, and improving the finishes of makeup. Due to their very small size, and their variety in terms of shapes and availability in many different products, nanoparticles can enter the environment during the manufacture, use, or disposal of these materials. For example, the antibacterial nature of nanoparticles might inhibit helpful bacteria in wastewater treatment or sewage plants. Additionally, nanoparticles may bind to other substances like cadmium or petrochemicals to contaminate finished water. Fish who have been exposed to nanoparticles may experience brain damage (large mouth bass) or toxicity (rainbow trout) (Chen, Dong, Zhao, & Tang,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

2009; Ernie, 2004). Nanoparticles may be able to biomagnify through the microbial food chain (Jonathan, Jason, Jason, & Paul, 2011) and are considered biopersistent, meaning they do not dissipate quickly.

Not only can nanoparticles get into water as an emerging contaminant, but also these particles can affect humans and produce profound effects. Entry can occur through three routes: inhalation, ingestion, and absorption through the skin. According to the National Institute of Occupational Health and Safety, workers may inhale nanomaterials as part of the production of these products and consumers may inhale particles when they spray on materials that contain nanos. This exposure may result in a wide variety of respiratory issues, as well as potential toxicity for the brain, blood and other organs (Silpa, et al., 2012). Unintentional ingestion occurs when products that contain nanoparticles are on people's hands and transfer from hand-to-mouth occurs. In addition to inhalation, the exposure to nanotechnology occurs through absorption, which is how the products are supposed to be used. Products containing UV nanoprotection have been shown to enter the blood stream in animal models in 24 hours, posing concerns about their effects in humans in the same time frame (Ryman Rasmussen, Riviere, & Monteiro Riviere, 2006).

Policy Implications

Both environmental and health organizations have raised safety concerns about products containing nanotechnology. Consumers and regulatory bodies are voicing similar concerns. Since limited safety testing is done with cosmetics or personal care products, it is hard to assess what are the safety concerns with these products. The U.S. FDA is being asked about oversight for these products. Yet, few studies exist about the potential health and safety concerns, and more and more products are containing these particles. The few studies that have been conducted have shown links between exposures to nanotechnology and some form of toxicity, to both aquatic organisms and laboratory animals. The European Union has updated its cosmetics directive to include information about nanoparticles and requires safety compliance and information about the materials. However, much like other chemicals such as phthalates or parabens, without a consistent global approach to nanotechnology, these materials will continue to be sold with limited safety and monitoring information. Additionally, instead of the cosmetic industry providing oversight about safety, it might be more efficient and effective if a third party group provided that information. Research of this nature, which is globally funded through a mixture of government and industry funds to assess the safety and monitoring of emerging products such as nanotechnology, could provide oversight and data for future decision-making about products.

LIFECYCLE

There are four areas for potentially reducing or eliminating waste from pharmaceuticals and personal care products in the environment: design and production; approval and regulation; use; and discharge and disposal.

Design and Production

The design, development, and production of PPCP should consider ways to increase effectiveness. For pharmaceuticals, this means that the bioactivity and absorption within the intended target is increased based upon individualized traits such as body weight or genetics. With PCP, the amount of residual chemi-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

cals that are not absorbed through the skin or hair should be decreased. To accomplish these goals, the use of green chemistry should be applied to PPCP. Green chemistry is defined as the invention, design, and application of chemical products and processes that reduce or eliminate the use and generation of hazardous substances (Khetan & Collins, 2007). Green chemistry would address two key challenges: improved absorption of PPCP in or on the body and better formulation to facilitate rapid removal upon release into the environment, decreasing their persistence, and creating a much shorter half-life for these products when they enter the environment through processing.

Producing PPCP is resource-intensive and generates significant amounts of waste worldwide. To produce an active ingredient used in PPCP, the waste generated can vary drastically, from 200 kilograms to 30,000 kilograms. The manufactured wastes may include biological compounds like fermentation wastes, or leftover solvents when active ingredients are extracted from natural sources. Sometimes pharmacologically active reagents such as anticoagulants and chemotherapeutic agents are created as byproducts of the production of PPCP. Additionally, cleaning agents, disinfectants, and extraction solvents are used to clean, sterilize, or purify active compounds (Henderson, Kindervater & Manley, 2007). For example, locations where the production of pharmaceuticals occurs discharge effluents that contain much higher levels of chemicals and active drug compounds (Langford & Thomas, 2009).

To reduce design and production costs, green chemistry offers great potential for savings. By reducing the use of water and hazardous solvents in the production process, green chemists have identified methods that provide PPCP with the same therapeutic effect using less active pharmaceutical ingredients. This method should help decrease the amount of drug that must be manufactured, decreasing production waste and the amount of drug in each dose, and ultimately resulting in reduced costs (Daughton, 2003; Becker, 2009). The downside to reformulation of pharmaceuticals is that it may take more than a decade to test and receive approval for any reformulation of a product in the U.S., costing the manufacturers millions or billions of dollars (Becker, 2009). Reformulating personal care products is costly, so it needs to be incentivized through reducing production costs or chemical bans before manufacturers will take the initiative. It needs to be done on a global scale since products are sold globally, and then the highest environmental and safety standards should set the industry bar for design and production.

With the design and production of PPCP, another issue should be considered besides green chemistry: the carbon footprint of design and production. The National Health Service of England (NHS) studied the carbon footprint of pharmaceuticals through procurement, defined as the manufacture and transportation of NHS goods and services used by humans (NHS, 2009). The NHS found that procurement constituted 60% of carbon emissions, with pharmaceuticals and medical equipment making up half of these emissions. Pharmaceuticals alone accounted for about a fifth of total emissions in the healthcare system. This is comparable to the emissions of entire sectors of the economy, including energy usage of buildings or travel.

Approval and Regulation

In the U.S., the development, collection, and discharge of pharmaceuticals are regulated by a number of federal laws and by at least three different federal agencies – 1) Federal Drug Administration (FDA - approval and regulation), 2) Environmental Protection Agency (EPA - environmental impact and waste disposal, but EPA does not have the authority to review pharmaceuticals for environmental consequences because drugs are exempted from the Toxic Substances Control Act [TSCA]), and 3) Drug Enforcement Administration (DEA – diversion and regulation of controlled substances). Pharmaceuticals used

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

prophylactically in animal feed for livestock are overseen through direction from the FDA for the types of medication and quantities, while the U.S. Department of Agriculture provides guidance for animal waste management (quantity and storage), yet the regulation of environmental impacts from animal waste is deferred to EPA. With so many agencies involved in different aspects of pharmaceutical regulation, there is little coordination among these agencies, creating both conflict and confusion about how to handle many aspects of this life cycle.

Personal care products do not have the same regulations as pharmaceuticals when it comes to their development but are often treated similarly when it comes to waste disposal. The U.S. EPA groups PCP with pharmaceuticals for their environmental impacts, because of their likeness to drugs' environmental impacts. PCP may be disposed in household trash without special precautions, which is different from disposing of pharmaceuticals at home.

In the U.S., the Federal Food, Drug and Cosmetic Act of 1980 empowers the FDA to regulate pharmaceuticals. When a drug seeks approval to come to market, it must meet the standard of "safe and effective," (FDA, 2009). Through the guidance of this Act, FDA is accountable for reviewing the potential environmental impact from human and veterinary medicines and their intended uses. An Environmental Assessment (EA) (42 U.S.C. §4371, et seq.) is required to be submitted to the FDA to assess the potential effects of a proposed compound, yet there are a number of exclusions to this requirement. For example, if the production of drugs is predicted to occur at less than one parts per billion (ppb) in the aquatic environment or 100 ppb in soil (*Id.* at § 25.31(b).), then the compound is excluded, which means that many drugs are included in this exemption (21 C.F.R. § 25.10, 2008). However, effects on aquatic life have been seen at very low, sub-therapeutic concentrations, suggesting that these benchmarks should be reconsidered and need to be coordinated with the EPA and the U.S. Geological Survey, since the latter group studies the effects of these compounds on fish and amphibians.

Use

There is no doubt about it, pharmaceutical use has increased over the past several decades, leading to more pharmaceutical discharge and waste into the environment. Every month in the U.S., 135 million people use prescription medicines, for a total of over four billion prescriptions filled each year (Henry J. Kaiser Family Foundation, 2008). In one study, almost 70% of Americans take one prescription drug, with more than 50% taking two or more, and older people and women representing the largest percentage of people using medications (CDC, 2009).

Prescription drug use will increase because of several factors: 1) an aging population who are living longer with at least one or more chronic diseases; 2) younger people diagnosed with treatable chronic diseases, including neurobehavioral developmental disorders; 3) the medicalization of obesity; and 4) personalized and tailored medicine (Becker, 2007; Zhong, et al., 2013). All of these factors contribute to the rise of prescription drugs, not only in the U.S. but also, worldwide. As this increase occurs, stakeholders such as the government, the industry, and the pharmaceutical industry will need to provide better public health and environmental protections. Increased regulatory guidance will be needed to improve environmental protection, and this includes how to dispose of unused, unwanted, or expired medications. The current shift from twice-yearly U.S. DEA drug disposal drop-offs at law enforcement agencies or community group-designated locations to pharmacy-based, year-round drop-off sites should help to decrease the amount of unwanted drugs in the home medicine cabinet. Additionally, a system to

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

encourage short-cycling of new prescriptions and prescribing smaller quantities of medications should be encouraged.

The Environmental Working Group found that the average person used at least nine personal care products each day (EWG, 2011). This may include, but is not limited to: soaps, body washes, perfumes, deodorants, moisturizers, shampoos, conditioners, toothpaste, and other products. Each of these products is made up of many chemicals that ultimately are washed off our bodies and into the water system. With little regulation or oversight on cosmetics and personal care products, much of what is known about these products is limited to the ingredient list posted on the packaging. And none of these products' manufacturers are required to demonstrate an Environmental Assessment to ascertain what potential impact it may have when it enters the environment. Since many of the chemicals used in these products may have similar properties to the ones used in drugs, the question arises if similar testing should be considered for cosmetics and PCP.

Discharge and Disposal

How PPCP enter the waste stream can be described as either unintentional or intentional. Unintentional releases suggest excretion of pharmaceuticals (metabolized and unmetabolized) from animals or humans. When we bath or wash, PCP, as part of our grooming habits, enter into the waste stream. Intentional releases refer to the disposal of unused, unwanted, or expired PPCP by flushing them down the toilet, or by throwing them into the trash. Intentional releases also include disposing of pharmaceuticals purposely as part of the manufacturing process (Boxall, 2004).

It is difficult to assess how much PPCP are disposed of on an annual basis. Several factors contribute to this. Some pharmaceuticals are prescribed but never filled, some prescriptions are filled and not used or used inappropriately, and some are prescribed, filled and used appropriately. In other cases, due to adverse reactions, people need to switch medications, leaving them with unused drugs from previous prescriptions. Similar factors apply to personal care products; people buy products and may or may not use the products to completion. A rough estimate can be made about the intentional releases of pharmaceuticals into the waste stream. In some studies, as much as 50% of many prescriptions and 80% of antibiotics are approximated to go unused, although pharmaceutical reports suggest that number is about three percent (Bound & Voulvoulis, 2004; National Association of Clean Water Agencies, 2005). Most unused or unwanted medications are put in the trash, flushed down the toilet, or rinsed down the sink (Kuspis & Krenzelok, 1996). Another factor that contributes to waste is the disposal of deceased persons' unused medications. Much of that medication is often trashed or put into the sewage system via flushing or rinsing. Lastly, hospitals, long-term care facilities, and other healthcare institutions contribute pharmaceuticals to the waste stream through large quantities of unused pharmaceuticals as part of patient treatment. The contribution from these sources to the waste stream is estimated to be between 20%-65% (Ruhoy & Daughton, 2007; Daughton & Ruhoy, 2009).

To estimate the amount of unintentional release from human and animal excretion, scientists are creating models. These models forecast the amount of active pharmaceutical ingredient (API) that potentially enters the environment by analyzing information about usage, rates of excretion of API, and effectiveness of treatment techniques used by wastewater and drinking-water facilities (Kostich & Lazorchek, 2008). However, the accuracy of these models have yet to be tested.

Two factors largely determine which PPCP enter the environment: the nature of the wastewater treatment plant (WWTP) where they are discharged and the type of contaminant. WWTPs can successfully

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

remove a few specific compounds; but overall, most removal rates are highly variable (Tauxe-Wuersch, De Alencastro, Grandjean, & Tarradellas, 2005; Kimura, Hara, & Watanabe, 2005; Lee, Sarafin, Peart, & Svoboda, 2004; Lindqvist, Tuhkanen, & Kronberg, 2005). Activated carbon, oxidation by chlorination or ozonation, and membrane filtration are advanced sewage-treatment techniques that can increase pharmaceutical removal rates. However, even with advanced techniques, many of the drugs may not be completely removed from wastewater. Unfortunately, with the diversity of pharmaceuticals, no single technique will effectively treat all the different kinds. Because of this variability and the increase of personalized medicine, the recommendation is to focus on upstream ideas through the use of green chemistry to decrease bioactivity, its persistence in the environment, and absorptivity. With personal care products, many of the same issues also are considered as pharmaceuticals.

Activated carbon, oxidation, activated sludge, nanofiltration, and reverse osmosis membranes are other technologies that have been used to remove pharmaceuticals from water (Bolonga, et al., 2009). None of these technologies eliminate pharmaceuticals from the water or consistently render them both biologically and chemically inert. Future technological developments need to be advanced to address this waste.

One detrimental byproduct of wastewater treatment is sludge. Some pharmaceuticals and their metabolites are hydrophobic and end up in this sludge. Even if removal from wastewater can occur, this process creates the potential for groundwater or surface water contamination when the resulting sludge, which contains hydrophobic pharmaceuticals/metabolites, is spread on fields as an agricultural fertilizer (Dizer, et al., 2002). Additionally, accumulation of pharmaceuticals in the soil may occur with repeated spreading of this sludge on fields (Golet, Xifra, Siegrist, Alder, & Giger, 2003).

To avoid flushing or disposal in the trash, collection programs for unused, unwanted, or expired pharmaceuticals have been developed. In countries such Australia, Canada, Portugal, and Spain, community pharmacies are used to collect medications for final destruction via incineration, funded by these governments (Northwest Product Stewardship Council, 2009). In France, the pharmaceutical industry funds the nationwide collection program. In all cases, a massive public education program accompanies the collection programs as well as education geared toward providers on proper disposal practices.

In the U.S., PPCP collection programs are at best, very local and participation is hit-or-miss, due to a lack of consistent funding and timing. Different programs such as Take Back" or Mail-In programs, where unused or outdated medications are returned to a hospital, pharmacy, reverse distributor, or a police station, have been conducted in various locales. Twice a year (Fall and Spring), the DEA has sponsored collections at many police stations in the country. But the availability of information about these efforts for the public has been highly variable, and achieving a desirable level of public participation requires much notification and outreach. Unlike what occurs in Europe, the pharmaceutical manufacturers have not offered alternatives, incentives, or funding to address this issue. While there have been several product stewardship bills introduced at the state level to encourage pharmaceutical manufacturers to fund disposal programs, little movement on this issue has occurred. The DEA has recently authorized U.S. pharmacies to begin to take back prescription, over-the-counter, and homeopathic medications, but it's unclear when pharmacies will begin to accept this waste and how this will happen. Patient education will be crucial in the success of having consumers use pharmacies to dispose of unused, unwanted or expired medications.

Incineration is used to dispose of pharmaceutical waste because the materials are permanently destroyed. Concerns about efficiency, efficacy, and environmental impacts need to be considered. These concerns include: air emissions and ash residue from the incinerators, the variations in temperature and

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

burn time to destroy pharmaceuticals, halogenated dioxins from burning of halogenated pharmaceuticals or containers containing polyvinyl chloride, and the costs and impacts of transportation to and from disposal sites for communities.

Solutions and Recommendations

With new technology or medical treatments, new emerging contaminants in water will continue to be an ongoing issue, and potentially an escalating issue. Specific ideas may help in decreasing the amount and types of emerging contaminants. These include:

1. Using green chemistry as the means to designing and producing PPCP. Green chemistry offers a number of advantages such as using less resources in the design and production of PPCP, increasing the absorptivity of a product, decreasing waste, decreasing the amount of time in the environment, increasing efficiency of production, and reducing the amount and toxicity of chemicals needed in this process. U.S. government policies should encourage the use of green chemistry in all parts of the PPCP lifecycle. Green chemistry use will become crucial not only in addressing bioactivity issues, but also in decreasing water usage in the design and production of PPCP products, as the scarcity of potable water sources increases..
2. Revamping U.S. federal policies that govern approval and regulation of pharmaceuticals, while expanding regulation to cover personal care products, needs to be considered. With new delivery systems (such as nanotechnology) and individualized medicine, the need to review which agencies have a role in the approval and regulatory process should be considered and streamlined to ensure better monitoring and oversight, decreasing the complexity of who does what. Since little interagency coordination exists among federal groups, simplifying and streamlining the process for development, distribution, access, and disposal of PPCP is imperative.
3. Shifting the focus to upstream approaches such as short-cycling prescriptions, decreasing selling large quantities of over-the-counter medications through chain stores, and educating people who prescribe and dispense medications about environmentally preferred ways to dispose of unused, unwanted, or expired PPCP. The need to eliminate the use of non-therapeutic antibiotics in farming practices altogether is essential for ensuring the future efficacy of this class of drugs.

FUTURE RESEARCH DIRECTIONS

When considering the gaps in knowledge on PPCP, a number of key questions should be considered for potential research: 1) What is the volume of PPCP produced within the U.S. and worldwide? 2) How much water is used in that production? 3) What are the potential adverse human and animal health effects at sub-therapeutic levels? 4) What are the synergistic effects (if any) when different PPCP are present in the same water samples? 5) How do these different PPCP affect the waste from the production of PPCP and how can this waste be processed? 6) Can we measure the efficacy of pharmaceuticals after long-term, sub-therapeutic, chronic exposure? These are a small fraction of the potential questions that can be considered when contemplating PPCP as emerging contaminants in drinking water.

Requiring new research to improve disposal practices and decrease discharges, including investment capital that can help discover ways to reduce chemical and biologic activity through non-incineration,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

is critical. Current wastewater treatment processes cannot remove PPCP from finished water. Decreasing the waste associated with PPCP needs to be addressed from an upstream perspective by prescribing less pharmaceuticals and being more selective in purchasing of personal care products. Going forward, implementing green chemistry, short-cycling, and other waste reduction efforts may reduce the quantity of waste, but it will not reduce the need for new methods of waste treatment. Research in these areas is essential to providing the needed data to drive policy decisions at the institutional and governmental levels.

CONCLUSION

Society is facing a confluence of factors: 1) an aging population that is living longer and relying on PPCP to address multiple chronic diseases and signs of aging; 2) a younger population that relies on pharmaceuticals to tackle long-term conditions such as obesity and Attention Deficit/Hyperactivity Disorder, and uses a multitude of personal care products; 3) the growth of personalized and tailored medicine; and 4) the increasing challenge of providing potable water to support human and animal populations. The combination of these factors will create an unprecedented use and development of PPCP as well as new medical therapies not only in the U.S., but also throughout the world. The challenge will be to find ways to decrease the chemical and biological activity, increase the use of green chemistry in all phases of the product lifecycle, eliminate non-therapeutic use of antibiotics for animals, mitigate prescribing of pharmaceuticals and purchasing of personal care products to promote less waste, and promote policies that foster practices to address these factors.

Our reliance on pharmaceuticals and personal care products including medical therapies to maintain our health and improve our quality of life will increase over time. Identifying these chemicals as emerging contaminants that may impact our drinking water provides us with opportunities to pursue new strategies and policies that can address current challenges and provide solutions into the future.

KEY TERMS AND DEFINITIONS

Active Pharmaceutical Ingredient (API): The primary chemical of action that a pharmaceutical is comprised of.

Antibiotic-Resistance: The phenomenon of pathogenic agents of disease building immunity against antibacterial agents that they were once susceptible to because of overuse and over exposure.

Bioaccumulation: An organism's retention of an API, chemical, or substance that it is exposed to in various concentrations.

Bioactivity: The biological effect(s) of an API, chemical, or substance on various organisms.

Ecotoxicity: The harmful effect(s) of an API, chemical, or substance on the environment, or more specifically an organism's ecosystem.

Effluent: The waste or sewage that is resultant of various industrial and agricultural processes. In can, more specifically, refer to the byproduct of wastewater treatment.

Endocrine-Disruptors: APIs, PPCP, or chemicals that can inhibit or alter the normal function of an organism's hormones or endocrine system to the point of causing adverse health effects on the organism or its offspring.

Green Chemistry: The development of PPCP that is considerate of and mitigates the effects of PPCP throughout its lifecycle, from design and production through discharge and disposal.

Half-Life: The amount of time it takes an API, chemical, or substance to decrease its concentration in an organism or ecosystem by half. In reference to radioactive isotopes, it is the amount of time it takes the radioactivity of an isotope to decrease to half of its original value.

Iodine 131 (^{131}I): A frequently used radioactive isotope that can be found in human and veterinary medical treatments, released from nuclear power plants (unplanned releases or from their laundry facilities), or as a tracer into the environment as part of hydraulic fracturing fluid to determine the location of fissures created in this process.

Nanotechnology: The manipulation of atoms and molecules on a subminute scale. This technology has been increasingly utilized in the production of a variety of personal care products (PCP).

Parabens/Phthalates: Common ingredients in PCP that are known to exhibit endocrine-disrupting properties.

Short-Cycling: The concept of encouraging consumers of PPCP to purchase smaller quantities, especially in regard to newly prescribed/first-time purchases, to prevent excess waste of product in the event of adverse reaction or disapproval of a product.

Wastewater Treatment Plant (WWTP): A municipal facility where water that has been utilized for residential use is filtered and sanitized to be redistributed for residential use.

Chapter 56
Toxicological Effects of Carbon Nanotubes

James C. Bonner
North Carolina State University, USA

ABSTRACT

The rapidly evolving field of nanotechnology offers many potential societal and economic benefits. Carbon Nanotubes (CNTs) are one of the most widely produced engineered nanomaterials and have diverse applications in engineering, electronics, and medicine. They have also been extensively investigated for their toxicological properties. Studies with rodents indicate that CNTs can cause lung fibrosis or granuloma formation, exacerbate pre-existing respiratory disease, cause injury to the sensitive pleural lining of the lungs, and have systemic immunosuppressive effects. CNTs have also been reported to cause genotoxic effects on cultured cells. The fiber-like structure of CNTs has led to comparisons with asbestos fibers; yet the debate over whether CNTs cause mesothelioma remains highly controversial, and evidence thus far is lacking. The aim of this chapter is to overview the evidence in rodent models that CNTs cause lung disease and to discuss the potential of CNTs to cause adverse immune, fibrogenic, or carcinogenic effects in humans as a result of occupational, consumer, or environmental exposure.

INTRODUCTION

Carbon nanotubes (CNTs) are proto-typical engineered nanomaterials that possess superior strength with minimal weight. CNTs also can be easily functionalized at the atomic level to enhance their properties for use in electronics, engineering, and biomedicine. While promising for many uses, the length and high tensile strength of CNTs also make them a potential risk for lung diseases and as well as other systemic sites of injury [Bonner 2010a]. The most likely route for human exposure is inhalation. A growing number of studies using rats or mice show that CNTs delivered to the lungs cause interstitial lung fibrosis, granuloma formation, or fibrogenic reactions at the pleura [Bonner 2011]. CNTs also exacerbate pre-existing respiratory disease and cause systemic effects in other organ systems such as heart and spleen [Thompson et al., 2013]. While rodent studies indicate that CNTs cause adverse pulmonary and systemic effects, there is currently no epidemiologic data demonstrating that CNTs cause disease

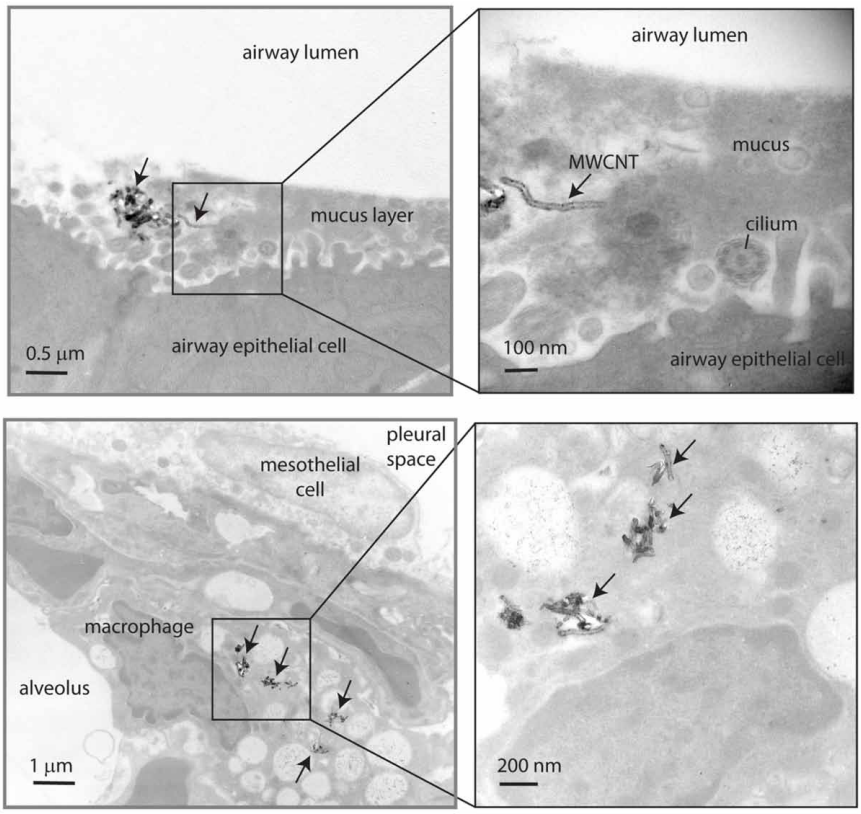
in humans. This is likely due to the infancy of the nanotechnology industry and the long latency time for chronic lung diseases in humans. A major goal for investigators in the field of nanotoxicology is to better understand the adverse effects and mode of action for engineered nanomaterials in rodent models of disease in order to predict the risk for human disease.

