20.	Pelargonidin; (Marketed)	*In-vivo* 10 mg/kg/day and/ or 2 days/ p.o. (male wistar rats)	STZ induced diabetes	3. Reduced MDA and nitrite levels in whole brain homeogenate 4. Elevated SOD activity in brain	Mirshekar et al., 2010
21.	Glabridin; *Glycyrrhizaglabra*(Fabaceae)	*In-vivo* 10, 20, 40 mg/kg/ day/p.o (male kunming mice)	STZ induced diabetes	3. Increased SOD activity in the liver, kidney and pancreas along with improvement in body weight and glucose tolerance 4. Lowered fasting blood glucose level and MDA level in the liver, kidney and pancreas	Wu et al., 2013
22.	Apigenin; *Genistatenera* (Fabaceae)	*In-vitro* Various concentrations *In-vivo* 4 mg/kg/day/i.p. (wistar rats)	Inhibition of AGE formation assay; STZ-induced diabetes	3. Inhibited AGE formation (IC_{50} = 89.9 μM) 4. Protected liver and kidney from diabetic damage, probably through antioxidant effect	Rauter et al., 2010; Yoo et al., 2008
23.	Puerarin; *Radix pueraria* (Fabaceae)	*In-vitro* 10, 25, 50 and 100 μM *In-vivo* 100 mg/kg/ day/p.o (male lean and obese zucker rats)	*In-vitro* assayson vascular smooth muscle cells; Neointimal formation in carotid arterial balloon injury model (obese Zucker rats)	3. Inhibited ROS formation and NADPH oxidase activity in vesicular smooth muscle 4. Inhibited phosphorylation and translocation of PKCβ2, Rac1, p47phox, and p67phox subunits responsible for activation of NADPH oxidase in vesicular smooth muscle and in rats	Zhu et al., 2010

Table 4. List of flavonoids having insulin mimetic and insulin signaling modifying potential

S. No.	Flavonoid (Source)	Dose	Model/Assay	Major Findings	Reference
1.	Myricetin; *Abelmoschus moschatus*(Malvaceae)	*In-vitro* 20 µmol/L; *In-vivo* 1 mg/kg/i.p. thrice daily (insulin resistant obese zucker rats)	InR in skeletal muscle cell line (C2C12 myoblasts); Obese Zucker rats	5. Reduced InR 6. Enhanced expression of GLUT4 in soleus muscle 7. Elevated phosphorylated IRS-1 protein, p85 PI3K expression and Akt serine phosphorylation level in soleus muscle 8. Attenuated InR in C2C12 myotubes by activating Akt and AMPK	Ding, Dai, Zhang, & Li, 2012; Liu et al., 2007
2.	Epigallocatechin-3-O-gallate; *C. sinensis* (Theaceae)	*In-vivo* 5 and 10 mg/kg/i.p. every 8 h; (male wistar rats)	Free fatty acid induced InR	4. Enhanced phosphorylation of AMPK, Akt and translocation of GLUT4 in skeletal muscle and adipose tissue 5. Alleviatedfree fatty acid induced peripheral InR 6. Improved insulin signaling	Li et al., 2011
3.	Rutin; Fruits and vegetables	*Iv-vitro* 500 µM and 10^{-18} -10^{-7} M; *Iv-vivo* 100 mg/kg/day/p.o. (male wistar and SD rats)	STZ-induced diabetes and isolated soleus muscles	4. Reduced glucose and elevated insulin levels in plasma 5. Stimulated glucose uptake into soleus muscle through PI3K, MAPK and PKA pathways 6. Activated calcium-calmodulin-dependent protein kinase II (CaMKII) mediated translocation of GLUT4 to plasma membrane and glucose uptake	Hao et al., 2012; Kamalakkannan & Prince, 2006; Kappel et al., 2013; Virginia Demarchi Kappel et al., 2013
4.	Apigenin-6-C-β-fucopyranoside; *Averrhoacarambola* (Oxalidaceae)	*In-vitro* 1, 10, 100 µM. *In-vivo* 20, 50 mg/kg/day/p.o. (male wistar rats)	Glucose uptake assay on soleus muscle; Glucose challenged rats	3. Dose dependently reduced serum glucose level 4. Improved insulin signaling via PI3K, PKC and MAPK and enhanced glucose disposal into skeletal muscle	Cazarolli et al., 2012
5.	Karanjin; *Pongamiapinnata* (Fabaceae)	*In-vitro* 2.5, 5, 10, 25 µM	Assayed on L6-GLUT4 mycmyotubes	4. Dose dependent glucose uptake and translocation of GLUT4 5. Unaltered GLUT4 protein, GLUT4 mRNA and other key molecule in insulin signaling 6. Increased activity of AMPK	Jaiswal et al., 2011
6.	Puerarin; *P. lobata* (Fabaceae)	*In-vivo* 20, 40 and 80 mg/kg/day/i.p. (male BALB/c mice)	STZ-induced diabetes	8. Elevated insulin level and reduced body weight, TG, total cholesterol (TC) and blood glucose level 9. Upregulated protein levels of IRS-1 and IGF-1 in pancreas 10. Elevated mRNA level of IR and PPAR-α in skeletal muscle	Wu et al., 2013
7.	Tangeretin; *Poncirus trifoliate* (Rutaceae)	*In*-vitro 25, 50, 100, 200 µM *In-vivo* 200 mg/kg/day/p.o. (male C57BL/6 J mice)	Various *in-vitro* assays on C2C12 myotubescells. High-fat diet induced obese mice	3. Improved insulin signaling, GLUT4 translocation, glucose tolerance and phosphorylation of AMPK and AS160 4. Reduced high fat diet-induced fat accumulation and TC/TG levels	Kim et al., 2012

Table 4. Continued

S. No.	Flavonoid (Source)	Dose	Model/Assay	Major Findings	Reference
8.	Baicalein; *Scutellaria baicalensis* (Lamiaceae)	*In-vivo* 400 mg/kg/day/p.o. (C57BL/6J male mice)	High fat diet induced diabetes	4. Phosphorylated and activated IRS1/PI3K/Akt pathway 5. Lowered abdominal obesity and abolished InR 6. Improved glucose intolerance and lipid profile	Pu et al., 2012
9.	Morin; Fruits, vegetables etc.	*In-vitro* 50 µM	Assayed on HepG2, NIH-3T3, and PC3 cells	3. Activated and phosphorylated IR and Akt 4. Inhibited gluconeogenesis and enhanced glycogenesis	Paoli et al., 2013
10.	Kaempferol 3-O-β-D-glucopyranosyl-(1→4)-α-l-rhamnopyranosyl-7-O-α-L-rhamnopyranoside(CO-1); *Cinnamomumosmophloeum*(Lauraceae)	*In-vitro* 5 and 20 µM	Assayed on 3T3-L1 adipocytes	4. Insulin mimetic effect with 12.2 fold elevation in adiponectin secretion 5. Increased phosphorylation of IRβ and activated insulin signaling pathway 6. Enhanced GLUT4 translocation	Lee et al., 2009
11.	Kaempferol 3-O-β-D-apiofuranosyl-(1→2)-α-larabinofuranosyl-7-O-α-l-rhamnopyranoside(CO-1); *C. osmophloeum*(Lauraceae)	*In-vitro* 5 and 20 µM	Assayed on 3T3-L1 adipocytes	4. Insulin mimetic effect with 12.2 fold elevation in adiponectin secretion 5. Increased phosphorylation of IRβ 6. Enhanced GLUT4 translocation	Lee et al., 2009

Table 5. List of flavonoids having PPAR-γ receptor modulating activity

S. No.	Flavonoid (Source)	Dose	Model/Assay	Major Findings	Reference
1.	Isoginkgetin; *Gingko biloba* (Ginkgoaceae)	*In-vitro* 0.1, 0.5 and 1 µM	Assayed on LiSa cells and mouse adipocyte 3T3-L1 mouse fibroblasts	3. Week agonistic activity on PPAR-γ receptor 4. Enhanced AMPK signaling and subsequent adiponectin production in LiSa and 3T3-L1 cells	Liu et al., 2007
2.	Luteolin; *Cirsiumjaponicum* (Asteraceae) and *Cynodondactylon* (Poaceae)	*In-vitro* various concentrations *In-vivo* 50, 100 and 200 mg/kg/day/p.o. (male SD rats)	3T3-L1 adipocytes and primary adipose cell lines;. STZ induced diabetes	4. Elevated PPAR-γ mediated transcription and insulin sensitization in 3T3-L1 adipocytes 5. Possessed PPAR-γ partial agonistic activity 6. Enhanced phosphorylation of Akt2 and lowered mRNA levels of inflammatory mediators along with increased adiponectin and leptin gene expression in adipocytes and primary mouse adipose cells	Ding et al., 2010; Puhl et al., 2012
3.	Licoflavone A, echinatin, kanzonol X, kanzonol W, shinpterocarpin, glabrol, shinflavanone, gancaonin L, glabrone and 5'-formyl glabridin; *G. glabra*(*Fabaceae*)	*In-vitro* 10 µg/ml	GAL-4-PPAR-c chimera assay(CV-1 monkey kidney cells)	2. Significant PPAR-γ ligand binding activity	Kuroda et al., 2010

Table 6. List of flavonoids capable of modulating enzymes involved in glucose metabolism

S. No.	Flavonoid (Source)	Dose	Model/Assay	Major Findings	Reference
1.	Diosmin; Citrus fruits	*In-vivo* 25, 50, 100 mg/kg/day/p.o. (male wistar rats)	STZ induced diabetes	3. Increased hexokinase and glucose-6-phosphate dehydrogenase activity in liver 4. Reduced glucose-6-phosphatase and fructose-1,6-bisphosphatase enzymatic activity in liver	Pari & Srinivasan, 2010
2.	Eupatilin; *A.princeps*(Asteraceae)	*In-vivo* 0.005 g/100 g or 0.02 g/100 g diet (male C57BL/KsJ-db/db mice)	db/db type 2 diabetic mice	4. Improved hepatic glucose metabolism 5. Lowered hepatic glucose-6-phosphatase and phosphoenol-pyruvate carboxykinase activity 6. Increased liver glucokinase activity	Kang et al., 2008
3.	Biochanin A; *Cicerarietinum* and other legumes (Fabaceae)	*In-vivo* 10 mg/kg/day/p.o. (male wistar rats)	STZ induced diabetes	4. Increased glucokinase, glucose 6-phosphate dehydrogenase activity in liver 5. Suppressed glucose-6-phosphatase and fructose 1,6-bisphosphatase activity in diabetic liver 6. Lowered hepatic glycogen content	Harini et al., 2012

Table 7. List of flavonoids having PTP1B, SGLT2, NFκB and JNK modulating activities

S. No.	Flavonoid (Source)	Dose	Model/Assay	Major Findings	Reference
1.	2',4-dihydroxy-4'-methoxydihydro chalcone; *A. dracunculus* (Asteraceae)	*In-vitro* 2.5, 5, 10, 25 µg/ml and 3.75 µg/ml	PTP1B activity in primary human skeletal muscle culture	2. Inhibited PTP1B activity (IC_{50} = 61 µM) Reduced PTP1B activity by 36% Reduced level of PTP1B mRNA by 29%	Wang et al., 2006
2.	2',4'-dihydroxy-4'-methoxydihydro chalcone; *A. dracunculus* (Asteraceae)	*In-vitro* 2.5, 5, 10, 25 µg/ml and 3.75 µg/ml	PTP1B activity in primary human skeletal muscle culture	2. Reduced PTP1B activity by 26%	Wang et al., 2006
3.	Morin; Fruits, vegetables etc.	*In-vitro* 50 µM	Assayed on HepG2, NIH-3T3, and PC3 cells	*3. In-vitro* and *in-silico* inhibition of PTP1B 4. Non competently inhibited PTP1B activity (IC_{50} = 15.0 ± 0.9)	Paoli et al., 2013
4.	Luteolin; *C.dactylon* (Poaceae)	*In-silico* docking	*In-silico* docking study on 2XQ2 PDB of SGLT2	*2. In-silico* docking analysis revealed inhibition of SGLT2	Annapurn--a et al., 2013
5.	Scutellarin; *E.multiradiatus*(Asteraceae)	*In-vitro* 0.1 and 1 µM	Assayed on human endothelial ECV304 cells	2. Inhibited high glucose induced elevation of NF-κB expression in ECV304 cell	Luo et al., 2008
6.	Baicalein; *S. baicalensis* (Lamiaceae)	*In-vitro* 400 mg/kg/day/p.o. (C57BL/6J male mice)	High fat diet induced diabetes	2. Inhibited MAPK, NF-κB and AMPKα2 signaling	Pu et al., 2012

Chapter 23
Food Allergy and Food Poisoning:
Toxicology on Culinary Sciences

Jose Iñaki Alava Marquinez
Basque Culinary Center, Mondragon University, Spain

Miguel Angel Lopez
Basque Culinary Center, Mondragon University, Spain

ABSTRACT

Taken into account data from which is considered a product not safe, estimate the safe level of a contaminant on food, for example, always have many unavoidable uncertainties. It cannot be overemphasized enough, that this also happens as in any other human activity. In most cases, we hope, to define as clearly as possible the eventual risk associated with particular conditions of exposure to a given substance in food. There are numerous toxic compounds that reside naturally in certain foods that unable these to be consumed above certain limits or even are fully prohibited in some other countries. Chapter starts with a clear explanation of differences and relationships between food allergy and food poisoning, continued with main allergens in food and main toxics. Finally, authors summarize different origins of toxins and allergens (natural from foods, from additives, pollutants and food processing).