BACKGROUND

Lung Exposures in Rodents



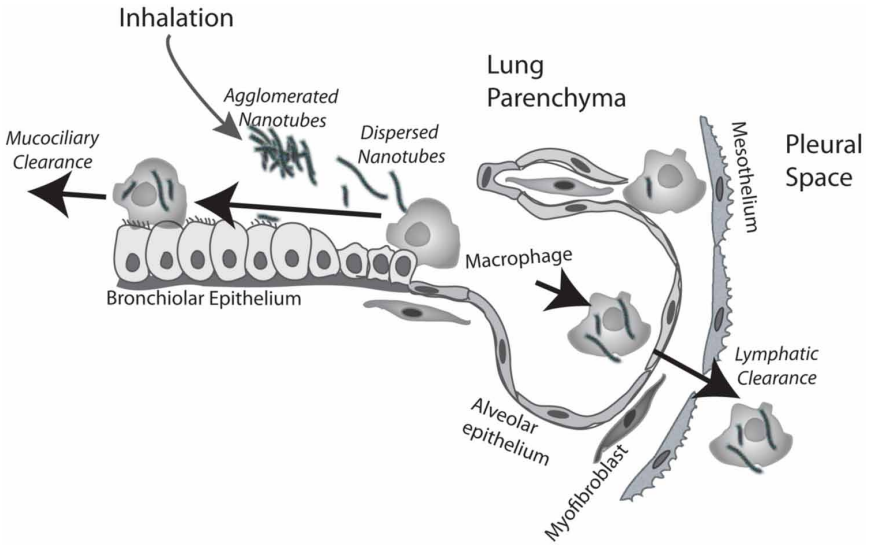
Inhalation studies are most relevant because they provide information on "real world" exposures and therefore more accurately model the true nature of deposition patterns for particles and fibers. Rodent studies show that inhaled CNTs are deposited in the distal regions of the lung, including alveolar duct bifurcations and alveolar epithelial surfaces [Ma-Hock et al. 2009; Pauluhn 2010; Mitchell et al., 2007; Shvedova et al., 2008; Ryman-Rasmussen et al. 2009 a,b]. CNTs are then mainly taken up by alveolar macrophages, which then remove shorter nanotubes (i.e., <10 μm) through airway mucociliary clearance or through the pleural lymphatic drainage. However, some individual CNTs evade phagocytosis by macrophages uptake and are internalized within epithelial cells or mesenchymal cells, or within the extracellular matrix [Ryman-Rasmussen et al. 2009a].

The site of deposition for CNTs following an inhalation exposure is determined by a variety of factors such as size, shape, electrostatic charge, and aggregation. Changing the surface features of CNTs through functionalization (e.g., carboxylation) can alter aggregation status and influence the toxicological outcome in the lung [Wang et al., ACS Nano 2011; Bonner et al., 2013]. In general, studies with mice show that inhaled, well-dispersed CNTs are deposited throughout lower airways of the lung and alveolar compartments [Figure 1]. The majority of published studies on CNT exposure in rodents employ intratracheal instillation (IT) or oropharyngeal aspiration (OPA) techniques rather than inhalation, due mainly to the relative ease and low cost of performing IT or OPA compared to inhalation. IT or OPA techniques deliver an aqueous bolus of CNT and therefore do not precisely reproduce the deposition patterns achieved by inhalation exposures with dry aerosolized or nebulized suspensions of CNTs. Many of the early reports of granulmona in the lungs of rodents caused by CNTs could be due to poor dispersion and non-specific reactions; i.e., highly agglomerated CNTs attract focal accumulations of mononuclear cells that stimulate the formation of fibrotic scar to "wall off" the CNT agglomerate. However, significant improvements have been made in dispersing CNTs in aqueous suspension by using surfactant-containing media to improve dispersal of CNTs for IT or OPA delivery to the lungs of rats and mice [Mercer et al. 2008].

CNTs are cleared from the lung by macrophage-dependent mechanisms; either via the airway mucociliary apparatus or via the pleural lymphatic drainage [Figure 2]. The mucociliary apparatus is comprised of a coating of mucus on the surface of the airways that is constantly moving up the airways by the coordinated movement of cilia on the airway epithelium [Bonner 2008]. Macrophages with engulfed particles or fibers migrate to the distal portion of small airways where they are transported by the escalator to larger airways and ultimately out of the trachea where they are swallowed or expelled through coughing. Migration of macrophages containing CNTs across the pleura, through stomata in the mesothelium that covers the pleura, could cause adverse effects (e.g. DNA damage to mesothelial cells) as CNTs could possess some physical characteristics (e.g., high aspect ratio, durability) that resemble asbestos fibers [Bonner et al., 2010a; Donaldson 2010]. However, the relative carcinogenicity of CNTs

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 1. Electron microscopic images of multi-walled carbon nanotubes in the lungs of mice 1 day following a single inhalation exposure at a dose of 30 mg/m3 for 6 hours. The upper panels show nanotubes deposited on the surface of airway epithelium. Lower panels show nanotubes within a macrophage that has migrated to the subpleural region of the lung.



compared to asbestos fibers remains a highly controversial topic and no reports of human lung disease have yet to be reported. Nevertheless, some CNTs, particularly long CNTs, remain embedded within the subpleural tissue of the lung for up to 3 months [Ryman-Rasmussen et al., 2009b]. Also, macrophages carrying CNTs that exit the lung via the pleural lymphatic system can be found in lung-associated lymph nodes [Ma-Hock et al. 2009; Pauluhn et al., 2010]. The clearance of inhaled MWCNTs from the lungs and lung associated lymph nodes (LALNs) of rats following a nose-only inhalation exposure was reported to be more than a year [Pauluhn et al., 2010]. These findings indicate that CNTs are relatively persistent in the lungs following inhalation.

Lung Inflammatory and Fibroproliferative Responses to CNTs

The acute response of inhaled CNTs, both SWCNTs and MWCNTs, is characterized by neutrophilic inflammation of the lower lungs within the alveolar regions and alveolar duct bifurcations [Bonner et al., 2013 EHP]. Macrophages provide a central role as the primary immune defense against particles CNTs, partly through clearance as mentioned above, but also the production of chemokines that drive neutrophilic inflammation. Both inhalation and instillation studies in rodents demonstrate that CNTs

Figure 2. Illustration showing the two major routes of carbon nanotube clearance, mucociliary clearance and lymphatic clearance, following inhalation exposure

cause acute lung inflammation within 1 day following exposure [Li et al., 2007; Shvedova et al., 2007; Ryman-Rasmussen et al., 2009a, b; Ma-Hock et al., 2009, Pauluhn et al., 2010]. Of greater concern are the chronic fibroproliferative effects of CNTs in the lung that may take weeks or months to manifest. Pulmonary fibrosis is a fatal disease in humans associated with occupational exposure to asbestos or certain metals such as cobalt [Bonner et al., 2010]. Fibrosis has also been reported in rodents exposed to CNTs [Mangum et al., 2006; Li et al., 2007; Shvedova et al., 2007; Ryman-Rasmussen et al., 2009a, b; Pauluhn et al., 2010]. As mentioned above, highly aggregated CNTs produce focal granulomatous lesions [Mangum et al., 2006; Lam et al., 2004; Muller et al., 2005; Shvedova et al., 2005; Warheit et al., 2004; Murray et al., 2012]. In contrast, well-dispersed CNTs, achieved by agents such as bovine serum albumin (BSA) and dipalmitoylphosphatidylcholine (DPPC), cause more diffuse fibrosis and alveolar wall thickening that is perhaps more destructive in terms of reducing lung function. Dispersed CNTs also stimulate increased growth factor (PDGF-AA, TGF-β1) production by lung cells compared to non-dispersed CNTs, supporting the idea that dispersal state determines profibrogenic cellular responses that correlate with severity of fibrosis [Wang et al., 2011].

The fibrogenic potential of CNTs is also determined by tube length; longer CNTs produce greater inflammation and fibrogenic reactions that shorter CNTs. Longer CNTs pose a problem for macrophage-mediate clearance and tubes longer than ten to fifteen micrometers (the approximate width of an alveolar macrophage) are difficult to clear from lung tissues as they impede macrophage migration and cause 'frustrated phagocytosis' that involves cell membrane damage and leakage of cytoplasmic components. This is important only with regards to certain types of rigid MWCNTs and other high aspect ratio nanomaterials and fibers, and likely does not apply to long SWCNTs which are more likely to fold upon themselves and are ingested by macrophages. Therefore, both rigidity and length are important factors in determining whether CNTs will cause frustruated phagocytosis by macrophages.

The presence of residual metal catalyst plays an important role in mediating CNT toxicity and disease potential. Nickel, cobalt, and iron are commonly used as catalysts in the manufacture of CNTs. These same

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

metals have also been reported to cause pulmonary diseases in humans, including pulmonary fibrosis and asthma [Kelleher et al., 2000]. For example, cobalt has been shown to cause 'hard metal disease' in welders and nickel is a known cause of occupational asthma and contact dermatitis. Iron has been linked to interstitial pulmonary fibrosis in occupational settings related to mining and metallurgy. Metal catalysts can be removed to some extent from CNTs by acid washing, although this process has yet to be shown completely effective in removing the metal catalyst. Nevertheless, reduction in Ni content has been shown to significantly reduce CNT-induced inflammation in the lungs of mice [Bonner et al. 2013]

Genotoxicity and Carcinogenesis

Because CNTs are cleared from the lungs in part through macrophage phagocytosis and trafficking across the pleural lining through lymphatic ducts, they have the opportunity to interact with the mesothelial lining that makes up the pleura. The durable nature of CNTs along with their fiber-like shape could pose a problem of long term lung persistence, which could result in carcinogencity and the formation of mesothelioma. CNTs have been demonstrated to migrate to the subpleural tissue in mice after a single inhalation exposure and produce aggregates of mononuclear cells on the pleural surface [Ryman-Rasmussen et al., 2009a]. MWCNT inhalation exposure has also been reported to cause subpleural fibrosis [Ryman-Rasmussen et al., 2009b]. These observations are directly relevant to early inflammatory or immune reactions that could preceed carcinogenic effects at the visceral or parietal pleura but do not directly provide evidence of tumor formation. However, a surrogate assay wherein long MWCNTs are injected into the peritoneal cavity of mice has shown granulmoma formation that suggests asbestos-like pathogenicity of CNTs [Poland et al., 2008]. Using this same intraperitoneal technique, transgenic p53 heterozygous null mice, which are susceptible to the development of mesothelioma by asbestos, were reported to have an increased incident of mesothelioma formation in the abdominal cavity after intraperitoneal injection of MWCNTs [Takagi et al., 2008].

Studies in mice have shown that MWCNTs delivered to the lungs of mice by nose-only inhalation exposure or by oropharyngeal aspiration migrate to the pleura [Ryman-Rasmussen et al., 2009a; Porter et al., 2010]. The biological response to inhaled MWCNTs was characterized by mononuclear cell accumulation at the pleural surface within 1 day after exposure and subpleural fibrotic lesions within 2 weeks, which resolved by 6 and 14 weeks, respectively [Ryman-Rasmussen et al., 2009a]. MWCNTs delivered to mice by oropharyngeal aspiration penetrate the pleural lining, suggesting direct mesothelial injury similar to asbestos fibers [Mercer et al., 2010]. However, these studies showed no evidence of mesothelioma. This may be because wild type mice are a relatively poor model for induction of mesothelioma, even when exposed to asbestos, a known inducer of mesothelioma in humans. Mesothelioma has been reported after exposure to MWCNTs in transgenic p53-deficient mice, which are susceptible to a variety of cancers [Takagi et al., 2008; Takagi et al., 2012]. Importantly, it has been demonstrated that MWCNTs or crocidolite asbestos delivered to the lungs of rats by intratracheal instillation both exhibit pleural mesothelial cell proliferation [Xu et al., 2013]. While no human data exist for cancer or other diseases as a result of CNT exposure, the issue of whether CNTs are capable of causing mesothelioma in humans remains a key topic of research that is relevant to disease prevention and an important issue linked to the regulation of engineered nanomaterials. For example, NIOSH set a recommended occupational exposure limit for MWCNT that was based on rodent studies [Castranova et al., 2012].

Cellular and Molecular Mode of Action

CNTs likely mediate toxicity similar to other fiber-like particles (e.g., ROS generation), but also might operate through unique and unexpected mechanisms since they interact at the molecular levels with cellular organelles, proteins, phospholipids, and nucleic acids. CNTs stimulate the release of a variety of cell-derived mediators such as growth factors, cytokines, chemokines, proteases, and lipid mediators that play important roles in inflammation, fibrosis, asthma, and cancer [Bonner 2010b; Thompson et al. 2013].

As mentioned above, lung macrophages play a central role in the inflammatory response to inhaled particles and fibers. CNTs have been shown to cause macrophage inflammasome activation [Palomäki et al. 2011; Meunier et al. 2012; Sun et al. 2012]. Inflammasomes are multi-scaffold cytoplasmic structures that cleave pro-IL-1β and pro-IL-18 to mature forms of these cytokines, which are then secreted by macrophages to mediate an inflammatory response. Inflammasome activation is initiated by CNT-induced lysosomal disruption and ROS production. Also, nickel catalyst in MWCNTs has been demonstrated to mediate inflammasome activation in macrophages [Hamilton et al., 2012]. Inflammasome activation is an important innate immune response and IL-1β release is important for recruiting neutrophils to the injured lung, which then play an important role the resolution of inflammation and tissue repair [Martinon 2009]. On the other hand, inflammasome activation could play a role in certain disease states, including fibrosis and asthma [Strowig et al., 2012]. Chemokines are also induced by CNT exposure and are important in orchestrating the inflammatory response in the lung. CXCL8 (IL-8), a potent neutrophil chemoattractant, is produced by a human bronchial epithelial cell line *in vitro* after exposure to MWCNT [Hirano et al., 2010]. The monocyte chemoattractantCCL2 is elevated in the lavage fluid of mice exposed to MWCNT inhalation [Ryman-Rasmussen et al., 2009a]. CCL2 is produced by a variety of cell types, including pleural mesothelial cells [Visser et al., 1998], and could play a role in mediating pleural inflammation in mice after inhalation of MWCNTs [Ryman-Rasmussen et al., 2009a].

Macrophages also play a role in lung fibrosis caused by CNTs, largely by producing soluble factors that activate lung myofibroblasts to proliferate, migrate, or produce extracellular matrix. Classically activated "M1" macrophages exposed to IFN-γ and LPS are important for microbial killing and innate immune responses. Alternatively activated "M2" macrophages exposed to Th2 cytokines IL-4 or IL-13 to produce growth factors (e.g., PDGF, TGF-β1) that are involved in the pathogenesis of fibrosis [Gordon and Martinez 2010]. CNTs, either single- or multiwalled-, delivered to the lungs of rats or mice increase PDGF and TGF-β1 [Mangum et al., 2006; Ryman-Rasmussen et al., 2009a; Cesta et al., 2010, Shvedova et al., 2005]. PDGF is a key mediator of lung myofibroblast survival, growth, and chemotaxis that serves to promote fibrogenesis [Bonner et al., 2004]. Mice exposed to SWCNTs have elevated levels of TGF-β1, which is a potent stimulator of collagen production by myofibroblasts [Shvedova et al., 2005; 2008]. Other factors in the lungs of rodents induced by SWCNT, such as osteopontin (OPN), could also serve to stimulate collagen deposition [Mangum et al., 2006]. Investigations of cell-cell interactions using co-culture systems could be very useful elucidating mechanisms through which CNTs mediate inflammation, fibrosis, or pleural disease. For example, because macrophages transport inhaled CNTs to the subpleural region of the lung, it is important to understand how CNTs influence the interaction between macrophages and pleural mesothelial cells. It has been reported that human Met5A pleural mesothelial cells do not produce inflammatory cytokines when directly challenged with MWCNTs, yet the supernatants from MWCNT-stimulated human THP-1 macrophages stimulate significant cytokine release from Met5A cells.

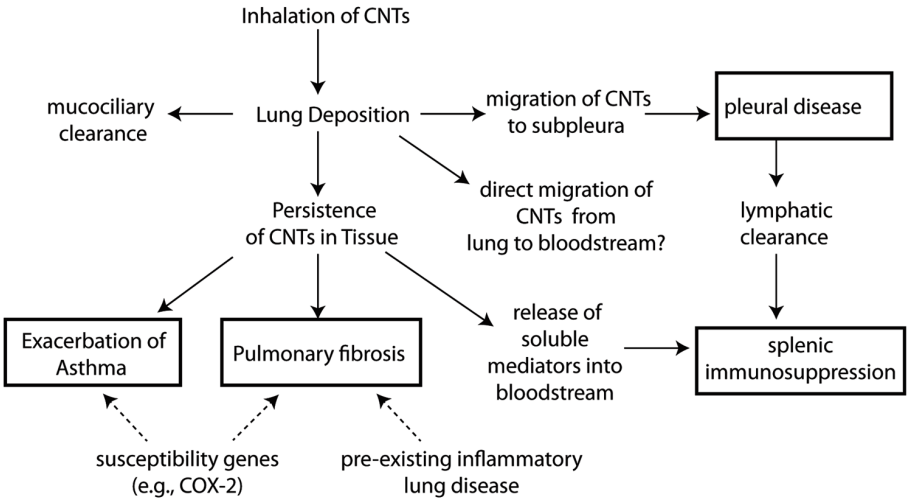
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Like other toxic fibers, CNTs mediate toxic effects on cells through the generation of reactive oxygen species (ROS). CNTs activate the antioxidant mediator Nrf2 in cultured human THP-1 cells [Brown et al., 2010]. CNTs also increase levels of the COX-2 enzyme through a MAP kinase-dependent signaling pathway in mouse RAW267 cells *in vitro* [Lee et al., 2012]. Also, COX-2 knock-out mice are susceptible to airway remodeling induced MWCNT exposure [Sayers et al., 2013]. COX-2 and Nrf2 are both protective factors against fibroproliferative lung disease that are increased to counteract ROS-induced injury initiated by CNTs.

A number of studies have addressed the possible genotoxic effects of CNTs using lung cell types and in rodents *in vivo*. SWCNTs have been shown to cause fragmented centrosomes, mitotic spindle disruption, anaphase bridges, and aneuploid chromosome number in cultured primary or immortalized human airway epithelial cell types [Sargent 2009; Sargent et al. 2012]. CNTs were also shown to disrupt mitotic spindle formation and it has been speculated that the similar size and geometry of SWCNT bundles might account for physical interaction of SWCNT with the microtubules that form the mitotic spindle. MWCNTs have been reported to cause DNA damage in mouse embryonic stem (ES) cells [Zhu 2007]. Moreover, MWCNTs accumulated and induced apoptosis in mouse ES cells and activate the tumor suppressor protein p53, a marker of DNA damage. In addition MWCNTs have been shown to cause dose-dependent genotoxic effects of structural chromosome aberrations, DNA damage, and micronuclei formulation in mice when administered by intraperitoneal injection [Patiolla et al., 2010]. Persistent DNA damage was reported in rat lung cells one month post-inhalation exposure to MWCNTs [Kim et al., 2012]. Therefore, it appears that both SWCNT and MWCNT have genotoxic effects in cultured cells and in the lungs of rodents *in vivo*.

EMERGING ISSUES AND CONTROVERSIES

Human Exposure and Potential Risk of Disease



It is currently unknown whether CNTs will cause fibroproliferative or carcinogenic effects in humans. However, human exposure to CNTs is inevitable, especially in occupational settings where relatively high amounts of CNTs are synthesized, refined, or functionalized. The lack of human exposure data is due to the infancy of the nanotechnology field in general. Moreover, it could be years before any epidemiologic data are available, as lung fibrosis or cancer caused by inhaled toxic particles and fibers can take years to manifest in humans. Evidence from rodent studies indicates that some adverse effect will be observed in humans exposed to some types of CNTs, particularly long, rigid tubes that are more difficult to clear from the lungs.

Functionalization of Carbon Nanotubes

Nearly all of the published work on CNTs have used ‘pristine’ or unmodified nanotubes that are generated by processes such as carbon vapor deposition. These studies are probably most relevant to human occupational exposures where individuals will be exposed to CNTs directly after synthesis. However, most CNTs will likely undergo some sort of post-synthesis processing or ‘functionalization’ to modify the surface properties of the CNT. This means that most consumer and environmental exposures will be related to some type of functionalized CNT. For example, aggregation of CNTs due to electrostatic

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 3. Diagram showing potential adverse effects of carbon nanotubes on lung and other organs systems following inhalation exposure. Adverse disease outcomes are in boxes. Dotted arrows indicate factors that influence disease severity.

forces presents a problem for the purposes of many engineering designs and a variety of dispersal agents (e.g., surfactants) have been employed to improve dispersion by reducing electrostatic attraction. More dispersed CNTs delivered to mice cause a more severe chronic interstitial fibrosis in the lungs along with elevated levels of growth factors (PDGF and TGF-β1) that play important roles in fibrogenesis [Wang et al., 2011]. However, some functionalizations can reduce the fibrogenic response of CNTs, even though they remain dispersed. For example, carboxylated (COOH)-CNTs cause less neutrophilic lung inflammation as compared to unmodified CNTs [Bonner et al., 2013], and cause less pulmonary fibrosis [Wang et al., 2011]. In contrast to COOH-CNTs, polyetherimide (PEI) functionalized CNTs increased collagen deposition and fibrosis in the lungs of mice [Li et al., 2013]. Therefore, some functionalization processes reduce toxicity and lung injury while others increase toxicity and the potential for disease. Therefore, in order to carefully assess human health effects, consideration should be given to both acute and chronic effects of functionalized CNTs in particular and to engineered nanomaterials in general. A increasing variety of functionalizations are employed to modify specific characteristics of CNTs, which makes assessing the toxicity each type of functionized CNT in rodents impractical. In response to this growing challenge, high through-put screening techniques will be necessary to test the vast majority of engineered nanomaterials for toxic signatures [Nel et al., 2013].

Environmental and Genetic Susceptibility Factors

It is likely that CNTs might have the most profound adverse health effects on individuals with pre-existing respiratory diseases such as asthma, bronchitis, or chronic obstructive pulmonary disease (COPD) [Bonner 2010a, Bonner 2011]. A variety of environmental and genetic susceptibility factors will likely influence CNT toxicity [Figure 3]. Allergic airway remodeling in mice induced by ovalbumin allergen challenge is exacerbated by SWCNTs or MWCNTs, suggesting that CNTs have the potential to exacerbate asthma in humans [Ryman-Rasmussen et al., 2009b; Inoue et al. 2009; Inoue et al., 2010; Nygaard et al. 2009].

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

In addition to asthma exacerbation, repeated exposure to MWCNTs induces a Th2 allergic response in the absence of any allergen pre-exposure, suggesting that CNTs possess adjuvant-like properties [Park et al., 2009; Beamer et al. 2013]. However, it remains unknown whether CNTs will cause or exacerbate asthma in humans.

Bacterial or viral infection could also be important environmental susceptibility factors in determining CNT toxicity in the lung. Lipopolysaccharide (LPS) derived from gram-negative bacteria mediates a variety of occupational and environmental lung diseases in humans. SWCNTs or MWCNTs exacerbate LPS-induced lung inflammation, pulmonary vascular permeability, and production of pro-inflammatory cytokines in the lungs of mice [Inoue et al., 2008]. LPS pre-exposure also enhances MWCNT-induced pulmonary fibrosis in rats and synergistically enhances MWCNT-induced production of PDGF by rat alveolar macrophages and lung epithelial cells [Cesta et al., 2010]. These studies indicate that pre-existing neutrophilic inflammation caused by LPS is a major determinant in CNT lung toxicity and suggests that individuals with pre-existing neutrophilic lung inflammation would be at increased risk for CNT-induced lung disease.

In addition to environmental susceptibility factors, a variety of genes play important roles in determining susceptibility to CNTs and other engineered nanomaterials. For example, mice deficient in the COX-2 enzyme are susceptible to exacerbation of allergen-induced airway remodeling by CNTs [Sayers et al., 2013]. While COX-2 mediates pro-inflammatory effects, it has also been implicated in the pathogenesis of asthma and pulmonary fibrosis [Bonner 2010]. Mice deficient in myeloperoxidase (MPO) have fewer CNTs in their lungs compared to wild type counterparts, suggesting that MPO mediates the degradation of some CNTs in the lungs [Shvedova et al., 2012]. It is likely that many genes will influence the disease potential of CNTs and therefore relative expression of these genes will determine individual susceptibility in humans.