INTRODUCTION

Nowadays food allergy is a public health problem and a matter of concern for consumers. This is firstly, due to the way that affects the quality of life of individuals who suffer them, because is often difficult to choose the right foods for diet. Keep in mind that sometimes symptoms can be serious, or even lead to death. Secondly, the importance of food allergies prevalence that has been observed in the recent years, despite the lack of concrete data to estimate the prevalence precisely is because, among other factors,

the lack of uniformity of diagnostic methods and confusion regarding other adverse reactions to foods, it is estimated that between 1 and 3% of adults and between 4 and 6% of children have food allergies (CODEX, 2006).

This chapter reviews the general characteristics of food allergies and their current impact on society, based on a literature review of published literature.

It is known as food allergy a set of adverse reactions to food, due to their ingestion, or inhalation, proven immune pathogenesis. This only occurs in some individuals, maybe after taking small amounts of food not relating them with any physiological or pathophysiological effect. The term "food allergy" is being abused, improperly applied to any adverse reaction to a food or food additive, which is in fact a toxic effect.

Cooking related toxicology has achieved a leading state in recent years, as shown a considerable amount of information on social media (TV and news) and in different scientific journals and texts (Tareke et al, 2000; Berjia et al, 2014; Kima, 2015). Regarding the origin of toxins in the culinary, we can consider four main sources: natural, accidental / allergens, industrial and process generated. Although in some cases, toxins may belong to more than one of these categories simultaneously. Natural toxins can occasionally cause problems, because they can be found unexpectedly in foods with a higher concentration than usual, or toxic species can be confused with harmless ones as often happens with some herbs and plants. Accidental intoxication generally represents the greatest risk to health, unlike the previous ones, not the quantity, frequency, type of associated food is known, or how it came to food. Sometimes it is a little known toxic or popular use abroad as Tonka beans (Dolan et al, 2010) and difficulty to diagnose poisoning. Moreover, the presence of allergens in food is extremely difficult to control, despite the most advanced legislation (European) ((UE) Nº 1169/2011) is always possible the presence of uncontrolled allergens (Alcalá AESAN 2012). Industrial poisons are foreign substances to food, added in amounts known to achieve a particular purpose, such as additives or uncontrolled such as pollutants. These compounds are not safe, even some of them are potentially toxic to most consumers; who may have symptoms with varying intensity. However if additives were not used would be very difficult to have a wide variety and quantity of food in urban areas, which has concentrated the highest percentage of the population in recent years, demanding food for subsistence. Toxic generated by the process, are the result of the transformation of food through different stages of development; from cooking, stabilization, formulation, mixing, sterilization, transportation, etc. These toxins can result from such simple processes such as roast meats, doing different polycyclic aromatic hydrocarbons, many with mutagenic and carcinogenic molecules finally generated.

BACKGROUND

Some eats are inherently poisonous while others can lead to health conditions that sometimes prove fatal. From pre-hominids time to now every time that we eat something, we are suffering a (more or less) controlled risk to death. This risk will come, from the toxicity of the food eaten or from and adverse reaction of our organism to normal food composition. Obviously the age, sex, size and previous exposition, are factor that modulate the negative action of eaten food. Modern industrial processes, as well as culinary ones, introduce new molecules in our food-stock, creating new sceneries for food poisoning.

METABOLIC DIFFERENCES BETWEEN ALLERGY AND POISONING

In fact body reactions due to food intake may create a wide range of results. Adverse food reactions (food hypersensitivities,) include any abnormal reaction resulting from the ingestion of a food and might be the result of food intolerances (non-allergic food hypersensitivities) or food hypersensitivity/allergy (food allergy).

In many cases, differences between intolerance and a clear allergy are imperceptibles. Food intolerances (non-allergic food hypersensitivities) are adverse responses caused by some unique physiologic characteristic of the host, such as metabolic disorders. Food hypersensitivities/allergies are adverse immunologic. Toxic reactions might mimic food hypersensitivities and typically are due to factors inherent in a food, such as toxic contaminants (e.g., histamine in scombroid fish poisoning) or pharmacologic substances within the food, which can affect most healthy individuals when given in appropriate doses.

Food aversions also might mimic adverse food reactions but are not mounting a brisk protective response to dangerous pathogens (Sampson 2004).

The gastrointestinal immune response thus plays a pivotal role in maintaining protective immunity in health and a critical role in the pathogenesis of a wide variety of clinical disorders associated with food allergy (MacDonal & DiSabatino, 2009). Within both (food allergy and poisoning), food allergy reactions mediated by IgE immune pathogenesis (immediate hypersensitivity or allergic type) such as those produced by other immune mechanism known (non-IgE mediated reactions) are included. It is characteristic of the early presence of high titers of antibodies against IgE in food. (Bellanti et al, 2004) Also it can be found increased specific antibodies from other classes of immunoglobulins, immune complexes and most probably mediated immunity responses cells. The existence of a joint involvement, i.e. IgE mediated reactions partially and cells, in varying degrees are also possible. In any case, plus evidence of dependency between ingestion of a food and the appearance of symptoms, it is necessary that these altered immune parameters are directly involved in the pathophysiology responsible for the symptoms.

Some enteropathy such as celiac disease and enteropathy and other food protein enterocolitis (cow's milk, rice, chicken, soy, etc.) may be included within the concept of food allergy, because in them is proven or probably the existence of an underlying immune mechanism. Allergic reactions to foods must be distinguished from food intolerance reactions and toxic reactions to foods.

Food intolerance is a form of adverse reaction to a food or food additive in the pathogenesis does not exist or has not been demonstrated, unlike food allergy, immune-based mechanism. Senses, food intolerance and food allergy have been used and, sometimes, are still used indiscriminately and even with a similar meaning, which has favored the emergence of confusion when analyzing the pathogenic, clinical, diagnostic and therapeutic processes. Despite all, more than 20 years ago, for the first time was defined with a pathogenic base, the concepts used to describe adverse reactions to foods (Metcalfe, 1984), whose use, has allowed better communication in the scientific literature regarding the different reactions to food components.

Food intolerance reactions can occur by the following mechanisms:

- Enzymatic or metabolic, defects related to enzymes involved in the metabolism of food (Table 1).
- Pharmacological foods or intolerance due to the pharmacological action of chemical compounds naturally or added to food, such as caffeine, theobromine that may cause heart rhythm disturbances, tremor or migraine in certain individuals, even when ingested in moderate doses (Table 2).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

- Finally, there is food intolerance called indeterminate, to denote any intolerance reaction whose mechanism is not clarified production. At last, most adverse reactions include food additives.

Toxic reactions caused by food (food poisoning), include those for foodborne diseases and produced by chemical or biological agents contained therein.

Its main feature is that anyone can be susceptible to poisoning from these products, although the vast majority of them are not dangerous, because the amount that can be ingested in a normal diet is insufficient to cause any harm. Table 3 shows a classification of the agents capable of causing food poisoning. Some, such as additives or histamine may act by different mechanisms as poisoning agents.

Intolerance reactions and toxic reactions are characterized both by being dose-dependent. The clinical manifestations that occur are the more intense the higher amount of ingested food or food additive. This dose-response relationship cannot exist in allergic reactions, so that, in some of them, very small doses can lead to an exaggerated clinical response. Another peculiar feature is that toxic reactions can occur in any individual, whenever you eat food in sufficient quantity. Instead, both toxic and allergic reactions in intolerance, the onset of clinical manifestations before the ingestion of a particular product at a given dose is only in relation to individual characteristics, so that the same dose is perfectly tolerated by any other individual, otherwise healthy (Table 4). Probably small quantities of poisoning products (histamine-like), during the early development of immune system, are responsible of immunoglobulin's alterations in childhood and in correspondence early food allergy development (Taylor et al, 1984).

Issues, Controversies, Problems

Despite these differences, sometimes toxic reactions, intolerance or allergy can lead to very similar clinical pictures. This situation will occur when the agent responsible, in addition to a general pharmacological action, is acting on an individual who, for certain characteristics, has a response threshold decreased. It is also possible that the responsible agent, ex, histamine, also is a mediator of anaphylactic reactions, which may result in similar clinical pictures to them ("anaphylactoid reactions", "food pseudoallergy").

In contrast to the ingrained idea among laymen and even among some medical doctors, it is likely that food allergy constitutes only a quantitatively very small part of all the adverse reactions to foods. Data on prevalence of food allergy in the population are very limited in both children and adults, because the conceptual gap and the different diagnostic criteria used. If a method of controlled provocation is used to assess a possible adverse reaction to a food. No more than one third of the supposedly allergic children respond positively (Bock 1987) and less in the adult population (Jansen et al., 1994) (Young & Stoneham, 1994). Also, within the pediatric population, it appears that its incidence is higher in younger children.

Food Allergy

All foods can be potentially sensitizing. Its prevalence is related, among other factors, to feeding habits of the population studied. However, when excluding sensitizations with no clinical relevance, most patients respond only to few foods. Also, its prevalence may vary with age, associates regarding exposure to allergens and mainly to immunological and physiological processes of maturation factors. Approximately half of the cases of childhood food allergies are associated with animal allergens. In our environment, the child, the egg (protein clear) is the most common food allergen, followed by cow's milk and fish (Crespo et al., 1995). After that become dominated by sensitization to vegetables, such as

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

nuts, fresh fruits, legumes and vegetables; frequently found in these patients, associated sensitization to pollens (Kany et al., 2001). Food allergens are water-soluble proteins or glycoproteins with a size between 10 and 70 kDal. and consequently more stable to heat, acid and proteases. In foods are often one or several main, major or larger and other secondary or minor allergens allergen and which are regarded as respectively allergens to which respond most immunologically sensitized patients or relevant food allergens to which respond only a few individuals. Some are characteristic of a particular food can be shared with other species of the same or close family (eg, fish, legumes) and others may be present even in phylogenetically distant families.

This usually correspond to proteins with similar function (profilin, Trophomyosins, serum albumins, etc.). Some are widespread, being known as "panallergens". These panallergens may be involved in the poly-sensibilities detected in many patients,

1. **Food Allergens of Animal Origin:**
    a. **Cow Milk:** Although, it has been demonstrated, various mammalian milks cause allergic reactions. Cow milk, is most common and best studied. Milk human species, cow's milk, or a derivative formula are usually the first food that non-homologous individual receives in significant quantities. This means, that it is also the first food antigen which humans come into contact with in a usual way. Therefore, is not surprising that is, in the early childhood, the food that causes the greatest number of adverse reactions. In Spain, the incidence data of immediate allergy to cow's milk proteins (PLV) in infants varies between 0.4 and 1.9 per 100 (Sanz et al., 2001) (García et al., 2003).