Systemic Effects of Inhaled CNTs

Growing evidence indicates that inhaled CNTs move from the lungs into the circulation or lymphatic system to reach other organs [Figure 3]. Some of the CNTs delivered to the lungs of rodents are removed via the lymphatic system and localize in lymphoid tissues [Ma-Hock et al. 2009, Pauluhn 2010]. In addition, inhaled CNTs can cause systemic effects by stimulating resident lung cells to produce soluble mediators that enter the circulation and cause splenic immunosuppression [Mitchell 2007]. This particular mechanism involved the release of TGF-β1 from the lung which enters the bloodstream to signal COX-2-mediated increases in prostaglandin-E2 and IL-10 in the spleen, which in turn suppress T cell proliferation [Mitchell 2009]. CNTs delivered to the lungs of mice have been reported to exacerbate cardiovascular disease, although it is unclear whether this effect is due to direct translocation of CNTs to heart tissue or the release of soluble inflammatory mediators from the lungs [Erdely et al., 2009]. Recent evidence shows that CNTs delivered to the lungs of mice are capable of reaching multiple organ systems, including kidney, liver, and brain [Mercer et al., 2013]. Nevertheless, there is little information available on whether CNTs adversely affect the physiology of these organ systems and this is an important area for future research.

Transcriptomics and Proteomics Related to CNT Toxicity

The majority of studies on CNT toxicology have focused on selected mediators of tissue injury or disease progression. However, it will be increasingly important to consider how a rapidly growing number of engineered nanomaterials, including CNTs, affect large sets of genes or protein expression in cells or tissues. It is anticipated that such investigations will lead to gene or protein expression profiles that can be used to assess CNT risk for disease using cultured cells, thereby reducing the need for animal studies. For example, a recent transcriptomics study comparing lung tissue from CNT exposure of mice *in vivo* to cultured lung epithelial cells exposed to CNTs *in vitro* showed some similarities observed between the two models at the pathway-level, but many of the specific genes altered under these pathways were different [Søs Poulsen et al., 2013]. These findings indicated that the underlying mechanisms of responses are different in cells in culture as compared to lung tissue and the authors suggested that careful consideration should be given to the selection of relevant endpoints when substituting animal with *in vitro* testing. Proteomics have also been valuable in comparing CNTs to carcinogenic and fibrogenic fibers. For example, proteomic analysis of lung tissue from mice exposed to SWCNTs, crocidolite asbestos, or carbon black nanoparticles supported the conclusion that lung tissue responses to SWCNTs and crocidolite asbestos were similar, but the response was generally greater on a mass dose basis for SWCNTs than for asbestos [Teeguardin et al., 2011]. These examples highlight the utility of transcriptomic and proteomic analysis for predicting risk of CNTs in human disease. Such studies will be valuable to assessing the toxicity of a growing number of functionalized CNTs.

CONCLUSION AND FUTURE DIRECTIONS

Carbon nanotubes have enormous potential for technological innovation in engineering, electronics, and medicine. However, careful consideration should be given to the potential human health risks that CNTs pose in occupational, consumer, or environmental exposure scenarios. Predictions that CNTs will have the potential to cause fibrosis and/or cancer in humans are based on physical similarities to toxic fibers and growing evidence that CNTs cause fibrosis and perhaps cancer in rodents. As with other engineered nanomaterials, the nanoscale of CNTs make it difficult to predict how these structures will interact with intracellular structures such as DNA, cell membranes, and cytoskeletal proteins. Also, CNTs contain residual metals (e.g., nickel, cobalt, iron) introduced from the manufacturing process and many of these metals are known to cause fibrosis or cancer in humans. Finally, a variety of post-synthesis functionalization modifications will be applied to CNTs to enhance their novel properties and it is anticipated that high throughput screening techniques will be required to assess the toxicity of a growing number of CNT types.

KEY TERMS AND DEFINITIONS

Engineered Nanomaterial: An intentionally manufactured nanoparticle with precise physical and chemical characteristics.

Functionalized Carbon Nanotube: A carbon nanotube with intentional post-synthesis modifications to alter surface properties and functionality.

Immunosuppression: Reduced activity and function of immune cells resulting in impaired host defense.

Mesothelioma: Rare cancer affecting the mesothelial linings of the lungs and chest cavity and most often associated with asbestos exposure.

Multi-Walled Carbon Nanotube: A carbon nanotube composed of multiple concentric stacks of graphene.

Pulmonary Fibrosis: Tissue scarring in the lung alveolar region usually associated with environmental exposure to inhaled particles or fibers.

Single-Walled Carbon Nanotube: An engineered nanomaterial consisting of a cylindrical, hollow tube of graphene.

Chapter 57
Understanding Toxicity of Nanomaterials in Biological Systems

Irshad Ahmad Wani
Jamia Millia Islamia, India

Tokeer Ahmad
Jamia Millia Islamia, India

ABSTRACT

Nanotechnology is a growing applied science having considerable global socioeconomic value. Nanoscale materials are casting their impact on almost all industries and all areas of society. A wide range of engineered nanoscale products has emerged with widespread applications in fields such as energy, medicine, electronics, plastics, energy and aerospace etc. While the market for nanotechnology products will have grown over one trillion US dollars by 2015, the presence of these material is likely to increase leading to increasing likelihood of exposure. The direct use of nanomaterials in humans for medical and cosmetic purposes dictates vigorous safety assessment of toxicity. Therefore this book chapter provides the detailed toxicity assessment of various types of nanomaterials.

INTRODUCTION

The field of nanotechnology is a fast-growing research niche (Ostiguy et al., 2006). Nanoparticles are particles that have at least one dimension in nanoregime, i.e., less than 100 nm. Nanotechnology is a comprensive term that involves the ability to work with materials at a nanometre scale. Nanotechnology has a potential applications in a range of sectors including energy (production, catalysis, storage), materials (lubricants, abrasives, paints, tires, and sportsware), electronics (chips and screens), optics, and remediation (pollution absorption, water filtering and disinfection), cosmetics (skin lotions and sun screens), and medicine (diagnostics and drug delivery) to food (additives and packaging) (Joner, Hartnik, & Amundsen, 2007; Rana & Kalaichelvan, 2013). The word ”nano,” is derived from the Greek “nanos” meaning “dwarf”, and is becoming increasingly widespread in scientific literature. “Nano” word has

become so popular in modern science that many "nano-"derived words have recently find their places in dictionaries, including: nanometer, nanoscale, nanoscience, nanotechnology, nanostructure, nanotube, nanorod nanowire, and nanorobot and many more. Many new words like nanoelectronics, nanocrystal, nanovalve, nanoantenna, nanocavity, nanoscaffolds, nanofibers, nanomagnet, nanoporous, nanoarrays, nanolithography, nanopatterning, nanoencapsulation, etc. are used in respected and reputed publications, such as Science and Nature that are not yet widely recognized. The nanometer denotes one billionth of a meter or 10^{-9} meters and is a metric unit of length. The word 'nano' is popularly used as an adjective to describe objects, systems, or phenomena with characteristics arising from nanometer-scale structure and emphasize the atomic granularity that produces the unique phenomena observed in nanoscience. Most of the exciting properties begin to be apparent in systems smaller than 1000 nm, or 1 micrometer, 1 μm. Birth of the concept of nanotechnology is usually linked to a speech by Richard Feynman at the December 1959 meeting of the American Physical Society (Feyman, 1959) where he asked a very funny and strange question to the scientific audiences, "What would happen if we could arrange the atoms one by one the way we want them?"

Nanomaterials are materials possessing structural components smaller than 1 micrometer in at least one dimension. Many authors, however, limit the size of nanomaterials to 50 nm (Kittelson, 2001) or 100 nm (Borm et al., 2006), the choice of this upper limit being justified by the fact that some physical properties of nanoparticles approach those of bulk when their size reaches these values. However, a legitimate definition extends this upper size limit to 1 micron, the sub-micron range being classified as nano(Buzea, Pacheco, & Robbie, 2007b).

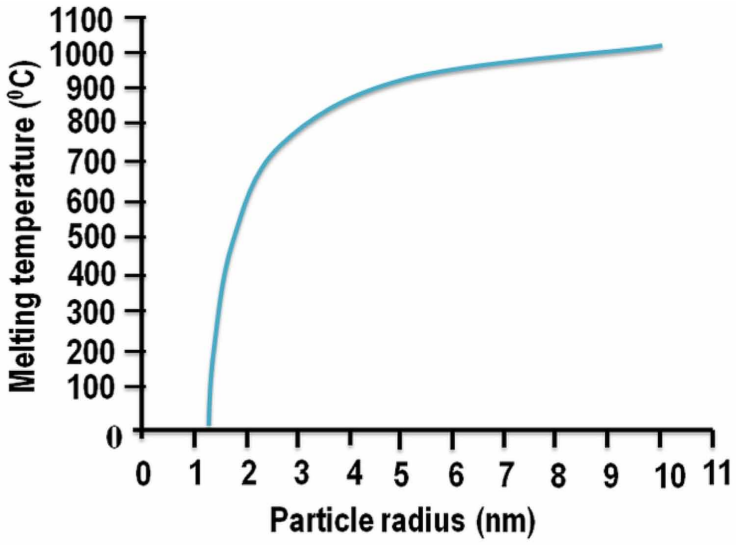
Nanoparticles are particles potentially as small as atomic and molecular length scales (~0.2 nm) or with at least one dimension falling in nanoregime. Nanoparticles can be amorphous or crystalline and their highly active surfaces can act as carriers for gases or liquid droplets. Nanoparticulate matter should be considered as a distinct state of apart from the solid, liquid, gaseous, and plasma states owing to their distinct properties like large surface area and quantum size effects.

Nanomaterials being versatile in nature has various applications in biology and medicine such as Fluorescent biological labels(Fu et al., 2007), drug and gene delivery(Yan & Chen, 2013)(Malmsten, 2013), bio detection of pathogens (Yang, Li, & Jiang, 2008), detection of proteins(Yi Zhang et al., 2013), probing of DNA structure (Mahtab & Murphy, 2005), Tissue engineering (Cipriano & Liu, 2013), tumour destruction via heating (hyperthermia) (Dutz & Hergt, 2014), MRI contrast enhancement (Na, Song, & Hyeon, 2009) etc

NANO VS. BULK MATERIALS AND NANOTOXICOLOGY PUBLICATION STATISTICS

Nanomaterials behave significantly different from bulk materials due to two primary factors which are surface effects and quantum effects (Roduner, 2006). These two factors affect the mechanical, electrical, optical and magnetic as well as chemical reactivity of the materials. Compared to the microparticles, nanoparticles have a very large surface area and high particle number per unit volume due to the high fraction of atoms at the surface. For example the ratio of surface area to volume (or mass) for a carbon particle with a diameter of 60 nm is 1000 times larger than a particle with a diameter of 60 μm. Since the material in nanoparticulate form presents a much large surface area, due to which chemical reactivity of the material is greatly enhanced roughly 1000 folds. The atoms situated at the surface has lower

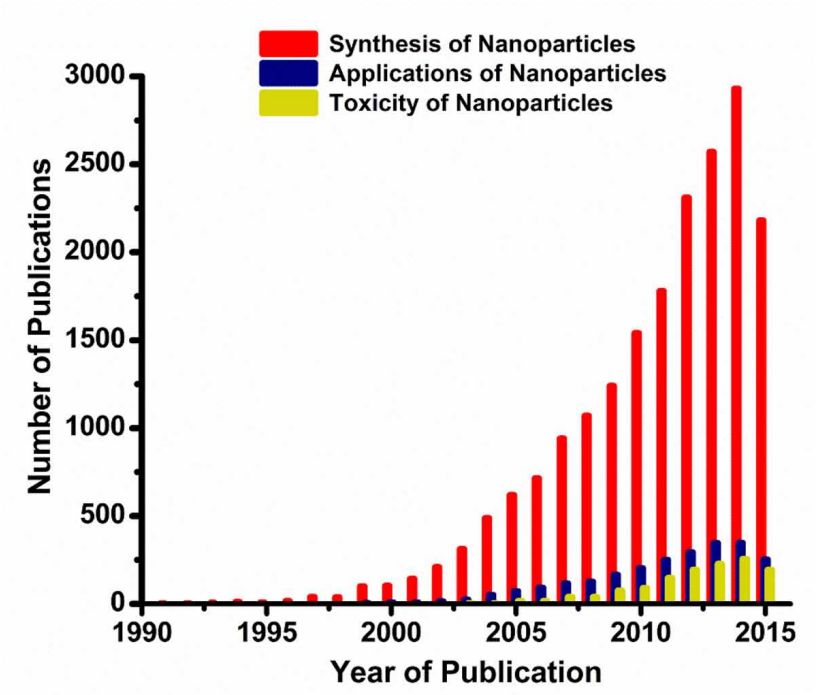
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



binding energy per atom due to the lesser no of neighbors than bulk atoms (Roduner, 2006). As a result, melting point reduces with reduction in particle size due to lesser binding energy at smaller particles sizes as followed from the Gibbs-Thomson equation. For example, the melting temperature of 3 nm gold nanoparticles is more than 300 degrees lower than the melting temperature of bulk gold (Roduner, 2006) (Figure 1).

There has been an exponential increase in the number of publications on the synthesis and properties of nanoparticles since 1090s (Figure 2) as indicated by the advanced search on Google Scholar Database. There is also an increase in number of publications discussing their toxicity for the past few years (Figure 2). However, the total no of papers on toxicity remains low in comparison to the total no of papers published on nanomaterials. Since Nanoscience and Nanotechnology encompasses a wide range of fields ranging from chemistry to physics, materials science and engineering, biology, medicine and electronics, which explains the reason of the vast no of papers published in this field. However, several reviews have been published addressing the nanotoxicology aspects of nanomaterials. Several are comparatively general(Borm et al., 2006; Nel, Xia, Mädler, & Li, 2006; X. Zhang, Hu, Li, Tao, & Wei, 2012) while others address selected aspects of nanoparticles toxicology such as occupational aspects of nanoparticle(Pfau, Sentissi, Weller, & Putnam, 2005); particle inhalation, retention, and clearance (Buzea, Pacheco, & Robbie, 2007a); pulmonary effects of inhaled particles (Oberdörster, 2000); inhalation and lung cancer(Borm, Schins, & Albrecht, 2004), oxidative mechanisms(Brown, Lockwood, & Sonawane, 2005; González-Flecha, 2004; Peters, 2005) and gastro-intestinal uptake of particles (Fubini & Hubbard, 2003).

Nanoparticle Synthesis



Various excellent review have been published on the synthesis and characterization of nanomaterials (Saber M Hussain et al., 2009; Rodriguez-Hernandez, Chécot, Gnanou, & Lecommandoux, 2005; Teow, Asharani, Hande, & Valiyaveettil, 2011; Y. Wang & Cao, 2006). Two different but complementary

Figure 1. A plot of melting temperature of gold as a function of size

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

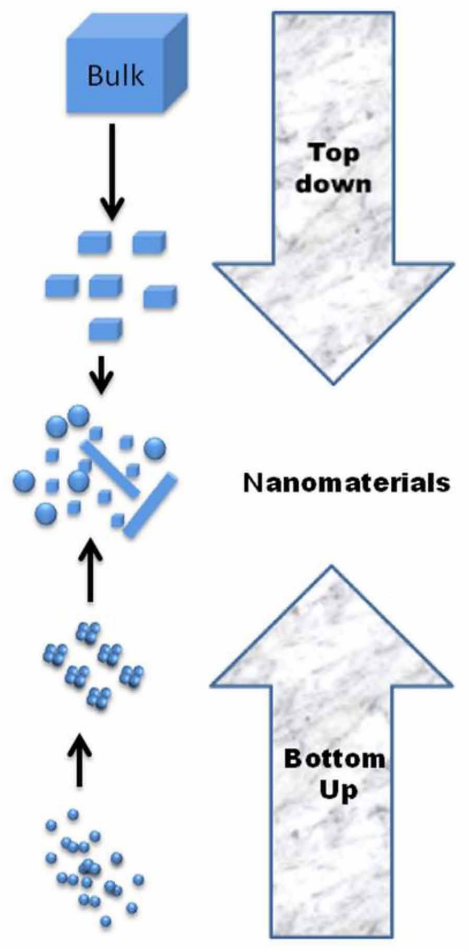
Figure 2. Evolution of no of papers on Synthesis, Applications and Toxicity on nanoparticles since 1990

approaches have been used for synthesizing nanomaterials (Figure 3). First one known as "top-down" approach where bulk materials are broken down into particles in nanorange by physical processes such as milling, grinding, etching and pyrolysis. In this approach particle size of the starting bulk material is reduced to nanorange using mechanical or chemical methods. Photolithography and silicon microfabrication are two processes often employed or prepared using the top-down approach (Mishra, Patel, & Tiwari, 2010). This approach has the advantage of the possibility of mass production for industrial purposes. However, this approach involves some disadvantages such as lengthy time consuming processes, generation of a broad feature size distribution, and imperfection or defects of the surface morphology generated. Since surface deformations can have a significant impact on the physical and chemical properties of the nanomaterials(Thakkar, Mhatre, & Parikh, 2010).e.g., pyrolysis involves the burning of organic precursor after forcing through an orfice at high pressures. The resulting ash produced is processed to recover the oxidized nanoparticles having wide particles size distribution. (Thakkar et al., 2010), thus consuming an enormous amount of energy so as to sustain high pressures. Bottom-up approach, involves creation of nano-objects by combining atomic scale materials. A variety of bottom up approaches exist involving comples coacervation of two oppositively charged polyelectrolyted, co-precipitation, salting out from aquous-organic mixture or solvent displacement, solvent emulsification, diffusion using oil-water microemulsions or using supercritical fluids. The process operated under ambient conditions leading to high energy saving. A wide variety of nanomaterials can be generated using this approach including nanoemulsions, liposomes, polymeric NPs, polymeric micelles, solid lipid NPs, protein NPs and carbohydrate such as chitosan, alginate, hyaluronic acid, dextran nanoparticles(Zonghua Liu, Jiao, Wang, Zhou, & Zhang, 2008; Szarpak et al., 2010). The most commonly employed method involves the

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

chemical reduction of metal ions by a suitable reducing agent in the presence of a capping or stabilizing agent. The metal atoms obtained after reduction of the metal ions aggregate to form metal nanoparticles. The further growth of these metal nanoparticles is inhibited by the addition of the suitable capping agent which works either by conferring a suitable charge to the surface which repels neighboring naoparticles or by sterically preventing the agglomeration of two NPs (Thanh & Green, 2010). Examples of such capping agents include carboxylic acids or amines. Capping agent also serves important function such as controlling particle size, shape, charge and surface functionality which can lead to special properties. There has been a growing interest in synthesis of nanoparticles using biological approaches using bacteria (Reddy et al., 2010), yeast (Kowshik et al., 2003) fungi, plants and algae (Thakkar et al., 2010). This method offers advantage over conventional chemical methods as avoid the use of toxic organic solvents and reagents, generation of hazardous side-products, high cost and energy consumption. The nanoparticles produced by this approach relatively non-toxic and biocompatible. Nanoparticles of different materials ranging from from Ag, Au, CdS, magnetite and uranium were produced using biological approach (Nanda & Saravanan, 2009). A similar method has been used in the synthesis of Ag NPs using fungal cell filtrate (Gajbhiye, Kesharwani, Ingle, Gade, & Rai, 2009).

Toxicity of Different Nanoparticles



There has been tremendous expansion in research on potential application of nanotechnology in medicine ranging from exploiting nanomaterials as carriers of active pharmaceutical drugs in delivery and targeting applications to medical imaging purposes (Moghimi, Hunter, & Murray, 2005). These nanosized materials can affect biological functions by interaction with the biological tissues. Recent studies on potential nanotoxicity to human health and the eco-environment have drawn attention from both government agencies and the general public (Crist et al., 2013; Monteiro-Riviere, Inman, & Zhang, 2009). With the increasing commercialization and increasing human exposure of animals to nanomaterials, a safety assessment of these materials is needed. To facilitate such efforts, we herein present a brief survey the toxic effects of several organic and inorganic several nanocatalysts, mainly used in environmental remediation.

Carbon-Based Nanomaterials

There are three well-known carbon-based nanomaterials like fullerenes (Da Ros & Prato, 1999), carbon nanotubes (CNTs) (Ajayan & Zhou, 2001), and graphene (Sun et al., 2008). Regarding the cytotoxicity of C60 nanoparticles on various cell lines, controversial results have been published (Lewinski, Colvin, & Drezek, 2008). C60 nanoparticles have been found to be cytotoxic to some cell lines such as such as human dermal fibroblasts (HDFs)(Sayes et al., 2004, 2005) human liver carcinoma cells (HepG2) (Sayes et al., 2004, 2005), human epidermal keratinocytes (HEK)(Saathoff, Inman, Xia, Riviere, & Monteiro-Riviere, 2011), rat C6 glioma cells(Isakovic et al., 2006), and human U251 glioma cells(Isakovic et al., 2006), whereas no significant cytotoxic responses to pristine C60 nanoparticles were observed in murine macrophages(Fiorito, Serafino, Andreola, & Bernier, 2006), human monocyte-derived macrophages (Fiorito et al., 2006; Porter, Muller, Skepper, Midgley, & Welland, 2006), and Guinea pig alveolar macrophages(G. Jia et al., 2005). However it has been observed that surface functionalization of C60 particles may partially alleviate their cytotoxicity and reduce reactive oxygen species (ROS) generation(Sayes et al., 2004), but not in all the cases, since polyhydroxylated fullerenes can still in-

Figure 3. Two different approaches viz., Top down and Bottom up approaches for synthesis of nanomaterials

duce photooxidative stress in human cells(Vileno et al., 2006; Wielgus, Zhao, Chignell, Hu, & Roberts, 2010). In comparison to C60 nanoparticles, both single walled carbon nanotubes (SWCNTs) and multiwalled carbon nanotubes (MWCNTs) exhibit cytotoxic effects at high concentrations. Cytotoxicity of both types of carbon nanotubes has been observed in HEK(Monteiro-Riviere & Inman, 2006), human embryo kidney cells (HEK293)(Cui, Tian, Ozkan, Wang, & Gao, 2005), rat alveolar macrophage cells (NR8383)(Pulskamp, Diabaté, & Krug, 2007), human alveolar epithelial cells (A549) (Pulskamp et al., 2007), human skin fibroblasts (HSF42)(Ding et al., 2005), and human embryonic lung fibroblasts (IMR-90) (Ding et al., 2005). MWCNTs and SWCNTs induced pulmonary inflammatory responses and granuloma formation after intratracheal instillation in animal models (Chou et al., 2008; Lam, James, McCluskey, & Hunter, 2004; Muller et al., 2005). However literature reports have proven that SWCNTs are more toxic than MWCNTs and C60 nanoparticles (G. Jia et al., 2005; Pulskamp et al., 2007; Tian, Cui, Schwarz, Estrada, & Kobayashi, 2006). With surface functionalization the cytotoxicity effects of pristine SWCNTs can be lessened and the extent of cytotoxicity depends upon the degree of sidewall functionalization (Sayes et al., 2006).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Likewise graphene and its derivative like graphene oxide have been shown to have cytotoxicity effects in a dose dependant manner in various cells including A549, Henrietta Lacks cells (HeLa), National Institute of Health 3T3 mouse fibroblast cells (NIH-3T3), Sloan Kettering breast cancer cells (SKBR3), Michigan cancer foundation-7 breast cancer cells (MCF7), human neuroblastoma SH-SY5Y cells and even normal human lung cells (BEAS-2B)(Chang et al., 2011; Lv et al., 2012; Vallabani et al., 2011). Size and surface coating have been observed to influence the cytotoxicity of graphene and its derivatives. Reduced graphene oxide nanoplatelets (rGONPs) with average lateral dimensions (ALDs) of 11 ± 4 nm caused considerable cell destruction at the concentration of 1.0 μg/mL, while the rGONPs with ALDs of 3.8 ± 0.4 μm exhibited significant cytotoxic effects only at high concentrations of 100 μg/mL(Akhavan, Ghaderi, & Akhavan, 2012). In addition, surfaces coated with chitosan significantly reduce the haemolytic activity of GONP to human erythrocytes (RBCs) (Liao, Lin, Macosko, & Haynes, 2011).

Metal Nanoparticles

Although great progress have been made towards production of metal based nanoparticles worldwide both at the academic as well as at the industrial level, but still there is a serious lack of information about the impact of NPs on human health and environment, especially the potential for NP-induced toxicity(Canesi et al., 2008). Preliminary reports of the inherent toxicity of some NPs are available and indicate that they can affect biological behavior at the organ, tissue, cellular, subcellular, and protein levels (Schrand et al., 2010).

Aluminum Nanoparticles

Cellular interaction of aluminum oxide and aluminum nanoparticles including their effect on cell viability and cell phagocytosis, with reference to particle size and chemical composition has been investigated by Wagner et al (Wagner et al., 2007). Experiments were conducted to know the in vitro cellular effects of aluminium nanoparticles in rat alveolar macrophages (NR8383). Characterization techniques employed showed agglomeration in cell exposure media and Aluminium (Al) NP in the dose range of 100 to 250 μg/mL produced significantly reduced viability after 24 h of continuous exposure. No significant effect on the cellular viability was observed at 50, 80, or 120 nm Al NPs at 25 μg/mL for 24 h but cell phagocytotic ability was significantly hindered by exposure to same concentration (25 μg/mL) (Braydich-Stolle, Hussain, Schlager, & Hofmann, 2005).

Copper Nanoparticles

Copper nanoparticles (Cu NPs) have been recently investigated as a novel antimicrobial material, i.e. antiviral, antibacterial, antifouling, and antifungal and used in applications as biocides, antibiotic treatment alternatives, and nanocomposite coatings(Anyaogu, Fedorov, & Neckers, 2008; Cioffi et al., 2005). However, severe toxicity of Cu NPs have been demonstrated including heavy injuries in the kidney, liver, and spleen of mice after ingestion, as evident via histological analysis(Z. Chen et al., 2006). The Cu nanoparticles (23.5 nm) with oral LD50 of 413 mg/kg, is considered to be moderate toxic similar to Zn powder(Z. Chen et al., 2006; Suzuki, Toyooka, & Ibuki, 2007) in contrast to Cu microparticles (17 μm) which did not produce similar effects and were classified as nontoxic with LD50 values of >5000 mg/kg. Moreover, mice exposed to Cu NPs showed glomerulitis degeneration, and necrobiosis of renal

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

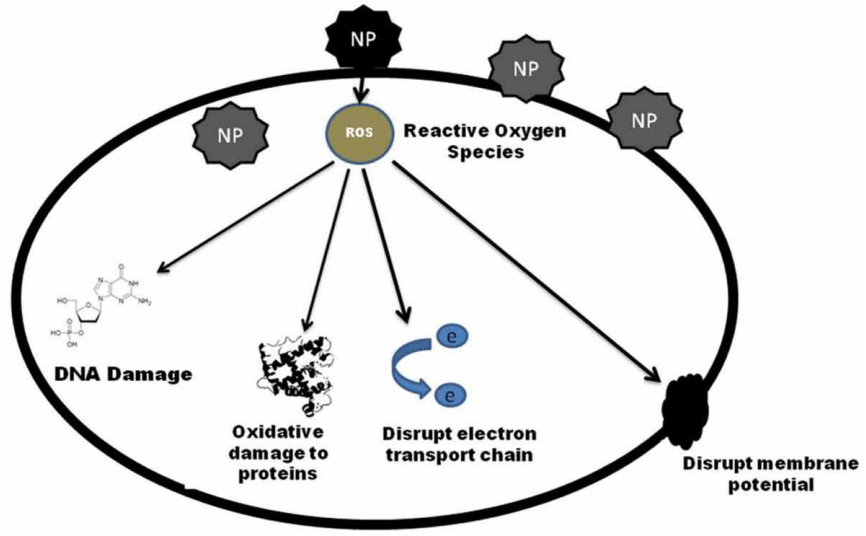
tubules, but not in the mice exposed to Cu microparticles indicating that particle size and surface area are important material characteristics from a toxicological perspective. Meng et al gave the supporting evidence for the more efficient deposition of Cu NPs compared to micro-sized particles in renal tissues. They proposed that once inside the kidney, Cu NPs reacted with gastric juices and were converted to more toxic cupric ions (Meng et al., 2007).

Toxicity of Cu nanoparticles (80 nm) (1.5 mg/L; LC50) was also investigated and reported in zebrafish showing a decrease in gill Na^+/K^+ ATPase activity(Griffitt et al., 2007). Cu NP treatment also decreased blood urea nitrogen (BUN) levels and increased plasma alanine amino transferase (ALAT) levels. Additionally, dose-dependent damage of gill lamellae characterized by proliferation of epithelial cells, as well as edema of primary and secondary gill filaments, was observed after Cu NP treatment, indicating that the gill was the primary target organ for CuNP in zebrafish (Griffitt et al., 2007). In zebrafish exposed to Cu NPs, RT–PCR results showed higher levels of gene expression changes compared to $CuSO_4$ exposed fish. Furthermore, cluster analysis of these gene microarrays demonstrated that the transcriptional response induced by Cu NP was highly divergent (Griffitt et al., 2007).

Gold Nanoparticles

Several factors play important roles in determining the cytotoxicity of GNP, most important being the surface properties which have been shown to affect the biological interactions of GNPs (S. T. Kim, Saha, Kim, & Rotello, 2013). In one of the studies, polyethylenimine-modified GNPs has been shown to cause decrease in cell viability of in monkey kidney cells (COS-7) (Thomas & Klibanov, 2003). However, surface modified GNPs with different surface charges exhibited different cell uptake (Su et al., 2012) and toxic effects (Goodman, McCusker, Yilmaz, & Rotello, 2004) in cells. For instance, during cellular uptake, positively charged GNPs were reported to modulate the cell membrane potential and cause cell membrane perturbations. However, peptide functinalized GNPs were found to enter cells and targeted the nucleus without decreasing cell viability (Tkachenko A G, Xie H, Coleman D, Glomm W, Ryan J, Anderson M F, Frazen S, 2003). Apart from the surface properties, the particle size is another important physical parameter that determines the cytotoxicity of GNPs. Triphenylphosphine derivative-stabilized GNPs of 1.4 nm diameter exert most prominent cytotoxic effect when added to HeLa cells, SK-Mel-28 melanoma cells, L929 mouse fibroblasts, and mouse monocytic/macrophage cells (Pan Y, Neuss S, Leifert A, Fischer M, Wen F, Simon U, Schmid G, Brandau W, 2007). GNP-induced cytotoxicity was also found to depend on the cell type (Patra, Banerjee, Chaudhuri, Lahiri, & Dasgupta, 2007). In addition to cytotoxicity, GNPs cause an immunological response in cells. For instance, the surface hydrophobicity of GNPs dictates the immune response of splenocytes (Moyano et al., 2012).

The GNP dose is important for the toxicity of the nanomaterial *in vivo*. Intraperitoneal administration of 13 nm GNPs at the dose up to 0.4 mg/Kg/day was found to cause no acute or subacute physiological damage (Lasagna-Reeves et al., 2010), daily intraperitoneal administration of GNPs at the rate of 1.15 mg/Kg/day for fourteen days caused severe sickness in mice (Y. S. Chen, Hung, Liau, & Huang, 2009). Keeping the particle size of GNP in consideration as an important factor in vivo, GNPs of 3, 5, 50, or 100 nm at a dose of 8 mg/kg/week did not show harmful effects in mice. However, GNPs with a size ranging from 8 to 37 nm at the same dose caused a loss of structural integrity in the liver with an increase in Kupffer cells and the diffusion of white pulp in the spleen (Y. S. Chen et al., 2009). There are also some reports showing size dependant toxicity of gold nanoparticles with gold nanorods showing higher toxicity than gold nanospheres (Yinan Zhang, Xu, Li, Yu, & Chen, 2012)



EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

The generation of ROS and reactive nitrogen species (RNS) is considered to be responsible for GNP-induced toxicity. Oxidative stress-related autophagy or necrosis in HeLa cells and MRC-5 human fetal lung fibroblasts were found to be induced by GNPs (J. J. Li, Hartono, Ong, Bay, & Yung, 2010; Pan et al., 2009). GNPs were also found to be responsible for the release of nitrogen oxide (NO) from endogenous *S*-nitroso adducts with thiol groups in blood serum (H. Y. Jia et al., 2008). GNPs also inhibited vascular endothelial growth factor (VEGF)-induced cell proliferation by affecting related signaling pathways (Bhattacharya et al., 2004; Kalishwaralal et al., 2011). Furthermore, respiratory activity of macrophages and the activity of macrophage mitochondrial enzymes (Staroverov et al., 2009) was found to be stimulated by both citrate-coated and antigen-conjugated GNPs (Staroverov et al., 2009). Figure 4 shows the schematic representation of the possible mechanistic pathway of nanoparticles on cell toxicity.

Silver Nanoparticles

Ag NPs have been previously seen wide use as antimicrobial agents and are have recently received considerable attention for use in possible defense and engineering applications (Arora, Jain, Rajwade, & Paknikar, 2008; Chadeau, Oulahal, Dubost, Favergeon, & Degraeve, 2010) Therefore, exposure to Ag nanoparticles underlines the underline the importance of assessing new uses of NPs for potential cytotoxicity. Such an evaluation was undertaken for Ag NP coated cotton fabric and the treated fabric caused no skin irritation and hence was found to be to be safe to guinea pigs (YeonáLee, KunáPark, MiáLee, & BumáPark, 2007). Ag NPs were has been reported to be safe to human cell carcinoma and human fibrosarcoma cell lines (Arora et al., 2008). However, Ag NPs have been found to agglomerate in the cytoplasm and in nuclei and induce oxidative stress-mediated cytotoxicity in human hepatoma cells Kim et al. (S. Kim et al., 2009). Interestingly, the mRNA level of oxidative stress-related genes was discovered to be regulated variably (S. Kim et al., 2009). Ag NPs due to their small size may also interact with the cellular genetic material but little is known about their genotoxicity. Surface chemistry based genotoxicty effects of Ag NPs on mouse embryonic fibroblasts, and on stem cells was reported

Figure 4. Possible mechanism of nanoparticle toxicity on cells

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

(Ahamed et al., 2008). It was found that polysaccharide functionalized Ag NPs exhibited more apoptosis than did uncoated Ag NPs (Ahamed et al., 2008). Ag NPs of 15 and 100 nm diameters reduced GSH levels, compromised cellular antioxidant defenses that led to ROS accumulation and induced toxicity in cells of a rat liver-derived BRL 3A cell line by generating oxidative stress. However, the mechanism of depletion of GSH by the action of Ag NPs is not yet known (S M Hussain, Hess, Gearhart, Geiss, & Schlager, 2005). Low and high concentrations of Ag NPs induced vasoconstriction and vasodilatation in isolated rat aortic rings, respectively when mediated by the endothelial cells of the aortic rings (Rosas-Hernández et al., 2009). Neurotoxic effects on rat hippocampal CA1 neurons were induced by Ag NPs, ranging from 32 to 380 nm in diameter. The resulting alterations in sodium current that probably led to the observed neuronal dysfunctioning were long lasting (Zhaowei Liu, Ren, Zhang, & Yang, 2009). Ag NPs (15 nm) though reported to be cytotoxic to a PC-12 Rattus norvegicus cell line and caused cell shrinkage but didn't affected cellular morphology (Saber M Hussain et al., 2006). Dose dependant cytotoxic effects were reported in some in vivo studies of Ag NPs (Sung et al., 2009). Free radical induced oxidative stress, alteration in gene expression, and apoptosis in brain tissue was reported due to the intraperitoneal administration of Ag NPs (Rahman et al., 2009).

METAL OXIDE NANOPARTICLES

Toxicity of some of the important metal oxide nanoparticles are briefly discussed below

Titanium Dioxide Nanoparticles

Both micro and nano structured Titanium dioxide (TiO_2) nanoparticles can break down environmental pollutants and hence have been widely used in environmental remediation due to their photocatalytic activity (Daghrir, Drogui, & El Khakani, 2013; Ingale et al., 2011; Tominaga, Kubo, & Hosoya, 2011). TiO_2 nanocatalysts combined with Ultraviolet A (UVA) radiations have been used in food processing industry to eliminate pathogenic microorganisms in food-contacting surfaces. Although considered to be non toxic, but with increased commercialization of TNP related products there are concerns about the possible toxicity which has motivated further research efforts in this direction (Griffitt, Hyndman, Denslow, & Barber, 2009).

Cytotoxicity assessments of TNPs have been performed in various cells, and the toxicity depends upon the cell type. TNPs up to the concentrations of 100 μg/mL have shown very little cytotoxicity in primary human peripheral blood mononuclear cells (PBMCs) (Andersson-Willman et al., 2012), monocyte-derived dendritic cells (MDDCs) (Andersson-Willman et al., 2012), rat peripheral blood neutrophils (Huang Tao, Nallathamby Prakash D, 2008) and primary cultures of human hematopoietic progenitor cells(Bregoli et al., 2009). However, in other cell lines a dose-dependent cytotoxicity was observed such as human skin fibroblasts (Dechsakulthorn, Hayes, Bakand, Joeng, & Winder, 2007), mouse fibroblasts (L929) (Jin, Zhu, Wang, & Lu, 2008), rabbit erythrocytes(S.-Q. Li et al., 2008), and human B-cell lymphoblastoid cells (J. J. Wang, Sanderson, & Wang, 2007). Moreover, genotoxicity studies confirms the DNA damage and increase the mutation frequency (Barillet et al., 2010; J. J. Wang et al., 2007; Wilhelmi et al., 2012) caused by TNP, but with a more serious DNA damage detected under ultraviolet radiation (Vevers & Jha, 2008). Therefore, the cell type appears to be a vital factor influencing the cytotoxicity of TNPs, which was also confirmed in a study of the responses of several eukaryotic cells to TNP exposure (Barillet et al., 2010).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

The in vivo toxicity of TNPs has been investigated in various aquatic organisms and in animal models. A general growth inhibition was observed with variable EC50 values, ranging from 5.83(Aruoja, Dubourguier, Kasemets, & Kahru, 2009) to 241 mg/L (Vallabani et al., 2011) in freshwater algae, and in Pseudokirchneriella subcapitata. Biodistribution and toxicity of TNPs was also evaluated in rats and mice. It was observed that TNPs predominantly accumulated in the liver, in addition to the spleen, lung, and kidney after a single intravenous injection (5 mg/kg body weight) in wistar rats (Fabian et al., 2008). However no obvious toxic effect, immune response, or change in organ function was observed. TNP accumulation in CD-1 (Imprinting Control Region, ICR) mice after an abdominal cavity injection was found to be highest in Liver and lowest in heart with the order: liver > kidneys > spleen > lung > brain > heart(H. Liu et al., 2009).

Iron Oxide Nanoparticles

In vivo mouse studies have shown that tumor-targeted superparamagnetic iron oxide nanoparticles (SPION) may act as antitumor agents. Entrapment of these NPs, in the growing intravascular thrombi, led to cell death, hence, tumor-targeted SPION can be used to inhibit tumor growth (Simberg et al., 2009). Intratracheal administration of Fe_2O_3 NPs to male Sprague Dawley rats induced oxidative stress in the lungs (M.-T. Zhu et al., 2008). Such oxidative stress produced follicular hyperplasia, protein effusion, pulmonary capillary vessel hyperaemia, and alveolar lipoproteinosis.

SPIONS after entering into cells are probabily degraded to iron ions within the lysosomes under the influence of hydrolytic enzymes. After crossing the nuclear and mitochondrial membrane these iron ions may generate reactive hydroxyl radicals via the Fenton reaction. These hydroxyl radicals then cause lipid peroxidation, DNA damage, and protein oxidation. In brief, cytotoxicity of SPIONP has been linked to cellular uptake and ROS generation. Although iron nanoparticles were shown to be biocompatible *in vivo* at a low concentration, these particles were found to be cytotoxic *in vitro*. Polyvinyl alcohol-coated superparamagnetic iron oxide NPs have caused shape and sizedependent toxicity to primary mouse connective tissue cells. Moreover, it has been observed that toxicity increases for NP forms in the following order: nanobeads > nanoworms > nanospheres. Moreover, with increase in hydrodynamic size toxicity decreased. Easy internalization of certain comparatively small particles into cells has been suggested as a possible reason for the size-dependent toxic effects (Mahmoudi, Simchi, Milani, & Stroeve, 2009).

Zinc Oxide (ZnO) Nanoparticles

Zinc oxide (ZnO) NPs have been widely used as ingredients in cosmetics, and in other dermatological preparations. Due to small size, these NPs always have some possibility to interact with DNA and cause damage. In fact, such cases have been reported on a human epidermal cell line (A431). Similarly, ZnO NPs have been reported to induce cytotoxicity in L2 cells (Hillegass et al., 2010). Lipid peroxidation (LPO) and oxidative stress mechanism are thought to be the causes of such genotoxic effects. Cytotoxicity has been found to be dependent on concentration and time of exposure. ZNO NPs showing higher cytotxicity at higher concentrations and higher exposure times (Sharma et al., 2009). Concentration and time-dependent increase in oxidative stress, intracellular [Ca^{2+}] levels, and cell membrane damage has been reported to occur in a cultured BEAS-2B cell line. In such cases alteration in gene expression from oxidative stress and apoptosis was considered to be the main reason behind the induced cytotoxicity (Huang, Aronstam, Chen, & Huang, 2010). ZnO NPs in 8–10 nm size range have induced more

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

toxicity to human colon cancer cells (RKO) than has the micrometersized ZnO of less than 44 mm size. Depolarization-induced neuronal injury in rats by the activation of voltage-gated Na^+ channels, after exposure to ZnO NPs has been reported thereby giving a clue that these NPs can probably cause neuronal apoptosis (Zhao, Xu, Zhang, Ren, & Yang, 2009). In rats, the intratracheal instillation and inhalation exposure of ZnO NPs for 1-3 h induced metal-fume-fever-like responses in lungs that was characterized by short term lung inflammatory or cytotoxic responses(Warheit et al., 2007). Invivo pulmonary exposure of both nano and fine sized ZnO in rats demonstrated potent, but reversible, inflammation. (Hillegass et al., 2010). The effect of ZnO NPs has also been tested on aquatic species. Dose-dependent reduction in hatching rate and induction of pericardial edema in developing zebrafish embryos, and in larvae has been reported. The Zn^{2+} dependent mechanism was responsible for the embryonic toxicity that resulted from ROS generation (X. Zhu, Wang, Zhang, Chang, & Chen, 2009).

Cerium Oxide Nanoparticles

There has been an increased use of nanosized cerium oxide (CeO_2) in polishing and computer chip manufacturing (Limbach et al., 2005; Mädler, Stark, & Pratsinis, 2002) and as an additive to decrease diesel emissions (Jung, Kittelson, & Zachariah, 2005). However, CeO_2 nanoparticles of sizes in range of 15nm, to 45 nm NPs caused toxicity, ROS increase, GSH decrease, and induced oxidative stress-related genes such as heme oxygenase-1, catalase, glutathione-Stransferase, and thiorexoxin reductase in cultured human lung epithelial cells (BEAS-2B). It was found that increased ROS by CeO_2 NPs triggered the activation of cytosolic Caspase and chromatin condensation, causing toxicity via the apoptotic process (Park, Choi, Park, & Park, 2008). On the contrary, other reports showed high biocompatibility of ceria nanostructures, prevented renal degeneration induced by intracellular peroxidases and conferred radioprotection to normal cells compared to no protection for tumor cells(J. Chen, Patil, Seal, & McGinnis, 2006; Tarnuzzer, Colon, Patil, & Seal, 2005). This apparent incongruity might be due to the surface oxidation state of nanoceria to scavenge superoxides or act in a catalytic manner. on the other hand, no significant change in LDH leakage or cell morphology is observed in A549 lung cells exposed directly to flamespray synthesized CeO NPs for 10–30 min (Perez JM, Asati A, Nath S, 2008) but resulted in a decreases in the mean total lamellar body volume per cell, reduction of cell-cell contacts and a significant increase in 8-oxoguanine positive cells, however NP induced oxidative stress resulting in altered gene expression (Rothen-Rutishauser et al., 2009).

CONCLUSION

Nanotechnology is a fast-growing field of activity that will allow development of materials with brand-new properties. Various scientific groups are keen about this technology and are devoting themselves to the development of more, new, and better nanomaterials. In the near future, expectations are that no field will be left untouched by the magical benefits available through application of nanotechnology. However, in this pursuit the number of Quebec workers exposed to nanoparticles should increase over the next few years. Presently, there is only limited knowledge concerning the toxicological effects of NPs. Before, NPs are commercially used it is most important that they be subjected to appropriate toxicity evaluation. Among the parameters of NPs that must be evaluated for their effect on toxicity are surface charges, types of coating material, and reactivity of NPs. Because of their very small size, these particles offer a large contact surface per mass unit.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Since Nanoparticles (NPs) have already found a wide range of applications around the world. In vitro and in vivo studies on NPs have revealed that most are toxic to animals. The types of effects that NPs have produced are those on the pulmonary, cardiac, reproductive, renal and cutaneous systems, as well as on various cell lines. After exposures, significant accumulations of NPs have been found in the lungs, brain, liver, spleen, and bones of test species. However, their toxic behavior varies with their size, shape, surface charge, type of coating material and reactivity. Dose, route of administration, and exposure are critical factors that affect the degree of toxicity produced by any particular type of NP. Since, toxicity of nanoparticles has been reviewed in several reports and the most severe problem is related to the carcinogenic potential of NPs that has been associated both to the chemistry as well as to the physical properties. In particular, chemistry was considered to be relevant for the oxidative DNA damage and the formation of radical oxygen species (ROS) involved *via* direct mechanisms, whereas size, morphology and surface seem to be more important in all the other indirect mechanisms that underlie of cancer. Nevertheless, the majority of studies on genotoxicity of NPs have been so far performed on cell cultures. Thus in order to obtain data more relevant to the knowledge on human exposure, more trials on animal and long-term exposure experiments should be carried out. We believe a careful and rigorous toxicity testing is necessary before any NP is declared to be safe for broad use. We also believe that an agreed upon testing system is needed that can be used to suitably, accurately, and economically assess the toxicity of NPs. Moreover, there is a timely need to pay attention on how to control the in vivo transport and toxicity of different type of nanoparticles as only few reports have been published in this direction (Y.-S. Chen et al., 2012).

ACKNOWLEDGMENT

The author thanks to Department of Chemistry, Jamia Millia Islamia, New Delhi, India, for providing excellent facilities and cordial research environment. The author also thanks to Dr. Tokeer Ahmad, Nanochemistry Laboratory, Jamia Millia Islamia, New Delhi and Dr. Mohd. Ashraf Shah, Electron Microscopy Centre, Department of Physics, National Institute of Technology, Hazratbal, Srinagar, for their encouragement and guidance.

ABSTRACT

Developing effective structure-activity/property/toxicity relationships (QSAR/QSPR/QSTR) is very helpful in predicting biological activity, property, and toxicity of a given set of molecules. Regular change in these properties with the structural alteration is the main reason to obtain QSAR/QSPR/QSTR models. The advancement in making different QSAR/QSPR/QSTR models to describe activity, property, and toxicity of various groups of molecules is reviewed in this chapter. The successful implementation of Conceptual Density Functional Theory (CDFT)-based global as well as local reactivity descriptors in modeling effective QSAR/QSPR/QSTR is highlighted.

1. INTRODUCTION

The properties of molecules mainly depend on the distribution of electron density within the individual molecules. It is, therefore, believed that molecules having similar structures will exhibit similar properties. On this hypothesis, the idea of structure-activity relationship (SAR) exists (Nantasenamat et al., 2009). Accordingly, it is assumed that molecules with similar structures exhibit comparable activities (properties), and, so on the basis of known properties of a set of molecules, prediction of the properties of unknown molecules having similar structures could be made, provided appropriate models are de-

veloped. Models which are able to predict the properties of an unknown molecule on a qualitative basis are termed as Qualitative Structure-Activity Relationship models (Arning et al., 2008), and, the ones which can quantify such relationship are termed as Quantitative Structure-Activity Relationship (QSAR) models (Gramatica, 2007). Such QSAR models are very useful in the design of molecules which can serve as a better drug or in the manufacturing of materials which could serve as better substance in terms of utility, economy, durability and environmental effects in totality. The quest for such molecules begins with SAR studies. On the basis of activities of a set of molecules of similar structures or parameters, different SAR models are designed. Thereafter, those molecules which are found to have a potential to show a desired characteristic (property/activity) are filtered with the aid of such models, and, then the systematic efforts towards their syntheses begin. Thus, such an approach helps in the reduction of the cost effectively. Since a molecule can have different kinds of properties, a large number of QSAR models could be developed for the same set of molecules depending on their properties. Such properties could be physico-chemical properties, quantum-chemical properties or even toxicity properties. It clearly implies that not only the unknown toxicity parameter of a molecule of whose different parameters are yet to be assessed, could be determined, but its other set of properties could also be determined provided effective QSAR models are generated. When the attempt is to determine the toxicological effect of a molecule based on a model having correlation between structure and toxicity of already determined molecules, then such an approach is defined as Quantitative Structure-Toxicity Relationship (QSTR) model (Roy and Ghosh, 2004). Such models are very effective in the prediction of toxicity of molecules which have potential to act as a toxic substance. Thus, QSTR helps in building up of an effective regression model that helps in predicting the reactivity of an unknown molecule on the basis of behavior of an analogous set of chemically or structurally similar compounds.

QSTR models are proposed based on different parameters. Most often these parameters are defined in terms of descriptors. These descriptors could be based on different experimental and theoretical properties such as physico-chemical and quantum-chemical properties, respectively. One of the most popular and cheap methods in the field of quantum-chemical prediction of the properties of molecules is Density Functional Theory (DFT) (Parr & Yang, 1989). It predicts the properties of a molecule based on its molecular electron density. A closely related method describing the chemical properties such as electronegativity, ionization potential, hardness etc with the aid of DFT method is known as Conceptual Density Functional Theory method (CDFT) (Chattaraj, 2009; Chakraborty et al., 2010; Chattaraj & Giri, 2009; Geerlings et al., 2003). This method has been successfully and exhaustively employed in the generation of different descriptors, which have been able to produce QSAR and QSTR models of very high efficiency. Thus, CDFT has helped in the assessment of activity and toxicity of different molecules within the ambit of QSAR and QSTR respectively. It has been found that CDFT is quite cheaper in comparison to other expensive quantum-chemical methods such as *ab initio* methods. CDFT has been proven to develop effective and efficient QSTR models.

In this chapter, at first we have provided a general introduction highlighting the necessity of structure-activity/toxicity based regression models. Various QSAR/QSPR/QSTR based methods are outlined in section 2. Section 3 describes the conceptual density functional theory and the related global and local reactivity descriptors. Section 4 deals with the utility of electrophilicity index and net electrophilicity index and their local variants in predicting toxicity of various classes of molecules. Section 5 mentions about the importance of the group philicity towards modeling an effective QSAR. Section 6 highlights the effect of studied levels and / or basis sets in constructing QSAR/QSPR/QSTR models. Section 7 concludes the chapter by mentioning the effectiveness of various CDFT based descriptors in building QSAR/QSPR/QSTR models.