Major allergen components include serum proteins in cow's milk (particularly, beta-lactoglobulin, alpha-lactalbumin and, to a less extent bovine serum albumin) and casein (alpha, beta and kappa). Comparing with purified proteins from cow's milk, it was observed that beta-lactoglobulin is the protein that more often induces clinical responses.

    b. **Egg:** The egg is a widely consumed food worldwide and the leading cause of allergic reactions in children (Crespo et al.,1995). The light seems to be more allergenic than the yolk. Egg the major allergen present in the clear, is the ovomucoid (Gal d 1) (Bernhisel-Broadbent et al., 1994). Is a trypsin inhibitor and represents 10% of the protein content of the egg white. The main feature of ovomucoid is its extreme resistance to degradation by proteases and thermostability, so allergen resulting affected by cooking in minimal amounts. Another allergenic protein is egg white or ovotransferrin, conalbumin (Gal d 3) having homology with other iron binding proteins, such as serum transferrin and more labile than previously commented. Other allergen is white egg white lysozyme (Gal d 4), 14.3 kDa protein, composed of a single polypeptide chain linked by four disulfide bridges.

Also the yolk can have a major allergen paper, since the involvement of yolk livetins. In syndrome called "feather-egg" (Mandallaz et al., 1988), based on clinical observation of patients showed that starts with respiratory allergy awareness feathers and subsequently develops egg allergy (in adults), with some special features like its beginning at a later age, presence of asthma due to sensitization to feathers and a recognition profile egg allergens different. In children with this clinical framework, feathers sensitization, usually occur, previous to egg sensitization (Añibaro et al., 1997). These patients exhibit

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

IgE antibodies to a protein of 65-70 kDa yolk, alpha-livetin, identified as chicken serum albumin and responsible for cross-reactivity.

c. **Fish:** Fish allergy is relatively common in countries where consumption is high, like Japan, Scandinavian countries and Spain. However, this distribution tends to change due to market entry of new food products derived from fish such as surimi, or by the use of fish oil rich in polyunsaturated fatty acids, given their beneficial effects on the cardiovascular system.

The fish species most frequently involved in allergic reactions are gadiformes (cod, hake) and flatfish (flounder, rooster); less salmon, clupeiforms (sardine, anchovy) and tuna (Pascual et al., 1992).

The first purified and well-characterized allergen fish was Gad c 1 (previously designated as Allergen M), found in cod (*Gadus callarias*) (Aas 1966). This allergen belongs to a group of proteins known as parvalbumins muscle, which control the flow of calcium through the cell membrane and are only found in the muscle of fish and amphibians. Gad c 1 is very heat-stable and resistant to proteolysis. Allergenicity is considerably reduced in canned fish.

The structural similarity of different fish parvalbumins makes in sensitized patients very often to arise cross reactions (Pascual et al., 1992). However, the differences make its importance not alike in all species of fish. A third of those allergies to fish, tuna patients tolerate as albacore (*Thunnus alalunga*).

d. **Crustaceans and Mollusks:** Crustaceans have been recognized as a common cause of food hypersensitivity reactions. Their allergens are thermostable. In recent years described the existence of cross-reactivity between different species of crustaceans and less, but also relevant to other allergens present in insects and mites (Dermatophagoides spp.).

Shellfish can be gastropods such as snails, bivalves such as clams, mussels, oysters and cephalopods such as octopus and squid. The major allergen seems to be also tropomyosin and is often is associated with sensitization to shellfish (Leung et al., 1996).

2. **Food allergens of plant origin:**

a. **Vegetables:** Legumes are dicotyledonous plants botanical order of *Fabaces* comprising three families: *Mimosaceae, Papilionaceae* and *Cesalpiniaceae.* Major species responsible for allergic reactions (lentil, pea, pea, peanut, soybean, lupine) belonging to the *Papilionaceae* family, commonly known as legumes. The vegetables are among the food allergens that most often cause immediate allergy in children (Pereira et al., 2002). In Mediterranean countries the introduction of nuts, including peanuts, not done before 2 or 3 years, although in recent times the use of peanut, soybean and lupine as additives makes its consume earlier and also hidden-form, which could be contributing to the incidence of allergy to legumes.

Peanut (*Arachis hypogaea*) is responsible for many serious allergic reactions, whose frequency has not only increased in recent years, but also its appearance is earlier, partly due to increased consumption, possessing proteins Very versatile, easily digested and various presentations; aperitif, fresh, grilled, butter or an oil.

The peanut is the major food allergen in US and the leading cause of anaphylaxis. It is estimated that allergy in the general US population may be about 1%. According to some authors would be the major

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

food allergen in children over three years (Bock and Atkins, 1989) but it is also rising at younger ages. In Europe, more specifically in Anglo-Saxon countries, their allergenic importance is increasing in recent years by the similarity of dietary patterns with the US, due to both changes in dietary habits (increased consumption of fast food, immigration and different dietary habits), and its role as hidden allergen. It has been found that roasting increases allergenicity, possibly due to changes in the molecular structure or enzyme function (Beyer et al., 2001).

In peanuts have been identified several major allergens in sensitized patients. The Ara h 1 allergen is a 63.5 kDa glycoprotein that has high homology with vicilins (storage proteins present in the seeds of many plants). The identification of this protein family may partly explain the wide immunological cross-reactivity between peanut and other legumes.

Soybean (*Glycine max*) is the basis of tofu, soybean paste and soy milk, also consumed fresh. It is common cause of adverse reactions, possibly helped by its wide use in the West as an additive and as a food supplement to enrich the protein content of other foods. Soy can be found in bread, cakes, ice cream, breakfast cereals, packet soups, canned tuna, hot dogs, sauces, Chinese food, etc. Also, their use in dietary formulas has been considered as a possible cause of sensitization in infants, sometimes with the presence of specific IgE to soy, but generally no demonstrable clinic for soybean (Cordle, 2004) (Martin, 2006).

Among the various allergens identified in soybeans, fractions with molecular weight 13-14 kDa and 25 kDa 22-, are the most powerful in three different groups except;whole soybean powder and shell, and have proven their allergenicity both inhalation and through the digestive tract (González et al., 1995).

The lentil (*Lens sculenta*) is the most consumed vegetable in Spain. In this country with a traditionally Mediterranean diet, lentils are legumes that most often cause IgE-mediated hypersensitivity, followed by chickpea. They are the fourth or fifth leading cause of food allergy in the child population. In addition, half the cases begin between the first and third year of life, predominantly in the second year (Pereira et al., 2002).

In lentil described a protein band between 12 and 16 kDa, which would be called a gamma-Len c 1 vicilin subunit, and a weight of approximately 66 kDa, Len c 2, corresponding to a biotinylated seed protein.

Has been identified Len c 1 as a major allergen and Len c 2 as a minor allergen lentil (López-Torrejón et al., 2003). Len c 1 shows a 45% similarity with Ara h 1 Peanut allergen greater.

b. **Other Vegetables:** The chickpea (*Cicer arietinum*) is similarly important cause of allergic reactions in the East and in our environment, due to their high consumption. The bean (*Phaseolus vulgaris*) is native to Central and South America. There are many edible species and can be divided broadly into two types: those that are eaten with pods whose seeds are not developed (green beans) and those which only the seeds (beans, beans, pinto bean) are eaten. The lupine (*Lupinus sativus*) is used as a protein rich in pastries and other food for its high content of nitrogenous substances, fats and minerals. It has been identified as a hidden allergen responsible for anaphylactic reactions (Rojas-Hijazo et al., 2006). The pea (*Pisum sativum*) is an herbaceous legume from Asia. It is rich in proteins, lipids, lysine, vitamins A, B and E, phosphorus and calcium. In children ingestion is rare before 2 or 3 years. There have been rare allergic reactions to this legume.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

c. **Cereals:** Described the major allergens in wheat flour, barley and rye are water soluble (albumins and globulins) and related symptoms are derived from no exposure inhalation and ingestion with (Houba et al., 1998).

The higher in baker's asthma allergen is a group of inhibitors of alpha-amylase. A 15-kDa allergen in wheat flour and other flour 14.5 kDa barley inhibitors trypsin / alpha-amylase have been identified. Also, homodimeric 25 kDa proteins of rye and barley have been isolated. Swallowed allergy to wheat and other cereals is rare in the West (Crespo et al., 1995a). Regarding intake, has been identified, frequently involved in sensitization to wheat flour in children with atopic dermatitis and more recently been shown that the alpha-amylase inhibitor is a wheat allergen relevant allergenic protein of 50 kDa Patients who experience hypersensitivity reactions with wheat protein intake (Palosou, 2003).

The major allergens of rice (Oryza sativa) have been identified as albumins 14 to 16 kDa molecular weight, belonging to the family of inhibitors of trypsin / alpha-amylase (Alvarez et al., 1995). They have also identified a lipid transfer protein as a major allergen in individuals with corn clinical signs after ingestion (Pastorello et al, 2000).

d. **Gluten:** The term "gluten"as a fraction of proteins from wheat, rye, barley, and oats, or crossed varieties and derivatives thereof and which is insoluble in water and in 0.5 M NaCl Prolamines form the gluten fraction which can be extracted with a 40-70 percent ethanol. The prolamin from wheat is gliadin, from rye is secalin, barley hordein and oats avenin. Oats currently appears separated from the three cereals referred to above and it may not be disease-inducing like other cereals (rice, corn), although this phenomenon is correlated with possibly fewer oats contains prolamine proportionally to the others mentioned cereals.

According to their amino acid sequences, the gliadins are subdivided into alpha, gamma and omega-gliadins and are rich in proline and glutamine. These prolamins are harmful to certain individuals and their intake triggers them celiac disease.It is often said that these patients have "gluten sensitivity". Prolamin content of gluten is generally reduced by 50 percent (Codex 2006).

e. **Fruits and Vegetables:** In the Mediterranean area fruits are a common cause of food allergy, particularly of oral allergy syndrome. They have been identified only in a few clinical studies species, causing IgE mediated allergy. The family *Rosaceae* (apple, pear, peach, albarcoque, plum, cherry) and *Cucurbitaceae* (melon, watermelon, cucumber, pumpkin, zucchini) have received special attention in clinical studies as well as bananas (family *Musaceae*) and kiwi (family *Actinidiaceae*).

Other families of fruits are abundant immunological and molecular data, but very little information on its possible clinical significance. Among vegetables, celery allergy is of particular interest for their ability to produce anaphylactic reactions (Ballmer-Weber et al., 2000).

The tomato, both raw and cooked is a regular feature in the diet. The awareness of this vegetable is particularly prevalent in the Mediterranean area, especially in children and adolescents, within is the most common clinical oral allergy syndrome. However, when there is an awareness associated latex, the most common manifestations are urticarial and anaphylaxis (Reche et al., 2001).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

There are very few communications allergy to other vegetables. It is very rare lettuce allergy can cause allergic contact dermatitis, but not enough of allergic reactions upon ingestion data (Franck et al., 2000).

The allergens in fruits and vegetables are thermolabile, which facilitates tolerance sensitized individuals after specific treatments that inactivate their antigens.

f. **Nuts ("Nuts in Shell"):** Under the name of nuts, tree nuts, walnuts ("nuts") various seeds from different botanical families are included. It is a heterogeneous group of foods without Botanical related, but with great allergenic similarities and consumption patterns. Oleaginous fruits are consumed in dried form among which are: almonds, hazelnuts, cashews, walnuts, Brazil nuts, Pecan nut, pistachio, pine nuts, and sunflower seeds. Its stability against heat and digestive processes favor its high allergenicity, so often the reactions are intense and immediate. Allergy to nuts is one of the most common food allergies, although its prevalence varies according to age and geographic area.

They occur most often in children than in adults (Ewan, 1996) and, sometimes, may appear before the first known contact with the nut. It is likely that exposure to small amounts unnoticed or sensitization by other means explain these intense reactions. They can lead to severe clinical manifestations, even in small quantities, due to its presence as food ingredients or flavorings in various food products.