2. QUANTITATIVE STRUCTURE-ACTIVITY/ PROPERTY/TOXICITY RELATIONSHIPS

Quantitative Structure Activity Relationship (QSAR) acts as a function which connects structure of a molecule to different properties. Those properties which show medicinal applications are considered as an activity of a molecule, and, are thus studied within the purview of QSAR. In the present world of global recession, such a technique is able to save money and time. Much of the efforts are now directed towards development of models which predict accurately the properties of a molecule on the basis of their structures. Thus, QSAR models are able to predict biological activities and physico-chemical properties and rationalize the mechanism of action for different chemical reactions. Normally, in order to develop a QSAR, five to ten compounds are necessary for each descriptor as argued by Topliss and Costello (1972) and further mentioned by Schultz et al. (2003c). However, in order to develop robust QSAR, many more compounds are required. With the advent of sophisticated techniques, new software, and, hardware which works on novel algorithms, has made the task of generation of an accurate model within the purview of QSAR simplier. QSAR has its genesis in the pioneering work of Hansch and coworkers (1962, 1964) wherein they used linear multiple regression models to describe the biological property of the compounds, which were not synthesized till then. Different parameters such as hydrophobicity, electronic effects and steric properties were utilized to generate a relationship among them and the concentration of the molecule. Free and Wilson (1964) and Fujita et al. (1971) developed non-parameteric methods to define biological activity. Later Linear Solvation Free Energy Relationship (LSFER) was proposed which predicted the properties of a molecule on solute-solvent interactions (Kamlet et al., 1983; Taft et al., 1985). It consists of different solvatochromic descriptors such as cavity/bulk term, polarizability term, and H-bond terms which are used to derive a relationship between overall property of a molecule and different parameters. A good account of the role of QSAR in chemical toxicology was elaborated by Schultz et al. (2003a, 2003b). Other articles also highlight the development of the QSAR methodology and their role in the prediction of bio-toxicity (Gombar et al., 2006; Kar & Roy, 2010; Nantasenamat et al., 2009; Puzyn et al., 2010; Selassie et al., 2010). Hammett (1935, 1937) by employing correlation principles, in 1930s had efficiently shown the effect of structural changes on reaction mechanism of substituted benzoic acid derivatives. It led subsequently to the birth of well known linear free-energy relationship essentially by connecting Gibbs free energy of reaction and Gibbs free energy of activation which in a broader sense established a connection between thermodynamics and kinetics. The concept was further extended by Taft (1956) for aliphatic compounds. This paved the way of strong QSAR models as was evident from the further work carried out by Hansch and coworkers (1993, 1996) wherein they discussed the role of QSAR. The role of QSAR in the study of chemico-biological interactions (Blaney & Hansch, 1990; Debnath et al., 1994; Gao et al., 1999; Hansch et al., 1986, 1989, 1995, 1997, 1998, 2001; Hansen et al., 1995; Langridge & Klein, 1990; Lien et al., 1968;) and also for the drug design (Bajot, 2006; Garg et al., 1999; Hansch et al., 1973, 1995; Kubinyi, 1997; Maddalena, 1998; Norinder, 1998; Voskresensky & Levitsky, 2002; Yang & Huang, 2006;) was also established.

In order to generate an effective QSAR model, the first and foremost requirement is the collection of data and generation of database. This helps in defining training sets which generally consist of known data obtained from various sources. With the aid of such data, different kinds of descriptors are developed on the basis of molecular formula (1-D descriptor), the 2-dimensional structure (2-D descriptor), and the 3-dimensional conformation (3-D descriptor) of a molecule. Generally, molecular descriptors generated from some special types of atoms or fragments counting or based on bulk and physico-chemical proper-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

ties like molecular weight, atomic number, number of OH groups, number of non-hydrogenic atoms and so on correspond to 1-D descriptors.2-D descriptors are usually obtained by applying algorithms to the topology based representation. 3-D descriptors, also called geometrical descriptors are generated from the spatial coordinates (x,y,z) of a molecular system whereas the interaction energy values between an embedded molecule in a grid and a probe will provide 4-D descriptors. In general, molecular descriptors should satisfy some basic requirements as suggested by Randić (1991). Different other articles also showed the role of QSAR in the generation of different algorithms (Karcher & Devillers, 1990; Roy & Mitra, 2009; Selassie et al., 2002).

Molecular descriptors are mathematical representations of various properties of a molecule which are generally derived after the application of a reliable algorithm to the molecular representation or are determined from experiment. Being related to the molecular Hamiltonian, the molecular descriptors like electron density, electrostatic potential, etc. would represent all the properties of a molecule (Bonaccorsi et al., 1970; Murray & Politzer, 2003; Pathak & Gadre, 1990; Politzer, 1988). These descriptors help in the development of models for chemistry, toxicology, health research, pharmaceutical sciences, etc. They are generated by the application of different principles from different fields and theory, such as organic chemistry, graph theory, quantum-chemistry, information theory etc. The electron localization and delocalization functions obtained from the quantum theory of atoms in molecules (QTAIM) are also very effective in modeling QSAR (Buttingsrud et al., 2007a, 2007b, 2007c; Chaudry & Popelier, 2003, 2004; O'Brien & Popelier, 1999; Popelier et al., 1999, 2004; Smith & Popelier, 2005). Popelier et al. (1999) showed that a QTAIM based approach called quantum topological molecular similarity (QTMS) could predict the toxicity of health-hazardous lipid-soluble environmental pollutants as efficient as that of comparative molecular field analysis (CoMFA). Very recently, Matta et al. (2014) reviewed the applicability of the electron density, electron localization and delocalization functions, and the electrostatic potential in developing effective QSAR models.

Bohari et al. (2011) adopted so-called analogue-based approach to predict the anti-cancer activity of 266 different compounds against 29 various cancer cell lines. Various models were constructed through 1 to 10 different descriptors. They found that in general three-parameters regression models could predict the anti-cancer property satisfactorily. Filho et al. (2012) performed QSAR studies on 32 Morita–Baylis–Hillman adducts against Leishmania amazonensis. Energy of the lowest unoccupied Kohn–Sham orbital, number of $o-NO_2$ group, number of $-CH_2-$ group and an increment in log P parameters were used to build the regression model. A reasonably good predictivity was found for this model. QSAR studies were also performed in two sets of antitumour drugs 2-(4-aminophenyl)benzothiazoles by using different indices encompassing constitutional, geometrical, topological, and electronic descriptors (Hilal & Elroby, 2011). Good correlation having a range of r^2 as 0.867-0.954 was attained between computed and experimental activities with these models. A number of molecular descriptors like polar surface area, Randic shape index, number of phenolic groups and energy of the highest occupied molecular orbital were used to predict the estrogenic activity of different terpenoid ester derivatives obtained from *Ferula* plants (Rasulev et al., 2007). An r^2 value of 0.892 implied the reliability of the regression model to predict the activity of these compounds. Li et al. (2010) carried out the QSAR studies on 27 diacyl-hydrazine derivatives by using DFT based method and semi-empirical AM1-MOPAC method. They found higher predictivity at the DFT level than that at the semi-empirical level. 3D-QSAR models were also generated based on the geometries obtained at the DFT level and electrostatic potential fitting charges. The results of the QSAR and 3D-QSAR were found to be comparable. For these compounds, it was argued that the electrostatic and hydrophobic properties are important in deciding their overall biological activities.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Zhang et al. (2009) combined DFT-based conformation analysis with QSAR to develop a simple new DFT/QSAR approach to predict the nature of bioactive conformation in the side chain of cyclic imide derivatives as protoporphyrinogen oxidase inhibitors. The potential energy surface scan, molecular docking and molecular dynamic simulation supported the reliability of this new approach. Damme and Bultinck (2010) employed conceptual DFT bsed quantum chemical molecular field in order to construct 3D-QSAR models to describe the antituberculotic activity of salicylamide derivatives. QSAR studies on the interactions between the terpenoid mosquito repellents and lactic acid were made by Song et al. (2013). They found that in addition to the structures of the repellents, the repellent–lactic acid complexes also have a role in deciding their activities. Use of ordered predictors selection algorithm and partial least squares regression was also made to select variables and to construct QSAR models of various 4,5-dihydroxypyrimidine carboxamide derivatives as HIV-1 integrase inhibitors (de Melo et al., 2009). The electronic distribution of the studied compounds appeared to have deciding role in their inhibition activities. The antifungal activity of N-nitrosopiperidone semicarbazone derivatives against the plant pathogens viz., *Fusarium oxysporum* and *Rhizoctonia solani* can also be predicted by the regression models devepoled by the descriptors like molecular electrostatic potential, charge on N center, dipole moment, minium surface area and log P (Hemalatha et al., 2012). The QSAR studies on the imidazole and benz-imidazole derivatives as corrosion inhibitors revealed that HOMO energy, polarizability, dipole, frontier orbital charge density, the interaction mode between inhibitors and metal surface and steric hindrance of molecules are deciding descriptors to represent their inhibiting potency (Zhang et al., 2005). Various DFT based descriptors like HOMO-LUMO energy gap, HOMO and LUMO energies, mean molecular polarizability, atomic charge, weighted nucleophilic atomic frontier electron density were employed in order to build regression models for the various cyclic imide derivatives as protoporphyrinogen oxidase (Protox) inhibitors (Wan et al., 2004). The DFT-based QSAR and 3D-QSAR approaches on the activity of aurone derivatives against chloroquine resistant parasite by Adhikari et al. (2013) are also notworthy. A review summarizing various quantum-chemical descriptors in developing QSAR and QSPR written by Karelson and Lobanov (1996) is highly recommended to get more details about these approaches.

Geometrical descriptors were designed and included in the QSAR during the development of 3D-QSAR models in mid 1980s. These included gravitational indices (Katritzky et al., 1996), shadow indices (Rohrbaugh & Jurs, 1987), EVA descriptors (Ferguson et al., 1997), GETAWAY descriptors (Consonni et al., 2002), 3D-Morse descriptors (Schuur et al., 1996), charged partial surface area descriptors (Stanton & Jurs, 1990), and WHIM descriptors (Todeschini et al., 1994).

The descriptors such as topological descriptors utilize molecular graph. Different topological indices such as those developed by Weiner (1947), Randić (1975), Balaban (1998), Kier and Hall (1995) were reported in literature to generate QSAR models. Other descriptors such as steric (Camenisch et al., 1998; Mezey, 1992) viz., volume, shape and surface, were found to be useful in representing the global structural characteristics of a molecule and different software such as VolSurf software (Cruciani et al., 2000) were employed to create effective QSAR models. In order to generate 2D and 3D descriptors for the prediction of physicochemical properties, the methods provided by Rekker (1992) were used.

CoMFA (Cramer et al., 1988) is an effective method in building effective 3D-QSAR, which was successfully applied in drug designing and other related applications (Aboye et al., 2004; Akamatsu, 2002; Amin & Welsh, 2006; Avery et al., 2002; Bhongade & Gadad, 2004; Hannongbua etal., 2001; Jayatilleke et al., 2000; Sippl & Holtje, 2000). History behind the idea of CoMFA in modeling QSAR is that in the classical QSAR, the different biological acitivies of drugs or other compounds of interest are correlated with various physico-chemical properties or quantum-chemical descriptors, provided

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

they could represent certain structural characteristics. Therefore, they did not take care of the information regarding their 3-D geometries and chirality. On the other hand, at longer distance an active site of a drug can only experience the electrostatic field of a target molecule and at shorter distance its hard body including the charge distribution (Kubinyi, 1998). Other two important observations were that the most of the molecular interactions which generate biological activity, are of non-covalent type and the most of the molecular mechanics force fields, wich describe the non-covalent interaction as steric and electrostatic forces, could explain a large variety of molecular properties. Therefore, it appeared that an appropriate sampling of the steric and electrostatic forces surrounding the considered molecules could give all the necessary information regarding their observed biological properties. Cramer and Milne (1979) compared the molecules for the first time by arranging them in space and by molecular field mapping in a 3-D grid. The same approach was then implemented in dynamic lattice-oriented molecular modeling system (DYLOMMS) method (Kubinyi, 1993). However, to obtain success in broader applications of this approach, certain factors like the use of partial least square analysis instead of principal component analysis and use of appropriate software are important (Kubinyi, 1998). In 1988, Cramer et al. (1988) termed this approach as CoMFA. The major precondition for this approach is that all the selected molecules under study must interact with the receptors of same kind and in same mechanistic way. Then in order to develop a CoMFA model, a traning set is chosen from a certain subgroup of the considered molecules and the remaining part is treated as a test set. This test set is used to verify the efficacy of this model to describe certain properties. The final output of this analysis provides a regression equation having several coefficients and they are very often depicted as a set of contour plots. From these plots, the favorable and unfavorable steric regions and favorable and unfavorable regions for electropositive or electronegative substituents could be identified. Then one could predict the desired properties of the test set or other related samples by qualitative examination of these plots or by computing the fields of these molecules quantitatively. Cramer et al. (1988) first employed this method to predict the binding affinities of steroids towards the human corticosteroid. The squared correlation coefficient (r^2) for the affinity values was found to be very high (close to 0.9). Since 1988, a lot of articles including reviews are reported in the literature on this topic (Adhikari et al., 2014; Blankley, 1996; Kim, 1995; Martin et al., 1996; Martin & Lin, 1996).

In addition to the development of the QSAR, quantitative structure-property relationship (QSPR) was also used to predict a certain property of the molecules. The hypothesis, that structural alteration changes the observed macroscopic properties of systems is the base of QSPR methods. Several research groups contributed significantly in the development of QSPR models (Abraham, 1994; Abraham et al., 1995; Balaban, 1997; Hilal et al., 1994; Katritzky et al., 1995; Kier & Hall, 1986; Lucic & Trinajstic, 1999; Murray & Politzer, 1994; Randic & Razinger, 1996; Stuper et al., 1979). The efficacy of QSPR as a useful tool in connecting molecular structure with the various physical, chemical, biological and technological properties was further demonstrated by Katritzky et al. (2000). The successful implication of QSPR in medicinal chemistry to predict different property was also available in the literature (Katritzky et al., 2002). A fair correletion between structure and property was obtained by using QSPR models made on an empirical basis even for large data sets. The importance of data reduction methods like principal component analysis (PCA) of a matrix generated by the different properties of the systems was also found in providing insight into these properties quantitatively (Leo & Hansch, 1999). The reviews summarizing the construction of QSPR models in predicting diverse properties of materials are highly recommended. Variuos approachs were also made to model effective QSPR for anti HIV drugs.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

The applicability of QSPR in pharmaceutical arena including different pharmacokinetic aspects towards drug designing was reviewed by Grover et al. (2000a, 2000b).

Further, quantitative structure-toxicity relationship (QSTR) is essential in order to have proper knowledge about the toxicity of various essential systems; hence it is an issue of environmental safety and security. The approach of QSTR modeling even becomes more popular since experimental determination of toxicity of each and every essential compound is hard with respect to time, cost, and the availability of resources. Different theoretical approaches have been made to connect the structural features (electronic, geometric, topological, quantum chemical, etc.) with the toxicity. An effective QSTR model could predict the relative toxicity/safety of different systems in a reliable way saving the experimental effort. Cronin and Schultz (1998) developed useful QSTR model for v*ibrio pscheri* toxicity including all probable mechanisms. Schultz et al. (1999, 2002) evaluated toxicity of numerous aliphatic chemicals and substituted benzenes towards *Tetrahymena pyriformis*.

The databases regarding toxicity of a number of fish species like the guppy (*Poecilia reticulata*) and zebrafish (*Brachydanio rerio*) are also available. The fish data sets for the fathead minnow (*Pimephales promelas*) to predict the acute toxicity and related modes of toxic action was built by studying the establishment of toxicodynamic profiles, and behavioral and dose-response interpretation of 96-h LC_{50} tests (Russom et al., 1997). Good correlation between fish toxicity and toxic potency measures in *T. pyriformis* was also found in few studies (Bearden & Schultz, 1998; Schultz, 1997). McFarland (1970) proposed quite simple toxicokinetic- and toxicodynamic-based approach in which chemical toxicity was expressed as a combination of uptake into or through biological membranes and the interaction of the toxicant with the site of action to predict toxicity. Different approaches in modeling QSTR were also reported in the literature (Chakraborty et al., 2013; Cronin & Schultz, 1996; Karabunarliev et al., 1996; Veith & Mekenyan, 1993). QSTR could also be applied to measure toxicity of disinfection by-products (DBPs) generated during disinfection of water (Moudgal et al., 2000).

Cronin et al. (1998) developed QSTR model by using LUMO energy and maximum acceptor superdelocalizability as descriptors to predict toxicity of various alkyl- and halogen-substituted nitro- and dinitrobenzenes towards *T. Pyriformis*. Mishra et al. (2014) employed various quantum-chemical descriptors like HOMO energy, electronegativity, electron affinity (EA), ionization potential (IP), total energy and log P to predict the toxicity of nitrobenzene derivatives towards *T. Pyriformis*. The topological descriptors were also found to be effective to describe the toxicity of nitrobenzene derivatives towards the same (Tripathi & Mishra, 2014). Further based on several energy descriptors, heat of formation, atomic charge, dipole moment and polarizability values, Bao et al. (2012) predicted the toxicity of several nitrobenzene derivatives towards the *Scenedesmus obliguus*. Very recently, Tawari et al. (2014) attempted to build QSTR model to describe the mutagenicity of nitroaromatic compounds. Pandith and Islam (2013) further built QSTR models by using log P, electrophilicity (ω) and LUMO energy to predict the acute toxicity of aliphatic compounds towards *V. fischeri*. HOMO energy, molecular weight, LUMO energy, chemical potential, zero point energy, and hardness were also used to model QSTR in order to predict 50% effective inhibition concentration of various substituted benzene derivatives towards the *algae Scenedesmus obliquus* (Haghdadi & Fatemi, 2010). Quite high correlation ($r = 0.91$) revealed that such properties can be properly described by using such molecular indices. Eroglu et al. (2007) used quantum-chemical descriptors like translational entropy, principal moment of inertia, the highest and the lowest vibrational wave numbers to predict the acute toxicity of several organic compounds towards *Fathead Minnow*. Further, toxicity of organophosphorus compounds was assessed using the regression models mady by different quantum-chemical and topological descriptors (Senior et al., 2011). Wiener

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

index, Harary index, modified Randic index, Kupchik modified connectivity index (Todeschini & Consonni, 2000), electronegative Randic index, heteroatom corrected extended connectivity Randic index as different topological descriptors and HOMO-LUMO gap, maximum positive charge, total negative charge, charge polarization, local dipole index, electronic topological index, etc. as quantum-chemical descriptors were used for this purpose. Attempt to predict the lethal toxicity of organophosphorous pesticides occurred in the tadpoles was also reported in the literature (Yan et al., 2008). Antifungal and insecticidal activities of perfluorophenyl antimony(III) and antimony(V) chlorides were predicted by several energy and CDFT based descriptors by Singhal et al. (2014). Regression model based on total energy and LUMO energy was also found effective in describing the toxicity of several substituted benzenes against *freshwater photobacteria* (Mo et al., 2011). The hardness, electronegativity and total energy descriptors were found to be useful descriptors for QSTR modeling on a series of aliphatic alcohol derivatives (Kumar et al., 2011). Trohalaki and Pachter (2003) showed that the use of reciprocal of LUMO energy could improve the correlation in predicting the toxicity of halogenated aliphatic hydrocarbons than that of LUMO energy. The acute fish toxicity of organic solvents was also described by using the octanol-water partition coefficient, LUMO energy, dielectric constant and surface tension as descriptors (Levet et al., 2013). Gironés and Carbó-Dorca (2006) reported the molecular quantum similarity measures approach in develping QSTR.

3. CONCEPTUAL DENSITY FUNCTIONAL THEORY

The conceptual density functional theory (CDFT) (Chattaraj, 2009; Chattaraj & Giri, 2009; Chakraborty et al., 2010; Geerlings et al., 2003) has become a powerful theoretical tool to shed light into the chemical reactivity of a molecule. Within the framework of the CDFT, several response functions were introduced in order to describe chemical reactivity, which are also called as reactivity descriptors. CDFT along with its different global reactivity descriptors viz., hardness (η) (Parr & Pearson, 1983; Pearson, 1997), electronegativity (χ) (Chattaraj, 1992; Parr et al., 1978) and electrophilicity (ω) (Parr et al., 1999; Chattaraj et al., 2006, 2007, 2011) and different local reactivity descriptors like Fukui functions (Parr & Yang, 1984) $f(\mathbf{r})$ and their condensed-to-atom variants (Yang & Mortier, 1986) (f_k), local softness ($s(\mathbf{r})$) (Wang & Parr, 1985; Berkowitz & Parr, 1988), local hardness ($\eta(\mathbf{r})$) (Wang & Parr, 1985; Ghosh & Berkowitz, 1985) and philicity ($\omega(\mathbf{r})$) (Chattaraj et al., 2003; Roy et al., 2006a) predict the reactivity behavior of a molecule as a whole and / or at a particular site.

The concept of electronegativity (χ) was first introduced by Pauling (1932, 1960), which represents the "power" of an atom in a molecule to attract the bonded electrons towards itself. Later, Mulliken (1934, 1935) described χ as the average of the first ionization potential (*IP*) and the electron affinity (*EA*), two experimentally obtainable parameters of a molecule. He showed that χ could be determined by an arithmetic mean of the corresponding *IP* and *EA* values as given in Equation 1.

$$\chi = \frac{IP + EA}{2}. \tag{1}$$

The chemical potential (μ) (Parr & Yang, 1989; Hohenberg & Kohn, 1964) of an atom/molecule may be quantitatively assessed by the theory of statistical ensembles. Suppose, an atom or a molecule is a part

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

of a grand canonical ensemble in which energy (E) and the number of electrons (N) are two independent parameters and continuous functions as well, then μ of the ensemble can be expressed as follows:

$$\mu = \frac{\partial E}{\partial N}\text{, at constant entropy} \tag{2}$$

Further, Gyftopoulos and Hatsopoulos (1968) put forward a definition of χ of a system where the electronic chemical potential (μ) was considered as the negative of χ. Now, following Mulliken's (1934, 1935) prescription for χ, the Mulliken chemical potential can also be expressed as a finite difference approximation of the derivative of E with respect to N as:

$$\mu_{Mulliken} = -\chi_{Mulliken} = -\frac{IP + EA}{2} = \left[\frac{\partial E(N)}{\partial N}\right]_{N=N_0} . \tag{3}$$

Pearson (1963, 1966, 1968a, 1968b, 1987) introduced the concept of "hardness" or "softness" in chemistry during the study of Lewis acid-base reactions

$$A + :B \rightarrow A:B$$

where A, an acid, acts as an electron acceptor whereas B, a base is the electron-pair donor. Global hardness (η) implies the extent of compactness of the electron cloud encompassing the nucleus/nuclei of an atomic/molecular system whereas global softness (S) is the reciprocal of η and hence represents the extent to which the electronic environment surrounding the nucleus/nuclei of an atomic/molecular species tends to loosen itself. Parr and Pearson (1983) expressed the qualitative concept of η quantitatively in the form of a mathematical descriptor. It is defined as the first derivative of μ or the second derivative of E as a function of N at a fixed external potential $v(\mathbf{r})$ as follows:

$$\eta = \left(\frac{\partial \mu}{\partial N}\right)_{v(\mathbf{r})} = \left(\frac{\partial^2 E}{\partial N^2}\right)_{v(\mathbf{r})} . \tag{4}$$

The convexity in the E vs. N curve signifies that the value of η would be always positive and from the finite difference approach the corresponding curvature equals to difference between IP and EA, which actually represents hardness. Hence

$$\eta = \left(\frac{\partial \mu}{\partial N}\right)_{v(\mathbf{r})} = \left(\frac{\partial^2 E}{\partial N^2}\right)_{v(\mathbf{r})} = IP - EA\,. \tag{5}$$

Therefore, η of a given system describes the extent of its reluctance towards the electron shift to another system in a general charge-transfer phenomenon in between a donor-acceptor couple.

Global softness (S) (Pearson, 1987), a reciprocal of the global hardness (η) of a system, is expressed as:

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$S = \frac{1}{\eta} = \left(\frac{\partial N}{\partial \mu}\right)_{v(\mathbf{r})}. \tag{6}$$

Electrophilicity (ω) (Parr et al., 1999; Chattaraj et al., 2006, 2007, 2011) and its recently reported mathematical refinement, net electrophilicity ($\Delta\omega^{\pm}$) (Chattaraj et al., 2009) are also important descriptors from the perspective of constructing useful SAR based models

In chemistry electrophiles represent those species, which have a special affinity towards accepting electrons. In general, electrophiles are electron-deficient species, which prefer to combine with electron-rich systems, nucleophiles. In an experiment of the human immunodeficiency virus type 1 (HIV-1) nucleocapsid protein p7 (NCp7) with various electrophiles, Maynard et al. (1998) found that the decay rates of fluorescence varied almost linearly with the ratio of the square of χ and η, χ^2/η. This ratio could further be rationalized as the ability of an electrophile to attract electrons from a nucleophile in forming a covalent bond. This observation of Maynard et al. (1998) led Parr et al. (1999) to describe electron-attracting power of a system in a more precise way.

Consequently, a new reactivity descriptor namely electrophilicity index (ω) was introduced in chemistry. Different from the approach of Maynard et al., (1998) Parr's postulate of ω was based on a thermodynamic background and thus ω becomes a measure of the favorable change in energy upon saturation of a system with electrons. ω as prescribed by Parr et al. (1999) is:

$$\omega = \frac{\mu^2}{2\eta} = \frac{\chi^2}{2\eta}. \tag{7}$$

Eqution 7 resembles $W = V^2/R$, where W, V and R are electrical power, voltage and electrical resistance, respectively. Hence, ω describes the electrophilic power of a system. Few reviews summarizing the different application of ω in understanding the chemical reactivity of different systems are also available in literature (Chattaraj et al., 2006, 2007, 2011).

In order to correlate the associated energy changes between the interacting acceptors and donors in a charge-transfer process, based on the second-order Taylor series energy expansion formula as a function of the number of electrons (N) in the intervals between N - 1 and N, and N and N + 1, Gazquez et al. (2007) showed that the electrodonating (ω^-) and the electroaccepting (ω^+) powers might be defined as:

$$\omega^- = \frac{(\mu^-)^2}{2\eta^-} \tag{8a}$$

$$\omega^+ = \frac{(\mu^+)^2}{2\eta^+} \tag{8b}$$

where μ^- and μ^+ are the chemical potential for electron donation and electron acceptance, respectively, whereas η^- and η^+ are the hardness for electron donation and electron acceptance, respectively. It was also proved that μ^- and μ^+ could be equalized to μ and η^- and η^+ could be equalized to η. Therefore, ω^- and ω^+ become equivalent with ω and thereafter ω, ω^- or ω^+ may be represented in terms of μ and η as $\omega^- =$

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

$\omega^+ = \omega = \mu^2/2\eta$. Further, Gazquez et al. (2007) proposed two different expressions for ω^- or ω^+ depending on two different approaches; one following the original formula as above and can be expressed as:

$$\omega^+ = \frac{EA^2}{2(IP - EA)} \tag{9}$$

$$\omega^- = \frac{IP^2}{2(IP - EA)} \tag{10}$$

and other by exploiting an alternative expression for energy as (Gazquez et al., 2007):

$$\omega^+ = \frac{(IP + 3EA)^2}{16(IP - EA)} \tag{11}$$

$$\omega^- = \frac{(3IP + EA)^2}{16(IP - EA)}. \tag{12}$$

It was also reported that the alternative expression of ω^- or ω^+ provided better correlations than the original one (Gazquez et al., 2007).

Chattaraj et al. (2009) recently put forward the concept of net electrophilicity ($\Delta\omega^{\pm}$) to describe the resultant electron-accepting power of a molecule arising from the combined attractive and repulsive effects due to the presence of both electrons and nuclei within a molecule. This dual descriptor ($\Delta\omega^{\pm}$) assesses the electrophilicity of a molecule relative to its own nucleophilicity, therefore is more meaningful descriptor in representing the "electrophilic power" of a system. Thus, net electrophilicity ($\Delta\omega^{\pm}$) in terms of ω^+ and ω^- can be expressed as:

$$\Delta\omega^{\pm} = \left\{\omega^+ - \left(-\omega^-\right)\right\} = \left(\omega^+ + \omega^-\right) \tag{13}$$

or,

$$\Delta\omega^{\pm} = \left\{\omega^+ - \left(\frac{1}{\omega^-}\right)\right\}.$$

The polarizability (α) of an atom or a molecule is the lowest order response of its electron cloud with respect to an external weak electric field (Dalgarno, 1962; van Vleck, 1932). The static dipole polarizability (α) can be defined as the second derivative of the total electronic energy (E) with respect to the external homogeneous electric field as:

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$\alpha_{xy} = -\left(\frac{\partial^2 E}{\partial F_x \partial F_y}\right)_{F=0} \tag{14}$$

where F_x and F_y are the electric field components along x and y direction. Qualitatively, polarizability (α) varies inversely with η (Ghanty & Ghosh, 1993, 1996; Fuentealba & Reyes, 1993; Pal & Chandra, 1995: Pearson, 1986; Politzer, 1987) and is proportional to S. A linear correlation was found between α and the third power of S (Chattaraj & Poddar, 1998; Simon-Manso & Fuentealba, 1998; Vela & Gázquez, 1990).

The magnetizability (ξ) (Griffith, 1999) for a molecule is a measure of the linear response of its electron cloud with respect to an externally applied magnetic field and is expressed as:

$$\left|\xi = -\left(\frac{\partial^2 \varepsilon(B)}{\partial B^2}\right)\right|_{B=0} \tag{15}$$

where B is the external magnetic field.

A softer molecule is also found to be more polarizable and hence more magnetizable (Chattaraj et al., 2007).

In addition to the various CDFT based global reactivity descriptors, the local reactivity descriptors like Fukui function ($f(\mathbf{r})$), philicity ($\omega(\mathbf{r})$), local softness ($s(\mathbf{r})$), local hardness ($\eta(\mathbf{r})$) and electron density ($\rho(\mathbf{r})$) are also important in providing valuable information regarding the reactivity pattern at a local atomic site in a molecule.

Information about $\rho(\mathbf{r})$ is important to get insights into site-selectivity for a molecule and can be determined in terms of the first order variation in energy (E) as a function of the external potential ($v(\mathbf{r})$) (Parr & Yang, 1989, 1995).

$$\rho(\mathbf{r}) = \left(\frac{\delta E}{\delta v(\mathbf{r})}\right)_N . \tag{16}$$

The Fukui function ($f(\mathbf{r})$) (Ayers & Levy, 2004; Fukui et al., 1952, 1954; Fukui, 1975, 1982; Parr & Yang, 1984; Yang et al., 1984) is very useful to evaluate quanlitatively the extent of local response at a particular atomic site of a molecule. It is defined as the differential change in $\rho(\mathbf{r})$ due to an infinitesimal change in the number of electrons (N).

$$f(\mathbf{r}) = \left(\frac{\partial \rho(\mathbf{r})}{\partial N}\right)_{v(\mathbf{r})} = \left(\frac{\delta \mu}{\delta v(\mathbf{r})}\right)_N . \tag{17}$$

Now, due to the discontinuity in the derivative in eq. 17, for integral values of N, by applying the finite difference and frozen core approximations three different types of Fukui functions can be defined as follows: (Ayers & Levy, 2004; Parr & Yang, 1984)

For nucleophilic attack:

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$f^{+}(\mathbf{r}) = \left(\frac{\partial\rho(\mathbf{r})}{\partial N}\right)^{+}_{v(\mathbf{r})} \approx \rho_{N+1}(\mathbf{r}) - \rho_{N}(\mathbf{r}) \approx \rho_{LUMO}(\mathbf{r})\,. \tag{18a}$$

For electrophilic attack:

$$f^{-}(\mathbf{r}) = \left(\frac{\partial\rho(\mathbf{r})}{\partial N}\right)^{-}_{v(\mathbf{r})} \approx \rho_{N}(\mathbf{r}) - \rho_{N-1}(\mathbf{r}) \approx \rho_{HOMO}(\mathbf{r})\,. \tag{18b}$$

For radical attack:

$$f^{0}(\mathbf{r}) = \frac{1}{2}\left[f^{+}(\mathbf{r}) + f^{-}(\mathbf{r})\right]. \tag{18c}$$

Yang and Mortier (1986) further proposed a coarse-grained atom by atom representation of the Fukui function, called condensed-to-atom Fukui function. Based on a finite-difference approach, they can be represented as:

$$f_k^{+} = q_k(N+1) - q_k(N) \text{ for nucleophilic attack} \tag{19a}$$

$$f_k^{-} = q_k(N) - q_k(N-1) \text{ for electrophilic attack} \tag{19b}$$

$$f_k^{0} = [q_k(N+1) - q_k(N-1)] \,/\, 2 \text{ for radical attack} \tag{19c}$$

where q_k is the electron population at a particular k^{th} atomic site in a molecule.

Therefore, condensed-to-atom Fukui function can be easily computed through the data obtained from the population analysis.

Mathematically, global softness (S) can be expressed as an integral of the individual local softness ($s(\mathbf{r})$). A normalized condition between S and $s(\mathbf{r})$ can be written as:

$$S = \int s(\mathbf{r})dr \tag{20}$$

$s(\mathbf{r})$ is connected to $f(\mathbf{r})$ through a chain rule as:

$$s(\mathbf{r}) = \left(\frac{\partial\rho(\mathbf{r})}{\partial\mu}\right)_{v(\mathbf{r})} = \left(\frac{\partial\rho(\mathbf{r})}{\partial N}\right)_{v(\mathbf{r})}\left(\frac{\partial N}{\partial\mu}\right)_{v(\mathbf{r})} = f(\mathbf{r}).S \tag{21}$$

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

f(**r** *)* acts mainly as an intra-molecular reactivity descriptor by describing the reactivity of the atomic sites in a particular molecule whereas unlike *f(***r***)*, *s(***r***)* acts as an inter-molecular reactivity descriptor by comparing and correlating the tendency of interaction between a pair of neighboring molecules during chemical response.

Local hardness (*η(***r***)*) (Ghosh & Berkowitz, 1985; Yang & Parr, 1985) quantified the unwillingness of a particular atomic site in a molecule towards chemical attack. However, *η(***r***)* cannot be normalized to η as was done for *s(***r***)* to *S*. *η(***r***)* can be expressed as:

$$\eta(\mathbf{r}) = \frac{1}{N}\int \frac{\delta^2 F[\rho(\mathbf{r})]}{\delta\rho(\mathbf{r})\delta\rho(\mathbf{r}')}\rho(\mathbf{r}')d\mathbf{r}' \tag{22}$$

where F[ρ(**r**)] is the Hohenberg-Kohn universal functional. *η(***r***)* can also be expressed as:

$$\eta(\mathbf{r}) = \left(\frac{\delta\mu}{\delta\rho(\mathbf{r})}\right)_{v(\mathbf{r})}. \tag{23}$$

However, due to the dependence of $\rho(\mathbf{r})$ on $v(\mathbf{r})$, the above expression is ambiguous and hence cannot be considered as a basic definition for $\eta(\mathbf{r})$. Unlike η and S, $\eta(\mathbf{r})$ and $s(\mathbf{r})$ do not have a reciprocal relationship. They can be linked as:

$$\int \eta(\mathbf{r})s(\mathbf{r})dr = 1 \tag{24}$$

Further, the global hardness can be obtained from *η(***r***)* and *f(***r***)* as: (Chattaraj et al., 2007)

$$\eta = \int \eta(\mathbf{r})f(\mathbf{r})dr \tag{25}$$

Chattaraj et al. (2003) introduced the concept of philicity (*ω*$^{\alpha}$*(***r***)*), which represents the aptitude of a local atomic site in a molecule towards towards reactivity (electrophilicity or nucleophilicity).

The relation between the local electrophilicity (*ω(***r***)*) and the global electrophilicity (ω) can be expressed as:

$$\omega = \omega\int f(\mathbf{r})dr$$

$$\text{or, } \omega = \int \omega f(\mathbf{r})dr = \int \omega(\mathbf{r})dr \text{ thus, } \omega(\mathbf{r}) = \omega f(\mathbf{r}). \tag{26}$$

Therefore, from the expression it is obvious that *ω(***r***)* includes information about both ω and *f(***r***)* but without the knowledge of ω, *f(***r***)* alone cannot give any clue about *ω(***r***)*. One can apply this concept of *ω(r)* in several types of chemical reaction. Therefore, it will be better to represent philicity as *ω*$^{\alpha}$*(***r***)* in stead of *ω(***r***)*. α has signs of +, – and 0 describing nucleophilic, electrophilic and radical attacks, respectively. Therefore:

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$\omega^{\alpha}\left(\mathbf{r}\right)=\omega.f^{\alpha}\left(\mathbf{r}\right)\ \text{and},\quad \omega_{k}^{\alpha}=\omega.f_{k}^{\alpha} \tag{27}$$

where ω_k^{α} is the condensed-to-atom local philicity variant for the k^{th} atomic site in a molecule.

The concept of group philicity (ω_g^{α}) (Parthasarathi et al., 2004a) was also put forward in order to describe the reactivity of a group or an atomic assembly. It is generally expressed as a summation of the individual ω_k^{α} over all the related atoms. Therefore:

$$\omega_{g}^{\alpha}=\sum_{k=1}^{n}\omega_{k}^{\alpha} \tag{28}$$

where n describes the number of atoms present in the reacting group and $\alpha = +, -$ and 0 represents nucleophilic, electrophilic and radical attacks, respectively.

The efficacy of various CDFT based global and local reactivity descriptors in predicting chemical reactivity are guided by the various electronic structure principles like the principle of maximum hardness (PMH) (Ayers & Parr, 2000; Chattaraj et al., 1995, 2000; Chattaraj, 1996; Pan et al., 2013; Pan & Chattaraj, 2013; Parr & Chattaraj, 1991; Parr & Zhou, 1993; Pearson, 1987, 1993), minimum electrophilicity principle (MEP) (Chamorro et al., 2000; Pan et al., 2013; Parthasarathi, 2005), minimum polarizability principle (MPP) (Chattaraj & Sengupta, 1996, 1997; Chattaraj et al., 1999), minimum magnetizability principle (MMP) (Tanwar et al., 2006).

With the structural changes and/or substituent effects in a system, the variation of related conceptual DFT based reactivity descriptors led light into the quantitative correlation between chemical reactivity and toxicity. They indeed become important tools in building effective regression models for QSAR/QSPR/QSTR analyses.

4. ELECTROPHILICITY INDEX, NET ELECTROPHILICITY INDEX, AND THEIR LOCAL VARIANTS IN PREDICTING TOXICITY

Electrophilicity index (ω), net electrophilicity index ($\Delta\omega^{\pm}$) and the local variants of ω were found to be very effective tools in predicting toxicity. Some examples are given below.

4.1 Prediction of Toxicity of Various Alkali, Alkaline-Earth, Transition-Metal Ions and Arsenic Ions

Roy et al. (2009) attempted to predict the toxicity of arsenic (As^{3+} and As^{5+}) ions by choosing a training set composed of various alkali and alkaline-earth metal ions (Li^{+}, Na^{+}, K^{+}, Mg^{2+}, Ca^{2+}) and transition metal ions (Cr^{3+}, Mn^{2+}, Fe^{3+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}) along with their experimental toxicity (50% Lethal concentration, LC_{50}) in order to get single-parameter regression models. Two training sets composed of experimental toxicity (50% Lethal dose, LD_{50}) (Leermakers et al., 2006; Hughes, 2002) of two different sets of arsenic derivatives were also considered in order to predict their toxicity by employing several selected parameters. The corresponding atomic number (Z), energy (E), electrophilicity (ω) and the experimental as well as the calculated toxicity values expressed in terms of LC_{50} at the B3LYP/6-31+G(d) level are provided in Table 1. The calculated LC_{50} values in terms of Z and ω were computed as follows:

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$\text{Calc. } LC_{50} = -0.0181 \times Z + 0.5272; \quad (29)$$

$R = 0.923$, $SD = 0.054$, $N = 10$

$$\text{Calc. } LC_{50} = -7.1 \times 10{-}04 \times \omega + 0.2987; \quad (30)$$

$R = 0.793$, $SD = 4.337$, $N = 10$.

In both Z and ω models, two ions were found to be outliers, being Li^+ and K^+ in case of Z- model and Cu^{2+} and Zn^{2+} in case of ω- model. However, the Z- model was found to be better in prediction of toxicity of ions than that of ω- model but being the same Z value, Z- model could not differentiate the toxicity of As^{3+} and As^{5+}. On the other hand, ω- model can predict the toxicity of As^{3+} and As^{5+} correctly, As^{3+} ($LC_{50} = 0.217$) being more toxic than As^{5+} ($LC_{50} = 0.169$).

Further, efficacy of different global descriptors like number of nonhydrogenic atoms (N_{NH}) and ω and different local descriptors like philicity (ω^+_{As}) and atomic charges (Q_{As}) at As site were tested in building QSTR taking two sets of As-derivatives, whose experimental toxicity were known in terms of LD_{50} obtained from two different biological assays (Leermakers et al., 2006; Hughes, 2002).

Table 1. Atomic number (Z), energy (E, au), electrophilicity index (ω, eV), and experimental and calculated LC_{50} values for various selected alkali, alkaline-earth, and transition-metal ions along with arsenic ions at the B3LYP/6-31+G(d) level

Metal Ions	Z	E	ω	Expt. LC_{50}	Calc. LC_{50}	
					Z	ω
Training set

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

In both sets, seven As-derivatives were included (Set-I members were Arsenite (As(III)), Arsenobetaine (AsB), Arsenocholine (AsC), Monomethyl arsonic acid (MMA), Dimethyl arsinic acid (DMA), Trimethyl arsine oxide (TMAO), Tetramethylarsonium ion (TeMA) and Set-II members were Arsenate [As(V)], Arsenite [As(III)], Arsenobetaine (AsB), Arsenic trioxide (As_2O_3), Monomethyl arsonic acid (MMA), Dimethyl arsinic acid (DMA), Trimethyl arsine oxide (TMAO)). For each individual descriptor, one-parameter regression analyses were performed. It was found that N_{NH} has reasonably good predictive power towards the toxicity of As-derivatives in both the sets except the case of TMAO molecule.

ω showed better prediction in set-II than in set-I. On the other hand, ω^+_{As} showed better prediction in set-I than in set-II and Q_{As} could not predict the toxicity of As(III) in both the sets as well as As_2O_3 in set-II. Nevertheless, none of these descriptors could predict the toxicity of all seven molecules in both the sets. Then possible combinations of these four descriptors were tested towards the prediction of toxicity. Two-parameter regressions were not found that much suitable in predicting toxicity of all the As-derivatives; however, three-parameter regressions composed of one global (N_{NH} or ω) and two local parameters (ω^+_{As} and Q_{As}) were capable to represent the toxicity of all the derivatives reasonably well (see Figure 1).

*Figure 1. Experimental versus calculated toxicity (LD50) values using three-parameter (N_{NH}, ω^+_{As}, and Q_{As}) regression model for the complete set of set-I (**1**) and II (**2**) As-derivatives and three-parameter (ω, ω^+_{As}, and Q_{As}) regression model for the complete set of set-I (**3**) and II (**4**) As-derivatives*

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

The corresponding regression models could be represented as follows:

Set-I:

$$\text{Calc.LD}_{50} = 1.983 \times N_{\text{NH}} - 5.360 \times \omega^{+}_{\text{As}} - 35.926 \times Q_{\text{As}} + 15.402 \quad (31)$$

$R = 0.866$, $SD = 2.516$, $N = 7$

$$\text{Calc.LD}_{50} = 1.805 \times \omega - 16.312 \times \omega^{+}_{\text{As}} - 85.353 \times Q_{\text{As}} + 51.415 \quad (32)$$

$R = 0.898$, $SD = 2.216$, $N = 7$

Set-II:

$$\text{Calc.LD}_{50} = 0.484 \times N_{\text{NH}} - 3.232 \times \omega^{+}_{\text{As}} - 16.968 \times Q_{\text{As}} + 10.065 \quad (33)$$

$R = 0.865$, $SD = 1.254$, $N = 7$

$$\text{Calc.LD}_{50} = 4.724 \times \omega - 10.881 \times \omega^{+}_{\text{As}} - 54.889 \times Q_{\text{As}} + 23.380 \quad (34)$$

$R = 0.963$, $SD = 0.671$, $N = 7$

It was also found that the toxicity prediction power of the combination, ω, ω^{+}_{As} and Q_{As} is better than that of the combination of N_{NH}, ω^{+}_{As} and Q_{As}.

4.2 Prediction of the Toxicity ($pIGC_{50}$) of 252 Aliphatic Compounds on *Tetrahymena Pyriformis*

Chattaraj et al. (2007) used global descriptors like the number of carbon atoms (N_C), number of nonhydrogenic atoms (N_{NH}) in a molecule, ω and local descriptors like ω^{+}_{max}, ω^{-}_{max}, q_k^{max} computed at the HF/6-311G(d) level in modeling effective QSTR of a large number of aliphatic compounds on *T. pyriformis*. Here ω^{+}_{max} and ω^{-}_{max} referred to the ω_k^{α} at an atomic site in which it was maximum. q_k^{max} implied atomic charge at the kth site having maximum charge. By studying 252 aliphatic compounds, it was found that apart from the set of aliphatic amines, the atom number (N_C and N_{NH}) was an important descriptor whereas ω was also turned out as an effective descriptor in most of the cases. The predictability towards toxicity of two-parameter models based on N_C and ω was also found almost same with respect to the corresponding three-parameter models built by N_C, ω and any one descriptor from N_{NH}, ω^{+}_{max}, ω^{-}_{max}, q_k^{max}. Different regression equations adopted in one (N_C)- and two (N_C, ω)-parameter models are given Table 2. N_C-based single parameter model could predict toxicity fairly in most of the cases. In few cases like carboxylic acids, halogenated acids, amino alcohols and amines, it did not work. However, except amines the predictability towards toxicity of the model was found to improve significantly in coupling N_C with ω. In cases of amines, q_k^{max} and ω^{-}_{max} were also found to be important in describing toxicity. With the observation that in many cases, similar results were obtained, N_C was termed as the crude alternative

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

of log P. The plots of experimental $pIGC_{50}$ versus calculated $pIGC_{50}$ values are displayed in Figure 2. Quite large R^2, R^2_{cv} and variance adjusted to degrees of freedom, R^2_{adj} values implied the effectiveness of these models in building QSTR.

4.3 Prediction of Toxicity of Several Polyaromatic Hydrocarbons (PAH)

The global and local electrophilicities computed at the B3LYP/6-31G(d) level were used to predict the toxicity of several polyaromatic hydrocarbons (PAH) (Roy et al., 2006c). The toxicity was represented in terms of pIC_{50}, which could be defined as the molar concentration of these chemicals required to displace 50% of radio-labeled tetrachlorodibenzo-p-dioxin (TCDD) from the arylhydrocarbon (Ah) receptor. As a training set, dependent and independent variables were considered as the experimental pIC_{50} values of the electron acceptor toxin like polychlorinated dibenzofurans (PCDF) and ω, respectively. Further, this model was also employed on another set of polychlorinated biphenyls (PCB). General structures of PCDFs, and PCBs are provided in Tables 3 and 4, respectively, along with the atom numbering, identitity number and substitution pattern. The fractional number of electrons (ΔN) shifted from the PCDFs, PCBs and amines (A) to the nucleic acid bases/DNA base pairs (B) was also used as a descriptor to describe toxicity. The positive values of ΔN for PCDFs and PCBs implied their electron accepting nature whereas the negative values for

amines recognized them as electron donors. Reasonably good correlation was found to exist between ΔN (in between toxin and guanine) and ω having R = 0.991. The correlation between ΔN and exp. pIC_{50} was 0.881 whereas that obtained from the two-parameter regression based on ΔN and ω and exp. pIC_{50} was 0.892 (see Figure 3). Similarly, in cases of interactions in between PCDFs and GCWC (Guanine-Cystosine Watson-Crick) base-pairs, good correlations were observed. The calculated parameters (ω and ω^{+}_{max}) along with the experimental and predicted pIC_{50} values of the training set of PCDFs and PCBs are given in Table 5. In case of PCDFs, ω values gave a correlation R value of 0.891 whereas in case of PCBs, it was 0.834 (see Figure 4). The toxicity of aliphatic amines expressed by the 50% inhibitory growth concentration (IGC_{50}) towards ciliate fresh-water protozoa *Tetrahymena pyriformis* was also assessed. Due to the lack of global nucleophilicity, local nucleophilicity (ω^{+}_{max}) was applied as a descriptor for this set. This model was then further employed for the test set of amino alcohols. It was found that despite the occurrence of a very good correlation, there was some cross validation problem. Additionally, the use of the amines and amino alcohols together as both training and test sets provided fair correlation.