Allergy to nuts is often associated with allergies to various pollens. Most individuals with allergies to hazelnut are sensitized to pollens of birch and hazel (Ortolani et al., 2000) and confirmed that the major allergen in hazelnut is a 18 kDa protein homologous to Bet v 1 birch (Pastorello et al., 2002).

The major allergen of Brazil nuts (*Bertholletia excelsa*), Ber e 1 is a methionine-rich 2S protein composed of two subunits of 9 and 3 kDa. This protein has been used in transgenic studies to correct the deficit in methionine levels having soybeans. However, the commercial development of this GM soy has been abandoned, and that gene transfer of allergen (Ber e 1), of the Brazil nut, also transfers its allergenicity of soybean (Nordlee et al, 1996).

g. **Sesame:** The *Sesamum indicum* is native to tropical Africa, whose cultivation is widespread, for the use of plant seeds. Allergenic importance is great in those places where consumption is common. It is an ingredient that should be clearly identified and separated from nuts and peanuts, which can also contaminate. The prevalence and severity of allergy seed sesame has increased in recent years in Europe (Gangur et al., 2005) due to its introduction from Asian countries in the diet as food ingredient or oil, especially in bakery products, fast food, new foods and vegetarian products. Given its characteristics, sesame must be identified when used as ingredient in packaged foods, as indicated by Directive 2003/89 of the European Union (EU, 2003). However, many products and ready meals containing sesame are sold at fast food places, bakeries, restaurants, etc., whose ingredients are not easily identifiable and where cross contamination is more likely.

h. **Mustard:** Mustard is one of the most allergenic of spices on record to date, therefore its prevalence as allergenic potency. As for other food allergens, sensitization depends on the eating habits of the population. Allergens have been isolated from the seed of yellow mustard (*Sinapis alba*) and Eastern (*Brassica juncea*) and their primary structures have been studied in great detail (González de la Pena et al., 1993) (Monsalve et al., 1993). No all allergens of yellow mustard seed is a 15 kDa protein. Structural homology of an occupational allergen,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Ric c 1, *Ricinus communis*, is known and is probably related to other 2S albumin present in soybean, cottonseed and pea.

3. **Other:** Latex, Anisakis, Mites, etc.: They are sometimes cause of serious clinical pictures, plus unexpected. Besides food used as additives, other conveyed by foods that can act as allergens. As most important, the following can be considered:
   a. **Latex:** Or natural rubber latex is a processed plant product obtained from the milky sap of many plants, though the only one who has been commercially exploited is from *Hevea brasiliensis* tree. Due to its elastic properties is used to make multiple everyday items such as gloves, condoms, pacifiers, baby bottle nipples, balloons, stickers, etc..; and more specific as medical supplies, catheters, tourniquets, gloves, masks, etc. It is estimated consumption worldwide of 5.5 million tons per year. Latex allergy occurs by type I or immediate hypersensitivity mediated by IgE antibodies to latex proteins.

The relationship between latex allergy and food allergy has two aspects to consider. On the one hand, it acts as a contaminant, in their contact with food proteins, handled with latex gloves. In this situation, there may be apparent signs of food allergy in patients allergic to latex. Furthermore, it is often an association of latex allergy and various fruits and vegetables allergens such as kiwi, chestnut, avocado, banana, papaya, figs, potatoes, peach, pineapple, grapes, celery, plum, tomato, etc…, which is known as "latex-fruit syndrome" (Wakelin & White, 1999), which is related to the existence in latex similar to those found in these plant antigens.

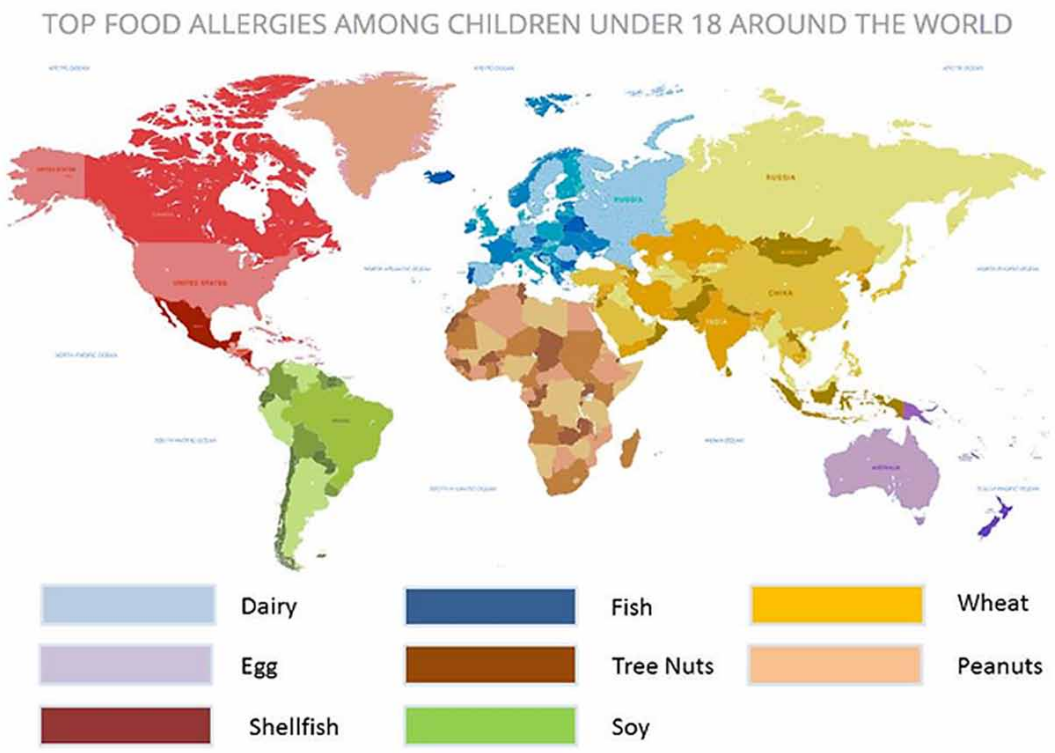
   b. **Anisakis:** The anisakiosis is a parasitic disease that is caused by parasitized fish larvae of Anisakis spp., consumed rare or undercooked. It is particularly important as health problem, in countries with high fish consumption. The adult parasite is found in the digestive tract of a variety of marine mammals, which act as definitive hosts (wales, dolphins, etc.) The larvae mature in the water and are eaten by small crustaceans that feed on various species of fish and cephalopods, which reached the stage of L3. The cycle is completed when the definitive hosts acquire carriers L3 intermediaries. Humans are an occasional host a result of eating contaminated fish larvae and he cannot complete its life cycle.

Clinical signs and symptoms develop as a result of inflammatory reaction caused by the penetration of larvae in the mucosa of the gastric wall. It can also cause manifestations of allergic reaction (hypersensitivity) immediate type ranging from urticarial or angioedema to anaphylactic shock and mixed frameworks with gastrointestinal and allergic clinic symptoms.

In patients IgE antibodies primarily directed against antigens of the various structures of Anisakis larvae are detected. To the consumer, it should not consume rare fish that has not been previously frozen under 24 h, or fresh fish cooked to no more than 60 ° C for at least 5-10 minutes. The cooked on the grill or microwave are less secure than cooking or frying (AESAN, 2005) procedures.

   c. **Mites (Dermatophagoides):** There are several publications of asthmatic patients sensitized to mites, *Dermatophagoides farinae* mainly no history of food allergy, anaphylactic reactions have presented different intensity by ingesting contaminated products made from flour mite. This contamination is common in places with warm, moist environment that favors growth

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



of these mites. In Spain is described on inhabitants of the Canary Islands (Garcia-Robaina et al., 1997).

d. **Residues of Veterinary Drugs:** Sometimes animal foods may contain residues from veterinary treatment. Depending on the nature and risk of the same to human health, mandating absence or maximum limits in foodstuffs is regulated. Specifically, allergic reactions have been reported after ingestion of foods with residues of antibiotics such as ß-lactams and macrolides for which there are maximum permitted residues (Dewdney et al., 1991). Long such allergic reactions have been associated with the presence of penicillin in milk (Wicher and Reisman, 1980). Surveillance studies show a low incidence of detectable residues in most products (Figure 1).

Toxics in Foods

Although an agent causes food poisoning may be chemical or physical, in food toxicology it refers exclusively to chemicals. A term widely used in the drug area to define any foreign substance to the body in question is that of xenobiotic agent. However as Paracelsus said: "dosis sola facit venenum" even oxygen, that is essential to maintain the life of any aerobic organism, an atmosphere of pure oxygen is

Figure 1. Top eight allergies distribution, in children around the world
Extracted from Prevalence of allergies around the world: the big eight (ten, thirteen?). M. Fernandez-Rivas, Symposium on Sensitizing Properties of Proteins, Prague, 11-13 April 2012 (http:www.hesiglobal.org/files/public/Committee%20Presentations/PATC/Fernandez%20Rivasfor%20websiteAPPROVED.pdf)

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

harmful to any mammal, as it is quickly consumed aminobutyric acid, moderator cerebral and nerve transmission, decrease and consequently serious nervous disorders occurs that end to convulsions and death (Repetto, 1981) occur. One could mention many examples which show the dictum of Paracelsus, indicating that the beneficial and harmful effect, of a substance depends on the dose. However, for each chemical there is a certain degree of toxicity.

Currently it is managing the concept of "potential toxicity," which has been proposed by Luckey and Venugopal, in an attempt to have a parameter to assess the toxicity of substances more accurately. This potential toxicity (pT) depends among other factors, the experienced animal species and route of administration. By definition, pT is the intake of base 10 logarithm of the inverse of the dose of a substance expressed in mol / kg, given produces a toxic effect. (Luckey & Venugopal, 1977; Repetto, 1981).

$pT = -\log T$

where,

T = toxic dose molar base.

Knowing the molecular weight (MW) of xenobiotic compound or agent is easy to calculate the pT, as shown in Table 5.

Fungal toxins are probably the main cause of chronic toxicity in foods. Since the discovery of protein synthesis inhibitory fungal toxins (Fando et al, 1985), many fungi species has shown dangerous toxins able to appear in foods (Varga et al, 2003, Abarca et al, 2000). These fungi and their spores are sprayed around human environment in building (Cooley et al, 1998, Shelton B.G. et al, 2002), air (Zukiewicz-Sobczak 2013), water (Gonçalves et al, 2006) and food making places (Simeray et al, 1995).

Aspergillus species are probably the most extended fungi and play a key role in fungal toxicity. *Aspergillus oryzae* is used, in much classical Asian fermentations like, soy sauce,

sake and miso. Unfortunately is very difficult to distinguish at lance, between *Aspergillus oryzae,* and *A.flavus, A.restrictus, A.fumigatus* etc… species producers of fungal toxins.(EPA 1997).

Biological Factors that Influence Toxicity

The biological system which acts on the toxic agent is critical, because the effect will vary considerably according to the agency. This factor should be taken into account, since it is well known that among the different species of animals and humans there is great variation in sensitivity to toxic agents. The knowledge of the origin, development and course of poisoning in a particular animal should be established to scientifically based, extrapolate to humans. Precisely in toxicology, a specific branch known as Comparative Toxicology, which indicates on the basis of substantiated studies, animal model can be used to extrapolate experimental results to man. About the above, are some examples of animal models (Melby & Altman, 1976; Hodgson & Gutherie, 1980).

The effect of a toxic agent on a biological system results in an alteration of physiological equilibrium (homeostasis), so that poisoning is an illness and as such should be considered under pathos- chronic criterion, or must observe the developments in line time and we can classify it as acute poisoning, chronic or subacute.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Acute poisoning is defined as exposure to a xenobiotic agent that produces an almost immediate manifestation (sometimes in minutes), with a single administration of the poison, which can lead to poisoned to death, or total or partial recovery, which they may be or not sequels or nagging injuries.