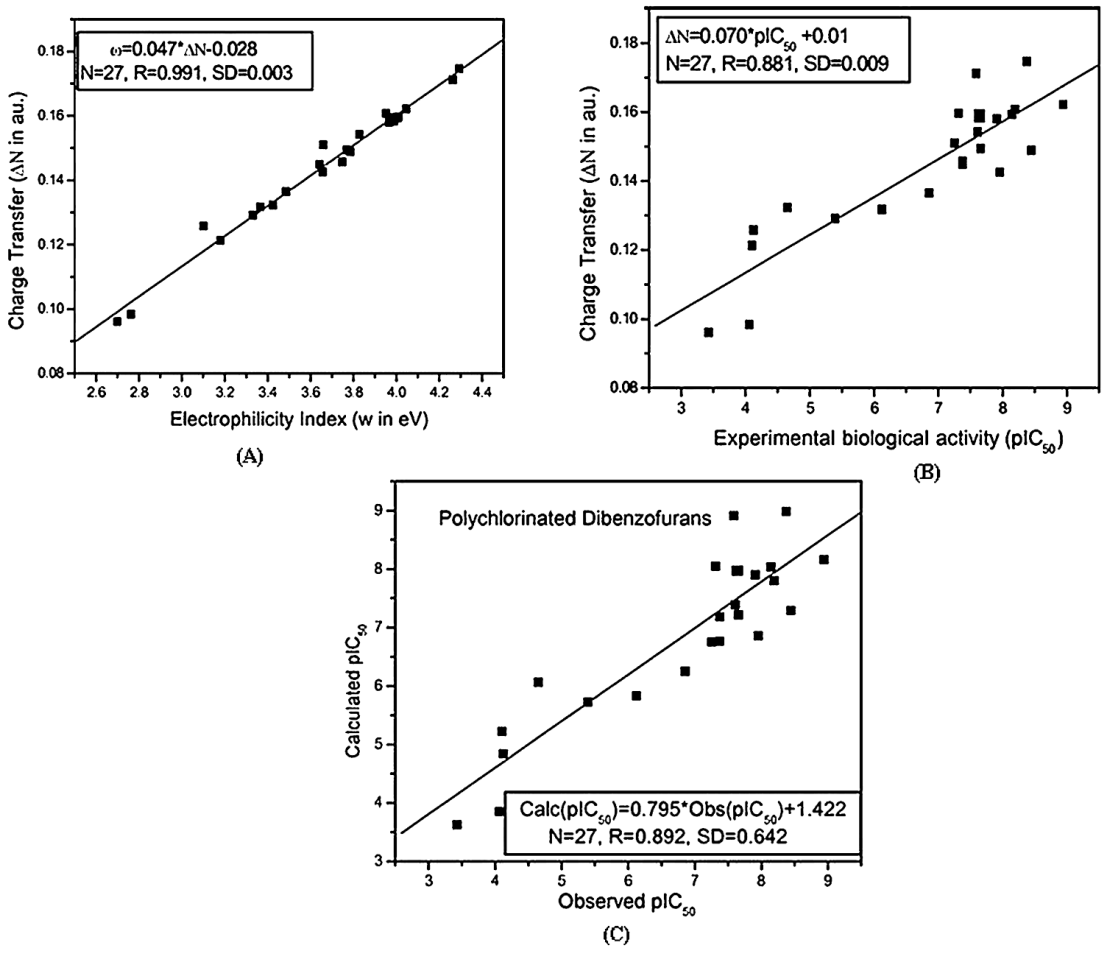
4.4 Structure-Toxicity Analysis on Chloroanilines

Padmanabhan et al. (2006a) further developed QSTR for aquatic toxicity ($\log(IGC_{50}^{-1})$) of a set of nine chloroanilines (CA) against *T. pyriformis* at the B3LYP/6-311++G(d,p) level as given in Table 6. The experimental and calculated $\log(IGC_{50}^{-1})$ are also given in Table 6. The regression equation considering experimental $\log(IGC_{50}^{-1})$ value (Schultz, 1999) as a dependent variable and ω as an independent variable was as follows:

$$\log(IGC_{50}^{-1}) = -4.414 + 56.035\ \omega \tag{35}$$

$N = 9$, $r^2 = 0.968$, SD = 0.144.



The plot between exp. and calc. $\log(IGC_{50}^{-1})$ (see Figure 5) showed that ω could describe the aquatic toxicity of these CA systems superbly having a correlation coefficient (r) of 0.984.

4.5 Prediction of Toxicity of Phenol, Nitrobenzene, and Benzonitrile-Derivatives

ω and its local variants, local electrophilicity index (ω^{α}_{k}) computed at the HF/6-31G(d) level were also employed in order to describe the toxicity of a large number (174) of aromatic compounds towards *T. pyriformis*, mainly belonging to the family of phenols, nitrobenzenes and benzonitriles (Roy et al., 2006b). At first, depending on their electron donating/accepting nature measured by comparing their χ values with those of the nuclei acid bases (adenine, thymine, guanine, cytosine and uracil) and DNA base pairs (GCWC and ATH), they were divided into two classes viz., 97 phenol derivatives having electron donating group and 77 nitrobenzenes and benzonitriles having electron accepting group. The regression models were used for the complete set of aromatic donors as

of nitrobenzene and benzonitrile derivatives (aromatic acceptors) and total Hartree-Fock energy (E_{HF}) could predict toxicity towards the *T. pyriformis* larger than 80% of cross-validation variance of data of these systems.

4.6 QSPR Model for the Prediction of Lipophilic Behavior of Polychlorinated Biphenyl Derivatives

Padmanabhan et al. (2006b) successfully developed effective QSPR model for the prediction of the lipophilic behaviour ($\log K_{ow}$) of a set having large number (133) of polychlorinated biphenyl (PCB) derivatives by using semi-empirical AM1 method. The effectiveness of a QSPR model depends on the accuracy in the selection of appropriate descriptors. CDFT based global descriptors like ω was employed in addition to the other descriptors viz., energy of the lowest unoccupied molecular orbital (E_{LUMO}) and number of chlorine substituents (N_{Cl}). Assuming experimental $\log K_{ow}$ values (Patil, 1991) of the training set of 100 PCB derivatives as dependent variable and these three descriptors along with their several combinations as independent variables, the regression models were developed (see Table 7). It was found that each descriptor individually could describe lipophilic behavior quite well ($r^2 = 0.81$-0.88); however the three-parameter model based on the combination of the ω, E_{LUMO} and N_{Cl} provided the best prediction.

This model was able to predict largest variation in data ($r^2 = 0.914$) with leave-one-out cross-validated squared correlation coefficient ($r^2_{cv} = 0.909$) having lowest SD value of 0.225. Figure 7 depicts the plots between exp. $\log K_{ow}$ vs. calc. $\log K_{ow}$ for the training set of 100 PCBs and the data set of 133 PCBs. In both cases, the three-parameter regression models gave excellent correlation coefficient, r value of 0.956 for these cases. Therefore, it clearly showed the efficacy of these descriptors in explaining lipophilic behavior of PCBs.

4.7 QSPR Models to Predict the Enthalpy of Vaporization of 209 Polychlorinated Biphenyl Congeners

The ω, E_{LUMO} and N_{Cl} were further employed to model QSPR in order to predict the enthalpy of vaporization ($\Delta_{vap}H_m$) of a set of 209 PCBs by using semi-empirical AM1 level of computations (Padmanabhan et al., 2007). A small data set containing only 17 PCBs, whose experimental $\Delta_{vap}H_m$ values were known, (Puri et al., 2001) was considered in building regression models. In general, data set is used to divide into training set and test set but here due to small number of data set, it was only considered as the train-

ing set. The different regression models based on the exp. $\Delta_{vap}H_m$ values as dependent parameters and individual ω, E_{LUMO} and N_{Cl} desciptors or their different combinations as the independent parameters along with the obtained r^2, r^2_{cv} and SD values are provided in Table 8.

The regression equation developed by each individual descriptor could predict $\Delta_{vap}H_m$ with high r^2 value (0.82-0.92); however the best correlation was provided by the three-parameter regression equation developed by ω, E_{LUMO} and N_{Cl} desciptors, which described the maximum variation in the data (r^2 = 0.976) having leave-one-out (LOO) cross-validated squared correlation coefficient, r^2_{cv} value of 0.948. This model could explain $\Delta_{vap}H_m$ value with higher efficiency (in terms of higher r^2_{cv}) than that model prescribed by Puri et al. (2001), where they obtained r^2_{cv} value of 0.852. Another advantage of this model was that it could provide excellent result even based on least expensive AM1 level of computations.

Now, another set of 27 PCDFs with their experimentally reported $\Delta_{vap}H_m$ values (Nakajoh et al., 2006) were considered to further test this model. Here 22 PCBs were taken as training set and remaining five PCBs as test set. It was found that the best regression equation in the previous set could describe maximum variation in the data ($r^2 = 0.915$) having leave-one-out cross-validated squared correlation coefficient, r^2_{cv} value of 0.856. It was also capable of predicting the $\Delta_{vap}H_m$ values of the test set within 4.2 kJ/mol error bars. Now including these five test set candidates in the data set, for all 27 PCBs, this model was able to represent the $\Delta_{vap}H_m$ values with $r^2 = 0.858$ and $r^2_{cv} = 0.758$. The plots between the exp. $\Delta_{vap}H_m$ and calc. $\Delta_{vap}H_m$ values for both the first set and the second set are given in Figure 12. In case of the first set, correlation coefficient (r) was 0.988 and in the second set it was 0.926. Based on this model, the $\Delta_{vap}H_m$ values for the remaining 183 PCB derivatives were predicted (see Figure 8).

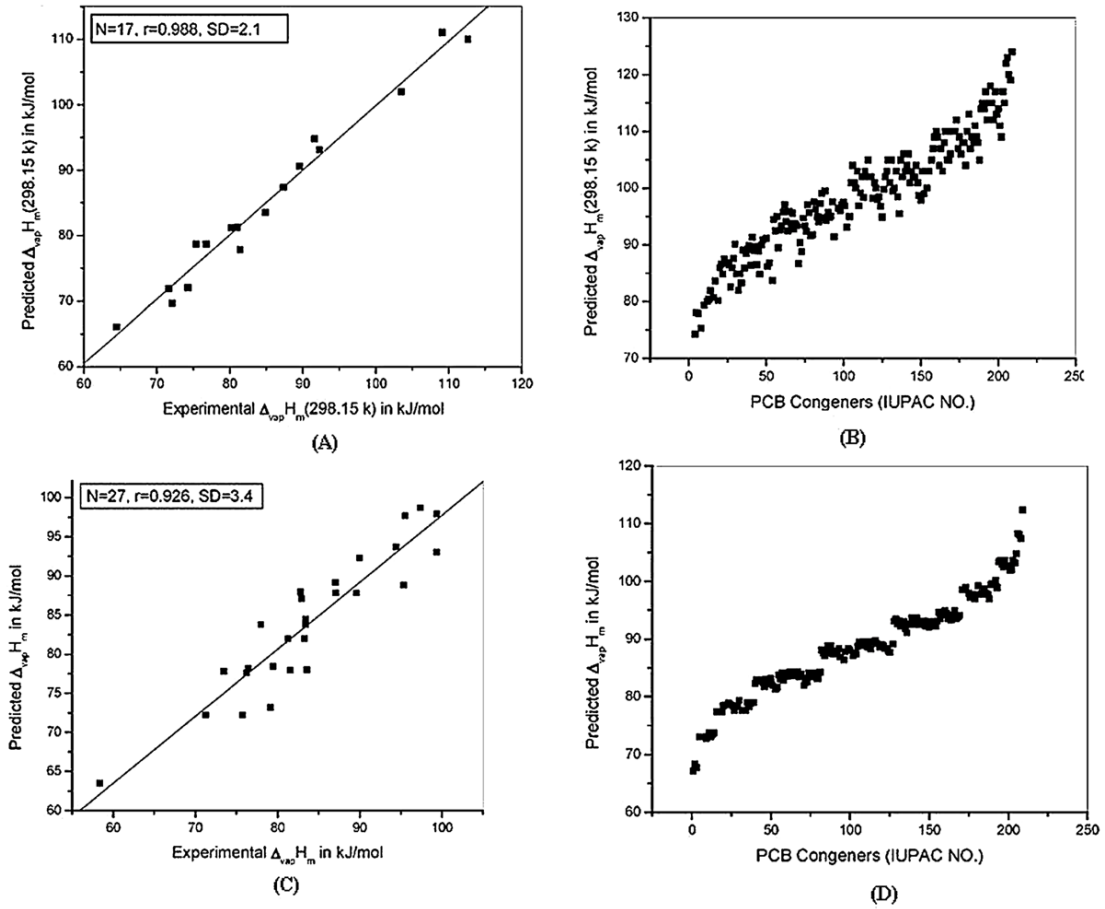
4.8 QSAR Model in Predicting Biological Activity of Testosterone and Estrogen Derivatives



Parthasarathi et al. (2004b) further employed electrophilicity to assess its efficacy as a probable biological activity descriptor in modeling QSAR for testosterone and estrogen derivatives. The geometry optimizations of all the systems were carried out at the semi-empirical AM1 level whereas the single point energy calculations at the B3LYP/6-31G(d) level were performed with those geometries obtained at the AM1 level. The biological activity of various testosterone derivatives was described by means of relative binding affinity (RBA) (Saartok et al., 1984), androgenic potency (Counsell et al., 1962), relative androgenic activity (Liao et al., 1973), therapeutic index (Sala & Baldratti, 1957), testosterone-binding globulins (TeBG) binding affinity (Cramer et al., 1988), relative competition indices (Liao et al., 1973), binding affinity for rat ventral prostate receptor protein (Wolff, 1955) and myotrophic to androgenic potency in temporal activity (Kochakian, 1976) (MAPT) whereas the same for estrogen derivatives was measured in terms of RBA values (Gao et al., 1999). In Figure 13, some representative plots between calculated ω and different biological activities of testosterone derivatives are presentated. In every case, a linear correlation between them was found; however, the correlations of RBA, relative competition indices and myotrophic to androgenic potency in temporal activity with ω were found to be better than the others. The corresponding regression models used to generate the plots were inserted within the Figures (see Figure 9). In all cases R^2 values were found to range from 0.61 to 0.90. It was also noted that B3LYP result was better than that of AM1 in predicting biological activity.

Similarly, in case of estrogen derivatives ω could predict their biological activity towards RBA having R^2 value in the range of 0.73 and 0.87. Therefore, it clearly showed that ω could predict biological activity of these systems quite efficiently.

Roy et al. (2007) also showed that the number of atoms in a molecule (N_A) along with ω values could explain the biological activities of testosterone and estrogen derivatives reasonably well ($R \approx 0.8$).

Figure 9. Relationship between various biological activities of testosterone derivatives with electrophilicity index
(Reprinted with permission from Parthasarathi et al., 2004b. Copyright © 2004, Elsevier).

Pasha et al. (2005) and Singh et al. (2004) developed QSAR models based on frontier orbitals information (E_{HOMO}, E_{LUMO}) and different CDFT based descriptors like η, S, χ, μ as well as different energy descriptors like total energy, heat of formation, electronic energy, and the highest negatively charge on an atom to predict different biological activities of testosterone and estrogen derivatives. They found that the regression models made by η and different energy descriptors possess better predicitivity than the other combinations. They argued that η represents the situation in these cases in a better way due to the associated maximum hardness principle. Srivastava et al. (2005) further showed that some other descriptors like IP and EA of an atom in a molecule, atomic softness could predict the biological activity of testosterone derivatives quite well, The differences in softness values of estrogen derivatives and lysine, histidine, tyrosine and cysteine receptors were also found to be an effective parameter in describing the biological activities of estrogen derivatives (Pasha et al., 2005). Rokhina & Suri (2012) further built QSPR to represent the estrogenicity of the natural estrogen hormones. They found that the information of frontier molecular orbital energies is very important to interpret this activity.

5. GROUP PHILICITY TOWARDS MODELING QSAR

In addition to the conventional global electrophilicity Padmanabhan et al. (2006c) used group philicity (ω_g^+, ω_g^-) computed at the B3LYP/6-31G(d) level to model QSAR for ecotoxicity of chlorophenols (CPs). The data set was made by 18 CPs, which was divided into training set having 16 CPs and test set containing two CPs. Then various regression models were developed by these descriptors in order to describe the experimental toxicity ($\log(1/EC_{50})$) (Devillers & Chambon, 1986) of the training set against *Daphnia magna* taking $\log(1/EC_{50})$ as a dependent variable whereas ω, ω_g^+ and ω_g^- as independent variables (see Table 9). It was found that two-parameter regression equation made by ω_g^+ and ω_g^- was capable of describing maximum variation data (88.7%) having large r^2_{cv} value of 0.826. The SD was also found to be the least for this model. This model was also found to predict the experimental $\log(1/EC_{50})$ value for the test set within ± 0.05 error bar. Now, regression analyses were carried out for all 18 CPs (data set) (see Table 9). In this set also, the combination of ω_g^+ and ω_g^- could explain maximum variation data (88.9%) along with r^2_{cv} value of 0.838. The second best model was three-parameter regression composed by ω, ω_g^+ and ω_g^-, which could also predict 88.9% variation data, however, the r^2_{cv} value for this model was 0.812. The plots of calc. $\log(1/EC_{50})$ vs exp. $\mathrm{Log}(1/EC_{50})$ are given in Figure 10(A), which shows a correlation coefficient of 0.942 for the best model. Further, these descriptors were used to explain the experimental toxicity of CPs against *B. rerio*, and *Bacillus*. It was found that in case against *B. rerio*, three-parameter regression model (ω, ω_g^+ and ω_g^-), being a very good model, could explain 92.8% variation data ($r^2_{cv} = 0.878$) having correlation coefficient value (r) of 0.964 (see Figure 10(B))

Table 9. Regression models for the toxicity [log(1/EC$_{50}$)] against D. magna using various descriptors for a training Set of 16 CPs and data set of 18 CPs

S.No.	Regression Equation	r^2	r^2_{cv}	SD
	For training set			
1	$\log(1/EC_{50}) = -2.2 + 198.0*\omega_g^-$	0.515	0.374	0.348
2	$\log(1/EC_{50}) = -0.9 + 28.7*\omega$	0.731	0.671	0.259
3	$\log(1/EC_{50}) = -1.4 + 24.8*\omega + 42.0*\omega_g^-$	0.741	0.630	0.264
4	$\log(1/EC_{50}) = -3.8 + 545.6*\omega_g^+$	0.874	0.835	0.177
5	$\log(1/EC_{50}) = -3.5 + 3.5*\omega + 491.3*\omega_g^+$	0.877	0.802	0.178
6	$\log(1/EC_{50}) = -4.0 - 0.6*\omega + 492.3*\omega_g^+ + 43.26*\omega_g^-$	0.887	0.792	0.182
7	$\log(1/EC_{50}) = -4.0 + 485.3*\omega_g^+ + 41.9*\omega_g^-$	0.887	0.826	0.175
	For data set			
1	$\log(1/EC_{50}) = -2.2 + 196.2*\omega_g^-$	0.529	0.409	0.326
2	$\log(1/EC_{50}) = -0.8 + 28.4*\omega$	0.704	0.644	0.260
3	$\log(1/EC_{50}) = -1.6 + 22.4*\omega + 65.5*\omega_g^-$	0.731	0.634	0.254
4	$\log(1/EC_{50}) = -3.8 + 545.5*\omega_g^+$	0.876	0.842	0.167
5	$\log(1/EC_{50}) = -3.6 + 3.3*\omega + 496.4*\omega_g^+$	0.879	0.817	0.171
6	$\log(1/EC_{50}) = -3.9 - 0.6*\omega + 477.3*\omega_g^+ + 40.2*\omega_g^-$	0.889	0.812	0.170
7	$\log(1/EC_{50}) = -4.0 + 484.6*\omega_g^+ + 41.4*\omega_g^-$	0.889	0.838	0.164

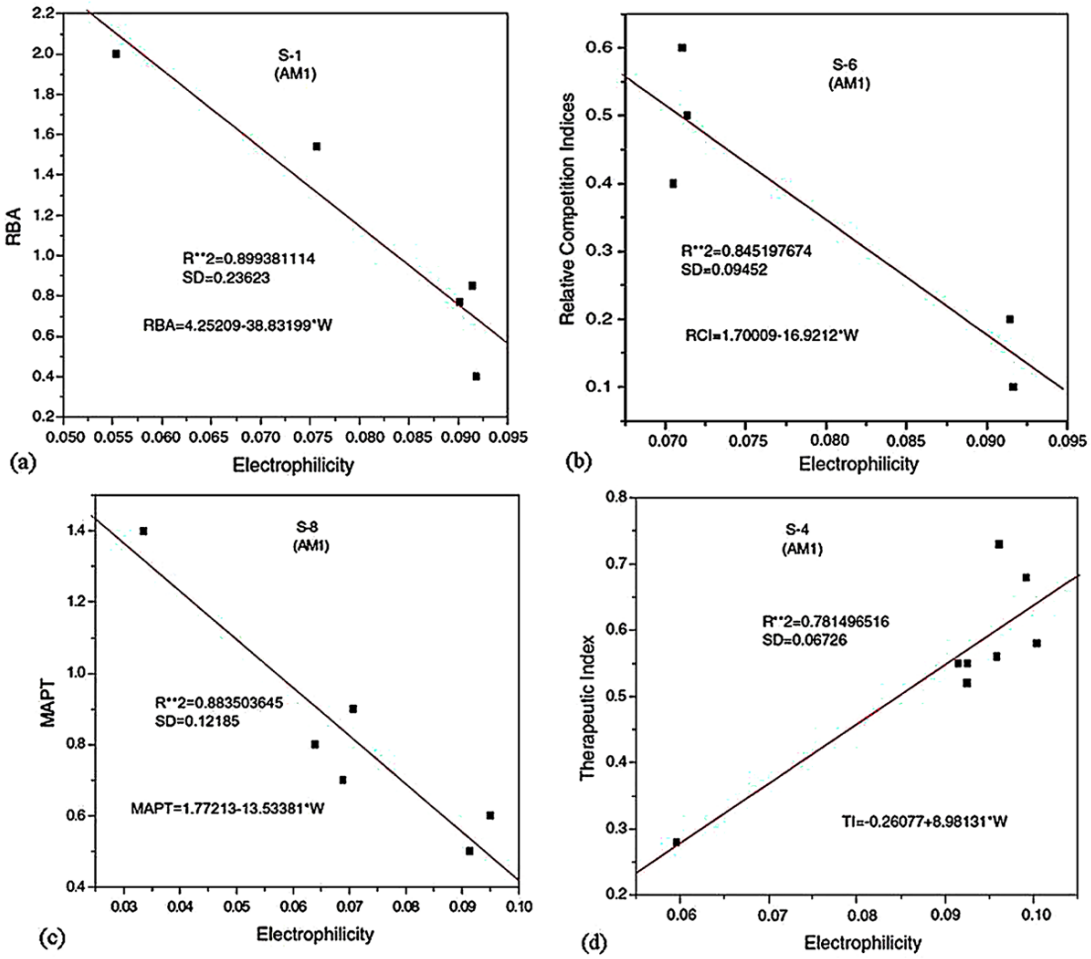
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



whereas in case against *Bacillus* this model was able to describe maximum variation in data (91.9%) along with r^2_{cv} value of 0.863 and r value of 0.959 (see Figure 10(C).

Therefore, this result implied that group philicity along with electrophilicity are very much effective in representing the toxicity of CPs against *D. magna*, *B. rerio*, and *Bacillus*. It in turn showed the importance of these reactivity indices as effective descriptors in ecotoxicological studies.

6. EFFECT OF CHOSEN FUNCTIONALS IN BUILDING GLOBAL REACTIVITY DESCRIPTORS BASED QSAR/QSPR/QSTR MODELS

Vijayaraj et al. (2009) assessed the effect of studied functionals on the ionization potential (*IP*) and the electron affinity (*EA*) of the systems, which were generally used to compute the CDFT based reactivity descriptors. Therefore, the dependence of *IP* and *EA* on the chosen functionals would raise questions

Figure 10. Plots between experimental and calculated toxicity of CPs against (A) D. magna, (B) B. rerio, and (C) Bacillus

about the level of theory chosen to construct QSAR, QSPR and QSTR based on the reactivity descriptors. In other words, the predictive power of a regression model might depend on the chosen level of theory. In order to explore the efficacy of various density functionals along with different basis sets in calculating *IP* and *EA*, hence, to benchmark, systematic computations were performed considering a series of chlorinated benzenes (CBs). Some common functionals of pure, GGA, hybrid, and meta and hybrid meta GGA types were employed. It was found that a good agreement between computed and experimental *IP* and E*A* values could be attained with the increase in the rigor of the level of computation. The prediction of *IP* and *EA* of CBs, computed using both Koopmans' approximation and ΔSCF method, was most accurately made by the use of M05-2X functional. Further, in between Koopmans' approximation and ΔSCF method, *IP* and *EA* computed by ΔSCF method matched more closely with the corresponding experimental values than that by the Koopmans' approximation.

Now, using those descriptors computed at different levels of theory, different regression models were designed to predict the toxicity of nine CBs against *Poecilia reticulata*. Different descriptors along with different approximations were included. It was found that although the computation of global reactivity descriptors at different levels and/or different basis sets yielded considerably different values, the mean deviation of a certain property among all the studied systems with respect to the chosen method/basis set was comparable. It meant that with the change in studied method and/or basis set, the values of computed global reactivity descriptors would be changed, however, the magnitude of the difference in between the systems were more or less same in all the methods. This finding was important in this sense that the efficacy of a regression model and hence the correlation coefficient would not alter significantly with the change in level of theory. For example, in spite of good agreement with the experimental *IP* and *EA* using ΔSCF method, it did not improve the correlation coefficient with respect to that obtained using Koopmans' theorem. In general, to construct a QSAR/QSPR/QSTR model, one has to consider a data set containing a large number of systems. Therefore, it can be concluded that if one considers computationally a very cheap level of theory to model QSAR/QSPR/QSTR, it can be possible to get reliable results similar to the one constructed from the results of a high level of theory, which will in deed save a lot of computational time.

7. CONCLUSION

In order to better understand the variation of property, activity and toxicity with the structural change of a molecular motif, the Quantitative-Structure-(Property/Activity/Toxicity) Relationship models are widely applied. Various types of methods and models were employed to construct effective regression equations. Both, global and local reactivity descriptors based on Conceptual Density Functional Theory are found to be very effective indices in order to predict biological activity or property or toxicity of a set of systems. We have specially drawn attention on the efficacy of the regression models built based on the different combinations of the parameters viz., electrophilicity index, net electrophilicity index, group philicity along with their local variants, atomic charge, number of carbon or Cl or non-hydrogenic atoms, atomic number, chemical potential, LUMO energy and Hartree-Fock energy in predicting the toxicity of various aliphatic compounds, polyaromatic hydrocarbons, chloroanilines, phenol, nitrobenzene, benzonitrile-derivatives, halogen, sulfur and chlorinated aromatic compounds, testosterone, estrogen derivatives, and different alkali, alkaline-earth, transition-metal, arsenic ions as well. Although individual

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

descriptors were found to vary with the change in level of theory and /or basis set, the efficacy of the overall QSAR/QSPR/QSTR models depend hardly on the level of theory. Therefore, very low level of theory can also yield reliable results.