In many cases of acute poisoning phenomenon, it happen reversibility except death. Overall subacute poisoning does not imply a lesser degree of severity of acute intoxication, but an evolution of subclinical disorders poisoning will appear.

Although this type of poisoning requires repetitive administration of toxic, not visible at the start conditions are present; however, the short term can present evidence of intoxication and some toxicologists believe that it is present, be exposed to the toxic biological system over a period that can range from one month to three months. Chronic poisoning occurs due to repeated exposure to the toxic agent.

This absorption occurs with relatively small toxic, which by itself does not produce visible amounts disorders initially, but the accumulation of xenobiotic agents in the body (typically in a specific organ or tissue) and over time are presented pathological conditions, and in most cases are irreversible. In this type of poisoning, initial conditions remain latent (subclinical) and are usually reversible; until for some reason, as it could be a decrease in normal physiological conditions (illness), you can highlight the poisoning. A classic chronic intoxication example, is the effect of carcinogenic substances, since in sub lethal doses, these compounds are not evident in the short term.

Poisoning requires three months to one or more years and when it manifests itself in clinical form, is very difficult to reverse the damage produced (Fabre & Truhaut, 1976; Repetto, 1981; Klaassen et al, 1986).

The concept of acceptable daily intake (ADI) or also called Acceptable Daily Intake (ADI), refers to the reduced expression of all available toxicological data for a given xenobiotic agent. DDA itself corresponds to the amount of a substance that can be ingested daily by an individual throughout his life, without as to cause damage to health. This level or dose is generally set by animal experimentation on acute and chronic toxicity (currently investigating mutagenic, teratogenic and carcinogenic) and preferably taking the value of the dose without observable effect (NOEL) for the most sensitive species. The maximum amount of xenobiotic that the most sensitive animal can ingest daily without adverse effect sought. However, it can be extrapolated to the human you have to take the safety factor (FS), which should generally consider interspecies or intra-species variation and the value of 100 (Pennington., 1998; Larry et al, 1990; Derache, 1990; Kotsonis et al, 1994).

Therefore the DDA is generally hundredth of NOEL for the most sensitive animal and expressed in mg / kg body weight. This DDA allows a high degree of probability, ensure a low risk of xenobiotic in question, but you will never say with absolute certainty safety.

Getting the DDA from NOEL: Acceptable Daily Intake or ADI

DDA = NOEL / FS

where,

NOEL = no-observed-effect dose (mg / kg pc- day)
SF = Safety factor (10 when the NOEL is of the same species; 100 for another)

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Naturally Toxic Agents in Foods

Natural toxins found inherently in plant or animal foods, can be harmful when consumed in sufficient quantities. Natural toxins serve specific functions in ecosystems as chemical signals or as chemical defenses against predators, parasites or infectious microorganism. Obviously the molecules used have a wide range of chemical structures and toxicity levels.

The most common intoxications are those produced by toxic fungi. Every year inexpert people around the world die by toxic fungi ingestion. Although only a few of the 70-80 species of poisonous mushrooms are actually fatal when ingested, many of these deadly fungi bear an unfortunate resemblance to edible species and are thus especially dangerous. (Karlson-Stiber., Perssons, 2003)

They are near 2.000 species of poisonous plants in the world. Many times more than those considered as food (few hundred). Even many of this "nutritious" plants can become toxic if they are taken in excess or if they are not cooked in the right way. In addition, the toxicity of poisonous plants will change in dependence of sub-specie, as well as the geographical and climate conditions.

In culinary sciences are usual some plants that are very dangerous if they are ingested untreated: Potatoes (Solanine and glycoalkaloids), manioc, bamboo (Cyanide generating compounds and saponines), green beans (enzyme inhibitors). (Wink et al, 2008).

In animals, toxins may come from their proper metabolism or a chemical passed along the food chain. Is more frequent, that poisoning happens, eating marine animals than terrestrial ones. Marine toxins generated by toxic microalgae (Dinoflagellates) are accumulated in shellfish, fish and crustaceans and at end consumed by humans. Also microorganism and coral will produce neurotoxins (Tetrodotoxin) that may cause lethality after ingested (Chun-Fai Yu et al, 2004).

Culinary technics are very important in decrease or annulation of heat-labile toxins. One of most relevant examples is squid ink, used in Spanish and Italian gastronomy. The squid ink, contains toxic microorganism, melanin, melanin related products and L-Dopa. A single thermic treatment of 20 min. at 80º C is enough to neutralize toxicity of squid ink, and let it ready for food use (Fiore et al, 2004).

Food Additives and Toxicity

Food additives are natural or artificial substances, which are added to food in order to preserve or enhance its qualities, either preserving them from microorganisms, enhancing its taste, color or improving its texture. Safety or toxicity of additives it's depends on the substance itself and the amount used in final food. Both natural and synthetic products can be potentially mutagenic or cause allergic reactions (flour improvers, etc.) Another danger is the possibility to be used as cover, tampering or alterations of food, causing poisoning. (FAO/OMS, expert committee, 1965).

Pollutants Toxicity

During the past two hundred years humanity, has been discharging industrial waste in natural environment. Many of this industrial waste are chemically organic and may introduce itself inside food chain.

Persistent organic pollutants (POPs), are chemicals of global concern due to their potential for long-range transport, persistence in the environment, ability to bio-magnify and bio-accumulate in ecosystems, as well as their significant negative effects on human health and the environment. Humans are exposed to these chemicals in a variety of ways: mainly through the food we eat, but also through the air we breathe,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

in the outdoors, indoors and at the workplace. Many products used in our daily lives may contain POPs, which have been added to improve product characteristics, such as flame retardants or surfactants. As a result, POPs can be found virtually everywhere on our planet in measurable concentrations.

The most commonly encountered POPs are organic-chlorine pesticides, such as DDT, industrial chemicals, most notably polychlorinated biphenyls (PCB), as well as unintentional by-products of many industrial processes, especially polychlorinated di-benzo-p-dioxins (PCDD) and dibenzofurans (PCDF), commonly known as 'dioxins'.

However, an overall dietary risk assessment would require inclusion of other dietary sources of dioxins and dioxin-like PCBs. In many countries, an inadequate use of newspapers as starting of fire in home grills will produce the excess of POP needed, to appear a disease.

In order to address these risks, several steps have been taken to reduce or eliminate emissions of dioxins, dioxin-like PCBs and other related persistent organic pollutants (often referred to as POPs). Many countries have now implemented the Stockholm Convention on POPs (2001), which suggests ending commercial use of 12 POPs and reducing or eliminating their emission into the environment. To monitor reduction in human exposure WHO and UNEP run a monitoring program for POPs in breast-milk. A steady decline in levels has been observed since 1980 for most countries. (ONU, UNEP/POPS/POPRC.10/10, 2014)

In regard to food contamination, the FAO/WHO Codex Alimentarius Commission, which is a risk management body comprised of 169 member countries, is developing a draft code of practice for dioxins and dioxin-like PCBs in food, which identifies source-directed measures to reduce their presence in food, including fish, as well as a position paper, which provides an evaluation of the need for possible regulatory measures, such as limits in food and feed. (WHO, Food Safety Program updates, 2015)

Toxic Agents Generated in Food Processing

1. **Ethil-Carbamate/Urethane:** Ethyl carbamate (EC, urethane), is a naturally occurring component of all fermented foods and beverages. Because EC has shown a potential for carcinogenetic when administered in high doses in animal tests, production of EC is tried to be reduced during food production. The winemaker industry is interested in reducing EC levels in their products (Butzke & Bisson 1997).
2. **Allyl-Isothiocyanate:** Onion derived substances (Allyl-isocianates) has been used as bio-protective gas additives, to increase self-live of packed foods. Their use is not extended inside industry and exist some controversial opinions, about the advantages of their use. In a hand, there are natural biocides in the other hand may change the natural flavor of the product by adsorption.
3. **Pyrrolizidine Alkaloids:** Thirteen plant families are well known to contain pyrrolizidine alkaloid (PA) (IPCS, 1988). PA's are hepatotoxic, carcinogenic, genotoxic, teratogenic and sometimes pneumo-toxic. World-wide many episodes of PA intoxications have been reported involving ruminants as well as humans. Ruminants may eat the PA-plants directly as part of the forager, humans in an unconscious way taking contaminated grain or through ruminant's products (milk, meat, etc...). Also the microflora of the rumen and the origin specie of plant PA may vary the intensity of poisoning (Wiedenfeld & Edgar 2011).
4. **Alkenyl Benzenes and Derivatives:** Eugenol and methyleugenol, are aromatic compounds present in many natural herbs and plants used in culinary (Miele et al, 2001). Also may be presents in packaging of foods (Aurela et al, 2001), as pollutants of non-vegetable foods. In both cases the

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

presence of these molecules, at high concentratios may increase the risk of cellular mutagenicity and finally cancer (Dean 1978).

5. **Tannins:** Tannins are in all plants as part of the metabolism of cellulosic structures and have potential antioxidant activity (Hagerman, et al, 2015) and biocidal and antibiotic activity (Scalbert, 1991). These biological activities give to tannins relative toxic activities at high concentrations in animal feeds (Makkar 2003)
6. **Ethanol and Coffee:** Both may be qualified as "social drugs" and need to be ingested in baste quantities to become deadly toxic for humans. Many foods and food additives that are safe for human consumption can be extremely toxic to pets (Gugler et al, 2013). Even chronic ingestion of ethanol causes digestive mucosa irritation and changes in pets' intestine adsorption patterns (Bell et al, 1985).
7. **Diacetyl from Adverse Fermentations:** Diacetyl, is an important component in the flavor of food and it is known to be the chief component of the aroma of butter. It has been found in adverse fermentations of *Sacharomices Cerevisae* and has long been known. (Suomalainen & Ronkainen, 1968). Recently some strain of *Enterobacter Aerogenes*, are found to be able produce high levels of diacetyl during fermentation. (Zhao Ling et al, 2007). The absorption of diacetyl by air in mice shows relationship with obliterative bronchiolitis (OB) disease. This relation it has been observed also by Centers for Disease Control and Prevention (USA), in flavor-manufacturing industry workers. (CDC, 2007).
8. **Flavonoids:** Flavonoids are phenolic compounds that represent substantial constituents of the non-energetic part of the human diet. A group of metabolites of increasing interest are the phytoestrogens and phytosteroids, which are agonist or antagonist to the action of human endogen steroids. There are many chemical characterization and several biological studies of these compounds and many of them indicate the various possible medical applications, for example, in the decrease of symptomatology of menopause and the prevention and treatment of related diseases, in the prevention and treatment of cardiovascular diseases and in some types of cancer (Leyva et al, 2011). The studies about the toxicity of this natural compounds show a protective effect more than toxic one. (Fotsis et al, 1998) (Mishra et al, 2008).
9. **Maillard Reactions:** The Maillard reaction, is fundamental in culinary sciences for the production of aroma, taste, and color during the cooking of many foods (meat, bread, etc..). Recently it has been shown that these reactions may be accompanied by a reduction in nutritive value and the formation of toxic compounds (Ledl, & Schleicher, 2003). The increase of Strecker degradation reactions (Van Boekel M.A.J.S, 2006) larger the amount of toxic by-products found. Mutagenic compounds like acrylamide are the final result of this decomposition reaction (Mottram et al, 2002).
10. **Lipid Thermodegradation:** When we heat food in contact with oil, a lot off physicochemical reactions happen at same time. To heat the frying oil to cooking, we have to raise the temperature above 100 ° C, trying not rise above the smoke point (which depends on the type of oil we use), normally in our houses, 120ºC. At this temperature, begins to realize the Maillard reaction. The sugars and amino acids from food react to give candy type products and finally decompose it into aldehyde compounds and pyrazines (Strecker degradation reaction) that are unhealthy enough.

Simultaneously, fatty acids (all oils are fatty acids, more or less purified), are degraded in a real chain of chemical reactions. Fatty acid of our oil, bind with oxygen from air to give hydro-peroxide molecules.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Food fat decomposition give more (generally saturated, climbing of cholesterol) free fatty acids and semi-decomposed fats (mono-glycerides, di-glycerides and glycerin). Finally, with increasing temperature, we obtain dimers, trimers, epoxides, alcohols, simple acids, hydrocarbons and ketones. That is, all a wide variety of organic compounds, more or less toxic.