Therefore, the reactivity descriptors within the purview of conceptual DFT will be a good choice in predicting the desired properties of a set of systems.

ACKNOWLEDGMENT

We are grateful to Professor Kunal Roy for inviting us to contribute this chapter. PKC would like to thank DST, New Delhi for the J. C. Bose National Fellowship. SP thanks CSIR, New Delhi for his fellowship.

KEY TERMS AND DEFINITIONS

Aliphatic Compounds: These are non-aromatic compounds made by carbon and hydrogen.

Electrophilicity: It is a measure of 'electrophilic power' of a molecule. It can be estimated as the electronegativity squared divided by twice the hardness.

Energies of Frontier Molecular Orbitals: They are the energies of the highest occupied molecular orbital and lowest unoccupied molecular orbital, respectively.

Group Philicity: It is a condensed philicity summed over a group of relevant atoms.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Net Atomic Charge: It is a non-integer charge at each atom in a molecule in elementary charge units.

Net Electrophilicity: It is the electron-accepting power of a molecule relative to its own electron-donating power.

Polyaromatic Hydrocarbons: These are compounds made by only carbon and hydrogen and contain multiple aromatic rings.

Polychlorinated Biphenyls: These are compounds containing two phenyl rings and several chlorine atoms are attached with phenyl rings.

***Tetrahymena Pyriformis*:** These are free-living ciliate protozoa, generally found in freashwater ponds.

ABSTRACT

The level of malondialdehyde (MDA) in wet tissue of different organs is utilized as a measure of toxic effect. The numerical data on the concentration of MDA in wet tissue of liver, kidneys, brain, and heart of rat is examined as the endpoint which are impacted by different dose (mg/kg), exposure time (3 and 14 days) and single oral treatment of aluminium nano-oxide (Al_2O_3) with 30 nm or 40 nm. An attempt to develop predictive model for this endpoint has been carried out in this work. SMILES is a traditional tool to represent molecular structure for QSPRs/QSARs. In contrast to traditional SMILES, so-called quasi-SMILES can be a tool to build up quantitative features – property / activity relationships (QFPRs/QFARs) for endpoints which are not defined by solely molecular structure, but by a group of physico-chemical and/or biochemical conditions. The quasi-SMILES is the representation of the above eclectic conditions whereas the QFPR/QFAR are models of endpoints which are modified under impacts of these eclectic conditions.

1. INTRODUCTION

The influence of various nanomaterials on the everyday life gradually increase owing to their high functional potential be very useful materials for different applications (Vanić and Škalko-Basnet, 2013; Ma et al., 2013; Singh and Gupta, 2014; Melagraki and Afantitis, 2014; Panneerselvam and Choi, 2014; Potrč et al., 2015; Sauer et al., 2015; Speck-Planche et al., 2015). However, a tool to risk assessment for

nanomaterials similar to quantitative structure – property /activity relationships (QSPRs/QSARs) (Toropova et al., 2012; Yilmaz et al., 2015) as research field is in an initial phase of the development (Muthu, 2012; Oksel et al., 2015). The solution of this task for regulatory purposes in the case of nanomaterials involved in the agriculture, food, cosmetics, drug discovery, etc. needs to be reached in the near future (Arts et al., 2014; Arts et al., 2015; Filon et al., 2015; Amenta et al., 2015).

In general, different measures of danger acting of nanomaterials upon cells are known (Long et al., 2009; Prabhakar et al., 2012; Diez-Ortiz et al., 2015; Toropova et al., 2015a; Hadrup et al., 2015). In particular, the level of malondialdehyde (MDA) in wet tissue of different organs is considered as a measure of toxic effect of nanomaterials (Long et al., 2009; Prabhakar et al., 2012).

Attempts which are aimed to build up models for such acting of nanomaterials using the traditional QSPR/QSAR approaches (De Abrew et al., 2015), as rule, are impossible excepting the cases of acting of small molecules together with a nanomaterial (Fourches et al., 2010; Toropov et al., 2013).

In the case of traditional materials where the molecular structure represented by SMILES is available to mathematical and computational analyses, the QSPR/QSAR is a tool to more or less satisfactory prediction of different endpoints (Veselinović et al., 2013; Achary, 2014a, 2014b; Comelli et al., 2014; Nesmerak et al., 2014; Worachartcheewan et al., 2014; Toropova and Toropov, 2014; Veselinović et al., 2015).

A possible way to build up such models can be expressed by paradigm: "Endpoint = f(SMILES)". In the case of nanomaterials where weak variation of molecular structure accompanied by intensive variation of conditions more appropriate paradigm is "Endpoint = f(Eclectic data)".

The quasi-SMILES can be the representation of eclectic data (Toropov and Toropova, 2015). The quasi-SMILES are analogies of traditional SMILES, but symbols involved in the quasi-SMILES are representations of features and/or conditions that are not representation of features of the molecular architecture only. (Toropova and Toropov, 2013; Toropov and Toropova, 2014; Toropova et al., 2015b).

The aim of this work is to build up models for level of MDA in wet tissue of different organs of rat under different action of Al_2O_3 nanoparticles.

2. METHOD

2.1. Data

The experimental data on the level MDA in wet tissue (nanomoles of MDA per gram wet tissue) of liver, kidneys, brain, and heart of rat under different conditions taken in the literature (Prabhakar et al., 2012). Table 1 contains the representation of different conditions of acting Al_2O_3 nanoparticles by quasi-SMILES. These data (quasi-SMILES together with endpoint values) were three times randomly split into the training, calibration, and validation set. The length of quasi-SMILES (the number of symbols) is important indicator for possibility of a model to be successful.

It is to be noted that length 1 for quasi-SMILES is nonsense, because in this case the prevalence of each attribute is zero in the training or in calibration set (the presence in both mentioned set is impossible), i.e. for each attribute, A, one can obtain:

$$N_{training}(A) \times N_{calibration}(A) = 0$$

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$P_{training}(A) \times P_{calibration}(A) = 0$$

where $N_{training}(A)$ and $N_{calibration}(A)$ are the numbers of attribute into the training and calibration sets, respectively; $P_{training}(A)$ and $P_{calibration}(A)$ are probabilities of presence of the attribute A in the training and calibration sets, respectively.

The length 2 gives possibility to obtain at least for part of attributes:

$$N_{training}(A) \times N_{calibration}(A) \neq 0$$

$$P_{training}(A) \times P_{calibration}(A) \neq 0$$

The total number of quasi-SMILES involved in built model has significant meaning:

Length 2 …$N_{max} = N_1 \times N_2$

Length 3 …$N_{max} = N_1 \times N_2 \times N_3$

Length 4 …$N_{max} = N_1 \times N_2 \times N_3 \times N_4$

For instance, two situations for quasi-SMILES with length 2 which are represented by a pairs of < Impact, Condition > are represented in Table 2. From practical point of view, the second situation is preferable, because 10 variables are more information about a phenomenon than 6 variables.

Table 2. Different eclectic sources for construction of the quasi-SMILES

Situation 1

	Impact 1	**Impact 2**	**Impact 3**
Condition 1	Endpoint 11	Endpoint 12	Endpoint 13
Condition 2	Endpoint 21	Endpoint 22	Endpoint 23

$Nmax = N_{condition} \times N_{impact} = 2 \times 3 = 6$

Situation 2

	Impact 1	**Impact 2**	**Impact 3**	**Impact 4**	**Impact 5**
Condition 1	Endpoint 11	Endpoint 12	Endpoint 13	Endpoint 14	Endpoint 15
Condition 2	Endpoint 21	Endpoint 22	Endpoint 23	Endpoint 24	Endpoint 25

$Nmax = N_{condition} \times N_{impact} = 2 \times 5 = 10$

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Using the formalism of the quasi-SMILES which are utilized to integrate eclectic data for the nanomaterials one can build up model for endpoints related to nanomaterials. Apparently, increase of length of quasi-SMILES is promoter of improving for the statistical quality of a model. In this work, the length of used quasi-SMILES is four.

2.2. Optimal Descriptors

The optimal descriptors are calculated as the following:

$$DCW(Threshold, N_{epoch}) = \sum CW(C_k) \quad (1)$$

where C_k is code of k-th feature (condition); $CW(C_k)$ is the correlation weight for C_k; The *Threshold* and N_{epoch} are parameters of the Monte Carlo optimization. The *Threshold* is a tool to define two classes of features (conditions): rare (noise) and not rare, i.e. active. The optimal descriptors are calculated with the correlation weights of active features. Correlation weights for rare features (conditions) are fixed equal to zero, i.e. these are not involved in building up model; The N_{epoch} is the number of epochs of the Monte Carlo optimization.

The *Threshold* = T* and N_{epoch} =N* which give preferable statistical characteristics for the calibration set of quasi-SMILES should be defined by means of several runs of the Monte Carlo optimization. These parameters should be used to build up the final model for endpoint, ***E*** (Toropova et al., 2015a):

$$E = C_0 + C_1 \times DCW(T^*, N^*) \quad (2)$$

Figure 1 represents the scheme of the selecting T* and N*.

The predictive potential of the model calculated with Equation 2 should be checked up with the external validation set.

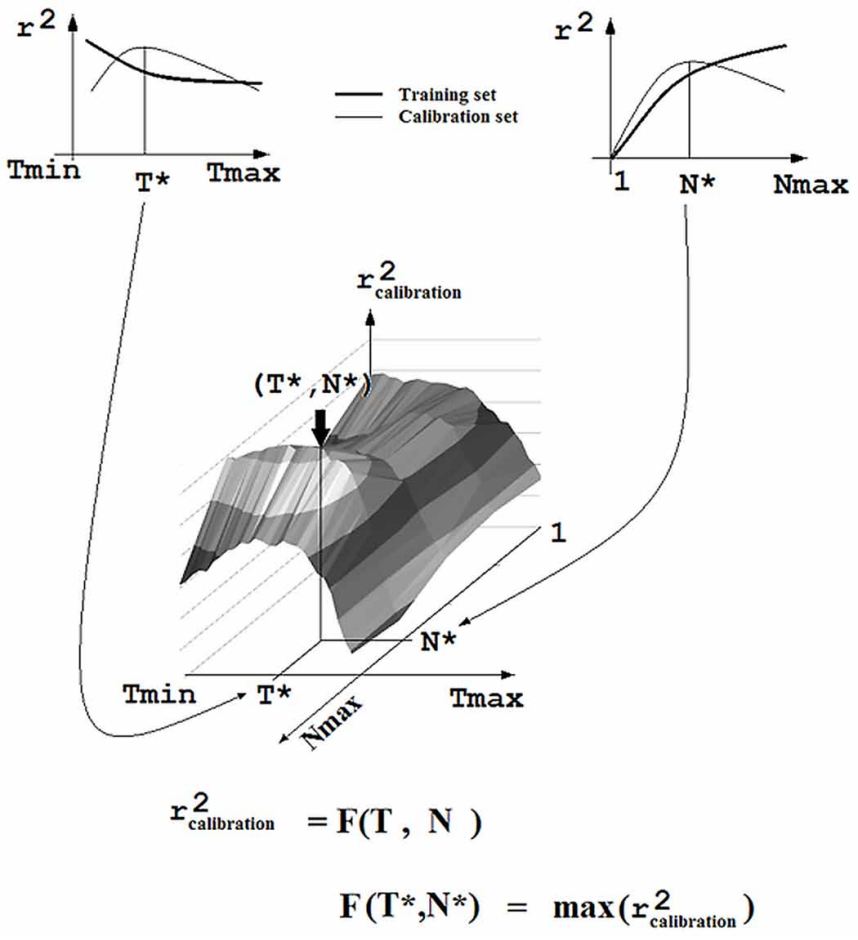
All operations with quasi-SMILES are carrying out by the same algorithms which were developed for the traditional SMILES (Toropov et al., 2012a, b; Roy, 2015).

3. RESULTS AND DISCUSSION

The optimal descriptors give for three random splits the following models:

E =-1357.4 (±57.96) + 344.21 (±14.61) * *DCW(1,3)* (3)

n=26, r^2=0.7382, q^2=0.6524, s=3.55, F=68 (training set)



n=9, r^2=0.7456, s=4.30 (calibration set)

n=13, r^2=0.7735, s=3.42 (validation set)

E =-617.60 (±17.64) + 155.21 (± 4.379) * *DCW(1,3)* (4)

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 1. The scheme of selecting of the T and N**

$$r^2_{calibration} = F(T, N)$$

$$F(T^*,N^*) = \max(r^2_{calibration})$$

n=29, r^2=0.7976, q^2=0.7479, s=3.52, F=106 (training set)

n=9, r^2=0.7711, s=3.76 (calibration set)

n=10, r^2=0.7234, s=3.51 (validation set)

E =-218.59 (± 7.953) + 54.172 (± 1.900) * *DCW(1,3)* (5)

n=28, r^2=0.7674, q^2=0.7007, s=3.76, F=86 (training set)

n=9, r^2=0.7041, s=2.71 (calibration set)

n=11, r^2=0.8254, s=4.08 (validation set)

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

In Equations 3-5, the n is the number of quasi-SMILES in a set (i.e. training set, calibration set, or validation set); the r^2 is the correlation coefficient; the q^2 is leave-one-out cross-validated r^2; the s is root-mean squared error; and the F is Fischer F-ratio.

Table 3 contains the correlation weights $\boldsymbol{CW(C_k)}$ for split 1 (Equation 3), split 2 (Equation 4) and split 3 (Equation 5) together with frequencies of $\boldsymbol{C_k}$ in the training and calibration sets.

Table 4 contains quasi-SMILES together with the numerical data on $\boldsymbol{E}$ for the models.

The third distribution into the training set, the calibration set, and the validation set should be estimated as the worst since attribute of quasi-SMILES "L" is absent in the calibration set. However, even for this distribution the prediction for the endpoint characterized by quite satisfactory statistical quality.

The mechanistic interpretation of a QSPR/QSAR model is important principle of building up predictive model (OECD, 2007; REACH 2011). The mechanistic interpretation for models similar to ones suggested in this work can be defined as the following. Having the numerical data on the correlation weights of features obtained in several runs of the Monte Carlo optimization, one can classify the features as promoters of endpoint increase (if the correlation weight of a feature every time is large) and promoters of endpoint decrease (if the correlation weight of a feature every time is small). In the examined dataset (Table 3), one can select doses ('1' and '2') together with the liver ('L') as promoters of increase the endpoint. Only heart ('H') is the promoter of the endpoint decrease. It can be interpreted as the following: the high doses (2000 and 1000 mg/kg) give increase of nanomoles of MDA per gram in wet tissue, liver accumulates the MDA more intensively than other organs, and heart accumulates the MDA less intensively than other organs.

Thus, the thesis that optimal descriptor can be a translator of eclectic data into endpoint prediction is confirmed.

Table 3. Correlation weights of quasi-SMILES attributes (conditions) for calculation of the DCW(1,3) for split 1, 2, and 3; T and C are frequencies of $\mathbf{C_k}$ *in the training set and calibration set, respectively*

4. CONCLUSION

The suggested scheme of the prediction for level of malondialdehyde in wet tissue of rat under action of the Al_2O_3 nanoparticles (oral exposure) based on described quasi-SMILES (Table 1) gives quantitative prediction for this endpoint. Since the suggested model is validated with a group of distribution into visible the training and calibration sets and invisible validation set, the approach can be used for regulatory purposes according to OECD principles (OECD, 2007) and REACH (REACH, 2011).

ACKNOWLEDGMENT

We show our gratitude to EC project PROSIL funded under the LIFE program (project LIFE12ENV/IT/000154) and the EC project PeptiCAPS (Project reference: 686141).

Toropova, A. P., & Toropov, A. A. (2014). CORAL software: Prediction of carcinogenicity of drugs by means of the Monte Carlo method. *European Journal of Pharmaceutical Sciences*, *52*, 21–25. doi:10.1016/j.ejps.2013.10.005 PMID:24514451

Toropova, A. P., Toropov, A. A., Benfenati, E., Korenstein, R., Leszczynska, D., & Leszczynski, J. (2015a). Optimal nano-descriptors as translators of eclectic data into prediction of the cell membrane damage by means of nano metal-oxides. *Environmental Science and Pollution Research International*, *22*(1), 745–757. doi:10.1007/s11356-014-3566-4 PMID:25223357

Toropova, A. P., Toropov, A. A., Rallo, R., Leszczynska, D., & Leszczynski, J. (2015b). Optimal descriptor as a translator of eclectic data into prediction of cytotoxicity for metal oxide nanoparticles under different conditions. *Ecotoxicology and Environmental Safety*, *112*, 39–45. doi:10.1016/j.ecoenv.2014.10.003 PMID:25463851

Toropova, A. P., Toropov, A. A., Rasulev, B., Benfenati, E., Gini, G., Leszczynska, D., & Leszczynksy, J. (2012). QSAR models for ACE-inhibitor activity of tri-peptides based on representation of the molecular structure by a graph of atomic orbitals and SMILES. *Structural Chemistry*, *23*(6), 1873–1878. doi:10.1007/s11224-012-9996-z

Vanić, Ž., & Škalko-Basnet, N. (2013). Nanopharmaceuticals for improved topical vaginal therapy: Can they deliver? *European Journal of Pharmaceutical Sciences*, *50*(1), 29–41. doi:10.1016/j.ejps.2013.04.035 PMID:23684936

Veselinović, A. M., Milosavljević, J. B., Toropov, A. A., & Nikolić, G. M. (2013). SMILES-based QSAR model for arylpiperazines as high-affinity 5-HT1A receptor ligands using CORAL. *European Journal of Pharmaceutical Sciences*, *48*(3), 532–541. doi:10.1016/j.ejps.2012.12.021 PMID:23287365

Veselinović, J. B., Toropov, A. A., Toropova, A. P., Nikolić, G. M., & Veselinović, A. M. (2015). Monte Carlo method-based QSAR modeling of penicillins binding to human serum proteins. *Archiv der Pharmazie*, *348*(1), 62–67. doi:10.1002/ardp.201400259 PMID:25408278

Worachartcheewan, A., Mandi, P., Prachayasittikul, V., Toropova, A. P., Toropov, A. A., & Nantasenamat, C. (2014). Large-scale QSAR study of aromatase inhibitors using SMILES-based descriptors. *Chemometrics and Intelligent Laboratory Systems*, *138*, 120–126. doi:10.1016/j.chemolab.2014.07.017

Yilmaz, H., Novoselska, N., Rasulev, B., Toropov, A.A., Guzel, Y., Kuz'min, V., Leszczynska, D., & Leszczynski, J. (2015). Amino substituted nitrogen heterocycle ureas as kinase insert domain containing receptor inhibitors: Performance of structure - activity relationship approaches. *Journal of food and drug analysis*, 23, 168 - 175.

This work was previously published in the Journal of Nanotoxicology and Nanomedicine (JNN), 1(1); edited by Bakhtiyor Rasulev, pages 17-28, copyright year 2016 by IGI Publishing (an imprint of IGI Global).

3Rs 1012, 1042

A

Ab Initio Modelling 1048, 1071
Ab Initio Prediction 557, 567, 885, 1047
Acetylators 17, 27
AcrAB-TolC 899, 901-903, 911-912, 915
Active Pharmaceutical Ingredient (API) 1288, 1466, 1475
Acute Lymphoblastic Leukemia 15, 27, 1217
Adaptive Trials 10
Adverse Drug Reactions 15, 274-275, 282, 288-290, 295, 314-315, 343, 700-701
Adverse Effects 13-15, 19, 141, 187-188, 195, 236, 298, 302, 355, 425, 428, 431, 440, 460, 472, 487, 491, 493-496, 503, 507, 644, 1195, 1212, 1216, 1221, 1224, 1258, 1269, 1314-1315, 1318-1319, 1339, 1367-1368, 1370, 1372-1374, 1378, 1386, 1411, 1432, 1440, 1477, 1483
Adverse Reactions 249, 365, 614-616, 619, 631, 1466
Ag NPs 1195-1197, 1201, 1401-1402, 1410, 1413, 1415, 1496, 1500-1501
AGO2 protein 712-713, 719, 721, 723
Aldose Reductase 572, 598
Aliphatic Compounds 1003, 1519, 1523, 1534, 1550, 1569
Allele 17, 19, 21-22, 27-28, 197-200, 202, 204-206, 315
Allelic Variation 15, 17, 28
Allergens 143, 613-614, 616-617, 619-622, 629, 631, 711-714, 716-718
Allergic Reactions 443, 472, 615-616, 618, 621, 626, 711-713, 716-717, 1374, 1437
allergy therapeutics 711, 717-718, 722-723
Alternative Therapies 284, 506, 1214, 1231, 1368
Amino Acid 16, 159, 189, 411-412, 437, 441, 526, 551-554, 556-557, 560, 563, 567-568, 598, 620, 672-673, 675, 715, 751-754, 757, 798, 811, 835, 838-839, 866, 878-880, 900, 910, 913, 928, 1047-1048, 1071, 1099, 1116, 1118, 1125, 1230, 1432
Amphiphilic 154-157, 160, 262-263, 273, 377, 915, 1222, 1260, 1325
Analgesic 204, 432, 441, 490-491, 493-496, 503-505, 507, 519, 670
Antiarrhythmics 17, 28
Antibiotic-Resistance 1475
Anticancer 131, 140, 142, 165, 185-186, 206, 208, 229, 231, 370, 372, 375, 377, 379, 427, 429-430, 434, 436, 438-439, 648, 670, 941-942, 957, 1261-1264, 1268-1269, 1356
Antidepressant 28, 201-202, 1372-1374
Antimalarial 434
Antimicrobial Agents 426, 899, 1195, 1500
Antioxidant 235, 427, 438, 461, 521, 523-524, 527-529, 531-532, 534, 536, 540, 571, 573-574, 576-577, 582, 598-599, 641-642, 646-648, 1411, 1482, 1501
Antipsychotics 17, 28, 502-503, 507, 657
Applicability Domain 1012-1015, 1023, 1025, 1030, 1036, 1042, 1344-1345, 1348
Argonaute Proteins 726
Artificial Neural Networks (ANN) 755, 853, 1320, 1343
Atovaquone 1300, 1313
Aurora Kinase Inhibitor 1129
Aurora Kinases 1127, 1129, 1142
AutoDock 690, 695-697, 702-703, 727-731, 733, 737-738, 783, 820-821, 827-828, 830-831, 834-835, 837, 840, 856-858, 863, 865, 1127, 1146, 1149-1150, 1155, 1185
Autonomy 277, 280, 291, 295
Ayurveda 1367, 1369-1370
Aβ peptide 727-728, 741

Staphylococcus Aureus 525, 529, 537, 900, 904, 909
STAT Protein 726
static structures 782-783
stochastic algorithms 730, 771, 777, 788
structural water 781-782
Structure-Activity Relationships 3, 567, 902, 916, 958, 970, 1315, 1339
Structure-Based 401, 560, 562, 683, 686, 689, 691, 728, 730, 780, 784, 821, 859, 862, 902, 1072, 1115, 1122, 1127, 1133, 1144-1146, 1150, 1152-1153, 1158, 1175-1179, 1181, 1191
Structure-Based Drug Design 560, 689, 728, 730, 780, 821, 902, 1072, 1115, 1122, 1133, 1144-1146, 1150, 1175, 1177, 1191
Subtype Selectivity 656-659, 662, 666-667, 669-670, 673, 675, 677, 682
SuperBihelix 660-661, 682
Superior Agents 281, 296
superparamagnetic iron 1410, 1416, 1502
Sustained Release 247, 250-251, 256-257, 259-260, 372-373, 1301, 1313
Synthetic Drugs 426, 443, 539, 1368-1370, 1372, 1374, 1386

T

Tanimoto coefficient 1081-1083, 1085, 1160
Targeted Drug Delivery 238, 311, 366-367, 380, 459, 1262-1263, 1286, 1288, 1302, 1313, 1379
Targeted Therapy 188, 195, 304, 311, 379, 1224, 1257
Tertiary Structure Prediction 551-552, 877-879, 882, 892, 1044, 1062
Tetrahymena Pyriformis 1523, 1534, 1537, 1570
Therapeutic Index 15, 17-18, 29, 139, 205, 316, 367, 376, 380, 460, 472, 862, 1261, 1379, 1386, 1546
Therapeutic Response 14, 17, 201, 205, 300, 1216
three-dimensional structures 690, 727, 958
Thromboembolism 24, 30
Thrombosis 24, 30, 189, 264, 316, 379
tissue targeting 128, 138
Titanium dioxide 1223, 1225, 1261, 1399, 1404-1405, 1411, 1501
Topology 559-560, 750, 755, 978, 1011, 1057, 1520
Toxicology 101, 403, 613-614, 623-624, 629, 945, 978, 1224-1225, 1317, 1325, 1328, 1485, 1494, 1519-1520
Traditional Medicine 425, 431, 539, 1367, 1370, 1374
Tumors 16, 30, 138, 186, 189-192, 194, 229, 233, 237, 308, 310, 367, 376, 439, 473, 527, 1120, 1127, 1214-1215, 1222, 1224, 1226-1227, 1229-1230, 1233, 1262, 1266, 1268, 1436
Type 2 Diabetes Mellitus 598