Regarding the type of oil oxidation by heat, always increases the acidity, so if we start heating an oil of lower acidity, it will take longer to upload this to levels that makes it disgusting sensory. Special oils, which sell for fryers are almost pure fatty acids (high oleic, etc....), this means they can be used longer without degradation, but its organoleptic characteristics are very low. In the market are also sold anti-oxidant compounds to add to the frying oil that make it longer shelf-life, but usually is cheaper to optimize the use of standard oil in the kitchen.

11. **Sucrose and Tooth Decay:** Relationship between sucrose, bacterial adhesion and tooth decay are well stablishing. Glycoprotein and plaque formation is a fast process that fixes anaerobic bacteria like *Streptococcus mutans*, in teeth surface. Lactic acid generated by bacterial metabolism causes teeth cavity.

In modern cuisine, use of polysaccharides based, food additives (thickening and gel-forming agents), modulate the effect of bacterial adhesion to tooth (Steinberg et al, 2005).

FUTURE RESEARCH DIRECTIONS

The main matter is the difficulty to obtain data about ADIS and NOEL, fine referenced, that may be used in food or culinary process. In the other hand, to understand this data is mandatory a minimum level of toxicology knowledge. Basic food toxicology and culinary sciences should be a basic knowledge to be study in food technology, food production and culinary sciences careers. Day by day, allergen and toxin detection thresholds are increasing in the same ratio than technology, but some answer remains unresolved (Taylor S.L. et al, 2004). Protective measures are running, but their real effect on population is unknown at time (Moneret-Vautrin, & Kanny 2004). Many review on food allergens thresholds, have

Table 1. Main food intolerances by enzymatic effect

Situation	Enzyme Deficiency
Disaccharidase deficiency	Lactose, sucrose
Galactosemia	Galactose-*1*-phosphate uridyl transferase
Hyperbilirubinemia	uridine diphosphate -epimerase
phenylketonuria	Fenilalanin-hidroxilasa
Alcohol intolerance	Aldehyde-dehydrogenase
Favism	*Glucose-6*-phosphate dehydrogenase

Table 2. Endogenous agents responsible for the pharmacological action of food

Vasoactive Amines	Diamines	Histamine
	Monoamines	Tyramine *Phenylalanine* Serotonin Dopamine
Methylxanthines		Caffeine Theobromine Theophylline
Others		Capsaicin Ethanol Myristin

Table 5. Acute toxicity of some representative substances

Substance	DL 50 (mg/K)
Ethylic Alcohol	10.000
Sodic Phenobarbital	150
Strychnine	2
Nicotine	1
Tetrodotoxine	0,1
Dioxin	0,001
Botox	0,00001

From Klaassen et al., 1986.

try to clarify this questions, but the relationships between allergen presence and toxic/immune-reaction remain unclear (Kirsch et al, 2009) (Green et al, 2002) (Crevel et al, 2008) (Morisset, et al, 2003) (Nowak-Wegrzyn et al, 2009) (Fernandez 2012)

CONCLUSION

Adverse reactions to foods produced by allergies, food intolerances and toxins, are an emerging health problem. The incidence of these diseases presents a continued increase in recent years. The most effective way to avoid the adverse food reactions is eliminated from the diet of susceptible people components that trigger the adverse effect, making an exclusion diet. For consumers with allergies, exposure to a small amount of food that is sensitive can provoke severe reactions, including anaphylactic shock which can compromise their life. There is great variation in sensitivity of different food allergens among the population, and there is currently no consensus on allergen levels, with the exception of gluten, which may lead to an allergic reaction in susceptible people. That is why they have to have all the necessary information about the composition of foods to make a right choice according to the needs and becomes an essential element of food safety.

Chapter 24
Food and Cardiac Health:
Protective Effects of Food on Cardiovascular System

Aditi Jain
Jaypee Institute of Information Technology, India

Vibha Rani
Jaypee Institute of Information Technology, India

ABSTRACT

Emerging influence of Cardiovascular Diseases (CVDs) and its impact on the society has raised much awareness for its prevention. Healthy food habits and physical exercise has drawn a lot of attention of the people from scientific as well as common world. The role of food-based bioactive compounds in reducing risk of CVDs has been established with various health benefits apart from the basic nutrition have been reported. The present chapter provides an overview of the role of different foods on cardiovascular health of humans. Biological effects of plant derived food products and their bioactive compounds in the context of relevance to cardiovascular health promotion are discussed in detail. The chapter also covers the effects of the consumption of functional food on the intermediate clinical markers of CVDs including cholesterolemia, hypertension, endothelial function and inflammation. The chapter will enable the better understanding of the current knowledge on the potential health benefits of different functional foods and bioactive compounds on cardiovascular health.

INTRODUCTION

Cardiovascular Diseases (CVDs) have a substantial influence on public health from past several decades and it still remain the major cause of mortality and morbidity throughout the globe. CVDs comprise group of different cardiac and vascular complications including hypertension, coronary heart, atherosclerosis, cerebrovascular disease (stroke), peripheral artery disease, rheumatic heart disease, heart failure etc. Major lifestyle causes of CVDs include tobacco intake, physical inactivity and unhealthy diet (World health organization, 2009). Major CVD events arise due to atherosclerosis, a pathophysi-

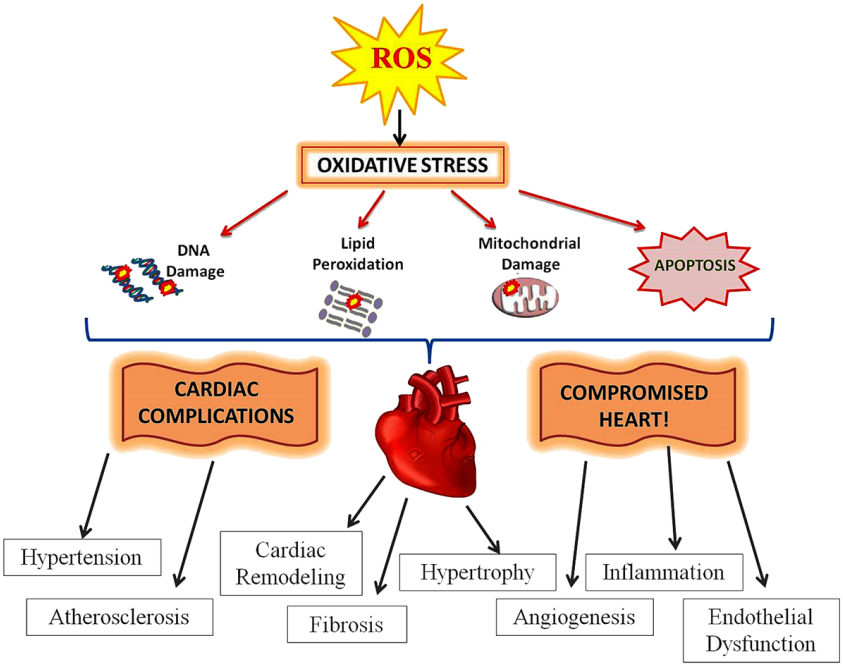
ological complication of innermost layer of arterial wall and such events can be prevented by nutritional supplementation (O'Toole et al. 2008). Different parameters have been studied in this regard and life-style changes have been suggested as the most helpful practices including physical activity and healthy food habits. Healthy diet and food habits show an inverse relationship with onset of vascular diseases as well as affect the longevity. Food provides both the essential nutrients required for basic life processes as well as bioactive compounds that help in disease prevention and health enhancement. Balanced diet including fruits, vegetables, whole grains and other plant foods helps in acquiring the required amounts of nutrients, antioxidants, bioactive compounds and phytochemicals thereby prevents various health related complications. Potential health promoting benefits of the natural bioactive compounds have been studied over time. There is keen interest in assessing the role of food-based bioactive compounds in reducing risk of chronic diseases including Cancer, CVD and diabetes mellitus.

For the reduction of coronary heart diseases, much emphasis is given on reducing the saturated fat, trans fat and cholesterol to lower the low-density lipoprotein-cholesterol (LDL-C) levels. Other pathways involved in the protective effects mediated by different food products with respect to CVDs onset has also been studied extensively. Oxidative stress results in cellular damage by affecting proteins, DNA and lipids, thereby increasing the risk CVDs. Oxidized LDL-C are a major factor that contributes to the cardiac diseases. Antioxidant potential of fruits and vegetables accounts for the most of the health promoting benefits and CVD prevention (Pandey & Rizvi, 2009). Major oxidative stress mediated events that lead to various cardiovascular complications are summarized in the Figure 1. Other factors include preventing vascular inflammation, reducing platelet hyper activity, vasodilation, cardiac hypertrophy etc. Inflammation is a critical factor in CVDs and its systemic marker, C-reactive protein, plays an important role in disease progression. Inflammation promotes atherosclerosis initiation and progression resulting in severe thrombotic complications of atherosclerosis (Shrivastava et al, 2015). Platelet activation and aggregation play a key role in the pathogenesis of myocardial infarction and ischaemic cardiac complications. Cardiac hypertrophy is a compensatory patholphysiological response of the heart to chronic pressure, and is a critical risk factor for ischemic heart disease, arrhytmia and sudden death. Dietary supplementation can promote the proper platelet function by reducing the hyper-reactivity of platelets and maintain cardiovascular health.



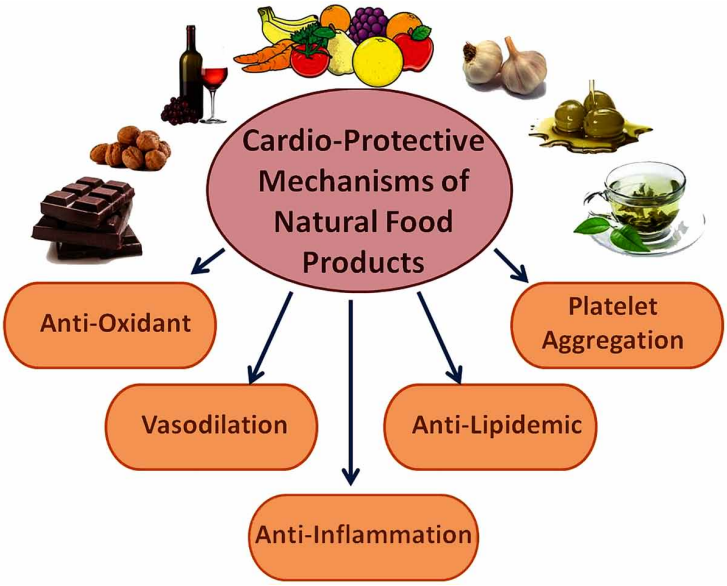
Based on the extensive studies done in the previous decades, a throughout general observation has been made to support the hypothesis that the precise intake of foods and beverages with high amount of flavonoids and polyphenols play an important role in reducing CVD risk by improving vascular function and modulating inflammation (Habauzit & Morand, 2012). There are ample epidemiologic evidences from numerous studies that suggest a strong relationship between the consumption of diets high in fruits and vegetables, legumes, whole grains, fish and cardiovascular disease protection. Phenolic compounds including flavonoids, tannins etc. are present in almost all the plants and vegetables. These compounds have been studied in detail for their protective and beneficial roles in human health.

NATURAL FOODS WITH CARDIOPROTECTIVE BENEFITS

There are increasing facts suggesting the uptake of natural food products as they are enriched in micro-nutrients including minerals, vitamins and essential fatty acids that are required to sustain the cellular antioxidant levels and other stress response mechanisms (Visioli & Hagen, 2007). It has also been demonstrated in various studies that intake of a healthy balanced diet including whole food is evidently

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 1. Oxidative stress induced cardiac complications



more beneficial as compared to the consumption of processed food. It may be contributed to the fact that isolated compounds either loses their biological activity or may not behave in the similar way as in the whole foods. Hence, the usually present combination of phytochemicals of natural food products is responsible for the various potential preventive effects. Number of food item has been reported to play a significant role in prevention and cure of CVDs. These are discussed in detail in the following section and their different mechanisms are depicted in Figure 2.

Fruits, vegetables, legumes, whole grains and fish are high in fiber and omega 3 (or *n*-3) fatty acids as well as low in saturated fat, trans fat and dietary cholesterol. Whole grains, nuts and green leafy vegetables are the rich source of vitamin E, which is well known for reducing the risk for atherosclerosis and coronary heart diseases. Fruit and vegetables have sufficient amount of antioxidants including phytochemicals, phenolics and carotenoids that protect cellular systems and reduces the risk of various diseases including CVDs. In a very recent UK Women's Cohort Study, it has been eastablished that total fruit intake lowers the risk of CVD mortality, with a 6–7% reduction in risk for each 80 g/day portion consumed. Also, women in the highest intake group of grapes and citrus experienced a significant reduction in risk of CVD and stroke as compared with the non-consumers (Lai et al., 2015).

Garlic, or *Allium sativum* has been used in daily food practices across the worlds from centuries and it has been studied for various medically important effects including hypocholesterolaemic, anti-atherosclerotic, antioxidant and cardioprotective (Bayan et al, 2013). Garlic comprises specific allyl sulphides and other organosulpfur compounds that express the characteristic protective properties of garlic in wide variety of patho-physiological conditions. These sulphide compounds restrict the oxidized LDL mediated cellular eNOS degradation as well as prevents the vasculae endothelium from oxidative stress mediated effects (Seki & Hosono, 2015). Garlic is well known for reducing total cholesterol and TAG thereby preventing cardiac complications (Tapsell et al, 2006). Garlic consumption decreases mortality and morbidity rates

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 2. Cardio protective mechanisms of different natural food products

of CVDs through its antithrombotic, hypoglycemic and lipid-lowering properties. Garlic oil is shown to decrease hypercholesterol mediated cardiac hypertrophy *in vivo* by modulating different signaling pathways and molecules including IL-6, p-extracellular signal-regulated kinase-5, p-MAPK-5, calcineurin, p-GATA binding protein 4 thereby improving hypertrophy-associated cardiovascular complications (Hseieh et al., 2014). It is also known for maintaining the homeostasis of the immune system by stimulating specific cell types and other mechanisms important for the development and advancement of various diseases including CVDs. Garlic modulates cytokine secretion thereby contributing to its action for many of the therapeutic effects (Arreola et al., 2015). Garlic supplements have also shown to reduce the high blood pressure. In a meta-analysis conducted by Wang et al., it was observed that garlic consumption directly modulates blood pressure and it is significantly effective in the hypertensive patients (Wang et al., 2015). Preventive effects of garlic powder on CVDs and risk factors were studied in another meta-analysis where it was found that garlic significantly reduces blood total cholesterol and LDL-C levels. Garlic was also found to decrease systolic and diastolic blood pressure (Kwak et al, 2014).

Green Tea, derived from *Camellia sinensis*, is well studied for its role in cardiac protection and CVD prevention (Cooper & Morre, 2005; Kuriyama et al., 2006; Sumpio et al., 2006). Green tea consumption has shown to inhibits cardiomyocyte apoptosis, a critical factor in the transition from hypertrophy to heart failure, prevents cellular damage caused by oxidative stress, p53 modulation and decrease in Bcl-2 expression (Sheng at al., 2007). It also reduces LDL-C levels thereby directly reducing different cardiac complications.

Syzygium cumini, also known as black plum or jamun, is a well-known for its medicinal properties including anti-inflammatory, hypoglycemic, anti-oxidant, antibacterial and cardioprotective (Chagas et al., 2015). Various *in vitro* and *in vivo* studies have demonstrated the cardioprotective potential of *S. cumini.* It has been shown to reduce isoproterenol-induced myocardial infarction in rats by inducing biochemical alterations (Mastan et al., 2009). It also exerts cardioprotective effects against glucose induced oxidative stress on cardiac myocytes by exerting free radical scavenging activity (Atale et al., 2013).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

In studies, nuts consumption as a part of diet has shown different potential health benefits despite of their high fat content (Coates & Howe, 2007). Nuts intake markedly decrease the risk of sudden cardiac arrest and other associated heart problems like high cholesterol levels. Walnuts, almonds and hazelnuts have drawn ample attention in the recent years for their cardio protective and other health benefits.

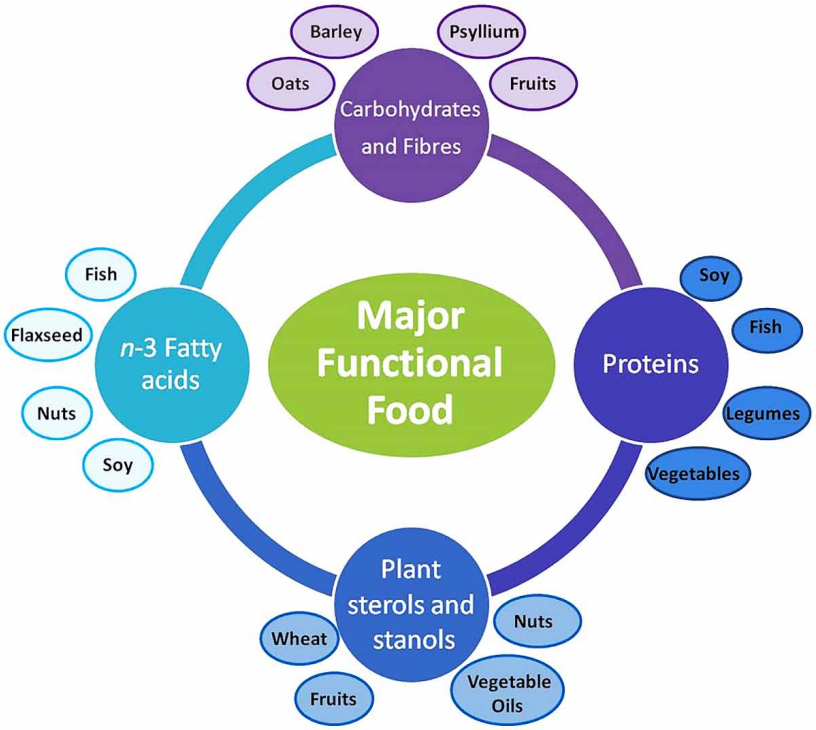
Oil derived from olives has been shown to decrease CVD risk by reducing LDL oxidizability and downregulate CD40-ligand expression and their downstream products (Castaner et al., 2012). Canola oil can reduce plasma cholesterol levels and influences various biological functions and biomarkers of cardiac disease risks. Canola oil consumption also increases tocopherol levels and effects insulin sensitivity, lipid peroxidation, inflammation, energy metabolism, and cancer cell growth (Lin et al., 2013).

In a recent study, it has been shown that the consumption of beans have hypercholesterolaemic with resulting in reducing the LDL-C levels without disturbing the HDL-c levels (Winham & Hutchins, 2007).

Xuezhikang, Chinese red-yeast rice, comprises statins that are used to supplement the diet for the prevention of cardio vascular diseases. Studies have shown that this rice can prevent the occurrence of cardiac complications in diabetic patients by 50% (Zhao et al., 2004). It has no adverse effects associated with the regular consumption and its commercial production should be encouraged in the other parts of the world as well. Buttermilk consumption has shown to be associated with reduced cholesterol and triglycerides concentrations in men and women by inhibiting intestinal absorption of cholesterol. Therefore, it should be recommended as a natural and low cost dietary product for improving lipid profiles in low risk patients (Conway et al., 2013).

These remarkable effects of natural food products thus reinforce the recommendation to raise the intake for the cardiovascular protection.

FUNCTIONAL FOOD AND CARDIAC HEALTH



Functional food displays advantageous effect on different body functions by improving the state of health and reducing the disease risk apart from its nutritional importance. Functional food comprises the food that we consume as a part of our diet with beneficial effects. It has been observed in various clinical and epidemiological studies that protective nutritional practices can reduce the risk of chronic heart disease upto 60% (Everitt et al., 2006; Kris-Etherton et al., 2002; Habauzit & Morand, 2012). These protective ingredients in our food reduce the major risk factors of cardiac abnormalities like reduction in blood cholesterol levels, hypertension and diabetes. Functional foods majorly comprise soluble fibres, phytostenols, sterols, long-chain *n*-3 fatty acids, soya proteins etc. These components majorly act upon the serum lipids and reduce the risk of heart diseases. The major classes of functional foods along with their main sources are illustrated in the Figure 3.

Dietary fibres help in reducing the cholesterol levels and considered as a safe approach for the prevention as well as cure of high cholesterol levels (Erkkila & Lichtenstein, 2006). Soluble fibres decrease the LDL-C levels thereby exerting hypocholestrolaemic effects and hence, recommended harmless. They are majorly present in fruits, oat bran, barley, flaxseed and psyllium.

β-glucan from soluble oats and barley is also well known for the reduction of LDL-C levels. It is primarily associated with the reduction in the bile acid absorption and cholesterol levels. Its consumption in the form of a fruit drink has shown significant reduction in cholesterol levels (Naumann et al, 2006; Nwachukwu et al., 2015).

Figure 3. Major categories of different functional foods and their sources

Long-chain fatty acids of the *n*-3 series are essential dietary compounds as they cannot be synthesized in mammals. They play an important role in modulation of membrane properties and lipid mediated signaling pathways by incorporating into the structural lipids (Sirtori et al, 2009). Intake of *n*-3 fatty acids, like eicosapentaenoic and docosahexaenoic acids result in decreased incidence of coronary heart disease and unexpected cardiac death (von Schacky C, 2004). They are generally present in animal diets, especially fish, with few exceptions of certain seeds like nuts, flaxseeds, linseed, rapeseed and soy. The role of fish consumption in reducing the risk of cardiovascular diseases was established several years back and has become the basis of using fish oils and other fish derived products in purified forms for supplementing the diet for the disease prevention (Elvevoll et al, 2006). It has been observed that *n*-3 fatty acids from fish oil are involved in a number of nuclear receptor-regulated mechanisms thereby regulating tissue lipid metabolism and other associated metabolic and lipoprotein disorders (Dubey & Cheema, 2006). The *n*-3 fatty acids also help in improving atherosclerosis risk factors like hypertension apart from triacylglycerolaemia and HDL-cholesterolaemia (Borghi & Cicero, 2006). Because of these beneficial effects, different forms of *n*-3 fatty acids have been incorporated into variety of easily available food items, for example, cow's milk and bread spreads.

Sterol compounds produced by plants can decrease the intestinal absorption of dietary and biliary cholesterol by interfering with their transporters thereby altering the cholesterol metabolism. Stanols are formed by saturating β-sitosterol and campesterol and incorporated in the different varieties of functional foods (Winter, 2005). Phytosterols and phytostanols have hypocholesterolaemic efficacy as the esterification of the fatty acids with plant sterols, improve the LDL-C:HDL-C ratio (Chan et al., 2007).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Soya proteins have shown various cardio protective effects in various animal and human studies mainly by reducing the total cholesterol, LDL-C and ischaemic events. Consumption of low carbohydrate diet including either soya or vegetable proteins have shown to reduce the cardiovascular risk (Halton et al, 2006). In 1999, US Food and Drug Administration approved the health claim for the role of soya protein intake in cardiovascular disease risk reduction based on the cholesterol lowering effect of soya proteins. Similarly to soya protein, fish protein also reduces cholestrolaemia and blood pressure thereby preventing cardiovascular risk. Protein derived from lupin seeds has also shown remarkable cholesterol-lowering effects in various studies (Martins et al, 2005). Lupin has an advantage of having the whole protective ingredients for the cardiac protection including fibres, phtosterols and protein. Lupin protein isolates have also shown to decrease the development of hypertension (Pilvi et al, 2006). Red wine and purple-grape juice has shown to exert platelet-inhibitory properties. The antioxidant potential of red wine provides cardioprotection by reducing oxidative stress in different pathological conditions of cardiac system (Das et al., 2007).

BIOACTIVE COMPOUNDS FROM FOOD AS CARDIOPROTECTANTS

Bioactive compounds are defined as the extranutritional components that are present in food in small quantities. Phytochemicals are the bioactive nonnutrient plant compounds present in fruits, vegetables and other plant based foods. They are known to reduce the risk of various chronic diseases directly or indirectly. Phenolic compounds and flavonoids are the extensively studied bioactive compounds as they are present in all the plants. They have been studied widely in cereals, nuts, olive oil, legumes, vegetables, fruits, tea etc. Studies have reported protective relationship among flavonoids and CVD. Their antioxidant potential reflects favorable effects on CVD risk factors. Different classes of bioactive compounds along with their natural sources and protective roles have been summarized in Table 1.

Various plant-derived foods and drinks, comprising chocolate, wine, berry juices, tea, coffee etc., have been extensively studied *in vitro* and *in vivo* for their potential benefits on cardiovascular health. They hold a wide range of phenolic compounds, including flavonols, flavanols, procyanidins and anthocyanins (Pascual-Teresa et al, 2010).

Flavonoids are the most common polyphenolic compounds present in plant derived food products. The reduction in CVD risk as observed after flavonoid intake is clinically significant (Hooper et al, 2008; Mursu et al, 2008). Based on an hypothesis for understanding the polyphenols portective effect, acidic nature of flavonoids may act as chemical uncouplers in the mitochondria leading to an increased resting energy expenses and results in the increased cell longevity (Modriansky & Gabrielova, 2009). Cocoa is rich in flavonoid content that has been well studied for its protective role in cardio vascular disorders (Ding et al., 2006). Other than flavonoids, Cocoa also contains catechins and procyanidins, which can reduce the oxidant-induced peroxynitrite production in vitro, enhance the NO synthase expression and NO-dependent vasodilation in the aorta and prevent hypertension (Grassi et al, 2005; Kurosawa et al, 2005). Cocoa polyphenols exhibit antioxidant, anti-inflammatory and anti-atherogenic activity and targets NF-κB and iNOS (Rimbach et al, 2009). These benefits make dark chocolate consumption, either in powder, as chocolate or from different cocoa flavanol-rich drinks, a very important measure for reducing cardiovascular risks (Corti et al., 2009).

Table 1. Bioactive compounds, their natural sources, and protective roles in human health

Bioactive Molecules	Major Natural Sources	Protective Roles
Anthocyanins	Red, blue and purple berries	Anti-oxidant, cardio protective, DNA damage protection
Proanthocyanins and Procyanidins	Cocoa, grapes, apple, cinnamon	Anti-oxidant, anti-carcinogenic
Phytoestrogen	Soy, flaxeed oil, whole grains, fruits and vegetables	Anti-oxidant, cardio protective
Hydroxytyrosol	Olive oil	Anti-oxidant, cardio protective
Reserveratol	Nuts, red wine	Anti-oxidant, anti-thrombonic, anti-inflamatory, anti-carcinogenic
Lycopene	Carotenoid fruits including tomatoes	Anti-cancerous
Organosulphur	Onion, garlic	Anti-carcinogenic, cardio protective, anti-oxidant
Isothiocyanates	Cruciferous vegetable	Anti-carcinogenic, cardio protective
Monoterpenes	Citrus fruits, cherries, herbs	Anti-carcinogenic, cardio protective
Quercetin	Onions, fruits, broccoli	Anti- inflammatory, cardio protective, anti-hypertensive, anti diabetic, anti cancerous
Myricetin	Berries, fruits, vegetables, herbs, tea and wine	Anti-oxidant, anti diabetic, anti cancerous
Kaempferol	Aloe vera, fruits	Anti-inflammatory, anti-apoptotic, anti oxidant, anti cancerous, anti bacterial
Luteolin	Fruits, vegetables, medicinal herbs	Anti cancerous, anti oxidant, anti- inflammatory, anti-hypertensive
Fisetin	Strawberry, onion, grapes, wine	Bone protective, neuro protective
Catechin and Epicatechin	Tea, chocolate, apples, pears, grapes and red wine	Anti oxidant, anti-obese, cardio protective
Tannins or Proanthocyanidins	Fruits and vegetables	Anti oxidant, cardio protective, anti-inflammatory, anti-carcinogenic and anti-mutagenic

Phenolic compounds and polyphenols have shown to regulate various signaling pathways involved in cell survival, growth and differentiation. Polyphenols represents the major contender to explain the protective effects of plant-derived food products. The anti-inflammatory action of phytochemicals present in wide variety of plants may play an important role in the prevention of CVDs. Phytochemicals have also been shown to have roles in the reducing platelet aggregation, cholesterol synthesis modulation and blood pressure maintenance.

Catechin and epicatechin are the most common flavonoids. Catechins are also called monomeric flavonols and they are the biosynthetic precursor of proanthocyanidins and well known for their anti-oxidant potential, but their protective effect on cardiovascular health is also accounted by other effects including mediating important mechanisms like hypertension, inflammation, cellular proliferation, hyperglycaemia and hypercholesterolemia. Epigallocatechin gallate is a major catechin of green tea and it has been shown to decrease vascular inflammation by synthesizing more of nitric oxide thereby blocking endothelial vascular inflammation (Yamakuchi et al, 2008). Nitric oxide production is also restricted by PPAR receptors in response to catechins (Danesi et al, 2009). Catechin consumption has also shown to decrease decreased atherosclerotic factors including TNF-α, sICAM-1, MCP-1 and CRP suggesting the effective role in reducing atherosclerosis and proinflammation (Hsu et al, 2007).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Quercetin is another flavonoid present in fruits, vegetables, nuts, seeds and flowers and has epidemiologic evidence for a protective effect against CVDs. It inhibits platelet aggregation and reduces thromboxane synthesis and may be helpful in reducing CVD risks (Egert et al., 2009).

Oligomeric procyanidins or flavan-3-ols have shown to activate of eNOS and mediating an endothelium dependent relaxant effect that modulates the NO/cGMP pathway (DalBo et al., 2008). Proanthocyanidins present in grape seeds have demonstrated to reduce the levels of proinflammatory markers such as CRP, IL-6, TNF-α and an increase in the production of antiinflammatory cytokines thereby suggesting the obesity-related adipokine dysregulation to manage cardiovascular and metabolic risk factors (Terra et al., 2009). In an *in vitro* study, catechin and proanthocyanidins have shown the cardioprotective effects on myocardial cells against the toxicity originated by the administration of anticancer drugs like doxorubicin (Du et al., 2008).

Anthocyanins are the bioactive compounds with dual benefits, firstly for their impact on the sensorial characteristics of food products and secondly for their health related properties with proposition on cardiovascular disease risk protection. Anthocyanins are the pigments responsible for the bright colors of many fruits and vegetables. (de Pascual-Teresa & Sanchez-Ballesta, 2008). They can act upon different cells involved in the pathogenesis of atherosclerosis, in addition to the effects on cholesterol distribution thereby protecting endothelial cells from CD40- induced proinflammatory signaling (Wallace, 2011; Xia et al., 2007). Anthocyanins have also shown decrease in NF-kB–related proinflammatory chemokines, cytokines, and inflammatory mediator responses in the plasma suggesting inhibition of NFkB activation by anthocyanins (Karlsen et al, 2007).

Curcumin or diferuoylmethane is an active ingredient of and well known for its different protective properties including anti-inflammatory, antioxidative and cardiovascular effects (Miriyala et al., 2007; Ahuja et al., 2011). Curcumin treatment reduces free radical generation, monocyte adhesion to activated endothelial cells and phosphorylation of c-Jun N-terminal kinase, p38 mitogen activated protein kinases. These effects results in the prevention of myocardial function following ischemic or biochemical stress to the heart. Curcumin can also reduce cardiac remodeling and suppresses cardiac hypertrophy (Kohli et al., 2013; Srivastava & Mehta, 2009).

Various phytoestrogens are present in soy, but also in flaxseed oil, whole grains, fruits, and vegetables. Many phenolic compounds have antioxidant properties Hydroxytyrosol is a phenolic compound present in olives and olive oil and well known as a potent antioxidant. Resveratrol is found in nuts and red wine and exhibits antioxidant, antithrombotic and anti-inflammatory properties. Lycopene is also an effective antioxidant present in tomatoes and other fruits. Organosulfur compounds present in garlic, isothiocyanates in cruciferous vegetables and monoterpenes in citrus fruits, cherries, and herbs are few other examples of cardioprotective effects mediating bioactive compounds.

CONCLUSION

Prevention is better than treatment and the same applies to the onset of CVDs. Novel dietary advances for cardiovascular prevention are of major significance at present as there is an increasing despise in primary prevention of CVDs by chronic drug usage. A correlation between CVD prevention and healthy diet has been demonstrated from the various studies. There are sufficient evidences recommending the consumption of food sources rich in bioactive compounds including flavonoids, fibres, plant proteins and phytosterols, polyphenols etc. Integrating plant foods with high levels of flavanols in the diet of healthy

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

individuals can decrease the risk of CVD significantly. The active compounds present in the plants have huge potential to reduce serum total cholesterol and LDL-C levels, thus directly improving cardiac health. Phenolic compunds are potent effectors of biological processes and influence CVD risk via modulating cellular pathways like MAPK signaling pathway and important mediators like NF-κB, AP-1 and Nrf.

There are sufficient evidences for recommending the consumption of food sources rich in bioactive compounds, that is, recommending a diet including variety of fruits, vegetables, whole grains, legumes, oils, and nuts. Various mechanisms of action of most the bioactive compounds have been conducted but more scientific research is need to be done to embark on science based dietary recommendations. Well-designed future investigations with the isolated bioactive compounds are needed to be done to derive the valuable information regarding the mechanism of action and doses to be taken. This will lead to commence recommendations for both the nature of the compounds and the optimal dose and better targets can be achieved in the area of cardiovascular health protection.

ACKNOWLEDGMENT

We acknowledge Department of Biotechnology (DBT), Government of India (BT/PR3978/17/766/2011) for the research grant awarded to Dr. Vibha Rani. We also acknowledge the Department of Biotechnology, Jaypee Institute of Information Technology, Deemed to be University for providing the literature and infrastructural support.

Chapter 25
Molecular-Docking-Based Drug Design and Discovery:
Rational Drug Design for the Subtype Selective GPCR Ligands

Soo-Kyung Kim
California Institute of Technology, USA

William A. Goddard III
California Institute of Technology, USA

ABSTRACT

Currently 30-50% of drug targets are G Protein-Coupled Receptors (GPCRs). However, the clinical useful drugs for targeting GPCR have been limited by the lack of subtype selectivity or efficacy, leading to undesirable side effects. To develop subtype-selective GPCR ligands with desired molecular properties, better understanding is needed of the pharmacophore elements and of the binding mechanism required for subtype selectivity. To illustrate these issues, we describe here three successful applications to understand the binding mechanism associated with subtype selectivity: 5-HT2B (5-Hydroxytryptamine, 5-HT) serotonin receptor ($HT_{2B}R$), H_3 histamine receptor (H_3HR) and A_3 adenosine receptor (A_3AR). The understanding of structure-function relationships among individual types and subtypes of GPCRs gained from such computational predictions combined with experimental validation and testing is expected the development of new highly selective and effective ligands to address such diseases while minimizing side-effects.

INTRODUCTION

G protein-coupled receptors (GPCRs) with >800 including 340 non-olfactory receptors are the largest superfamily in the human genome. These are customarily partitioned into 5 families: glutamate, rhodopsin, adhesion, frizzled, and secretin (Fredriksson, Lagerstrom, Lundin, & Schioth, 2003). GPCRs regulate essential physiological processes (e.g. cellular metabolism, cell growth, secretion, immune

defense, neurotransmission, and differentiation) through various endogenous ligands which include biogenic amines, peptides, lipids, nucleotides, and proteins, modulate (Lefkowitz, Pierce, & Luttrell, 2002). GPCRs also involves in various important cell recognition and communication processes (Ellis, 2004). Thus, GPCRs are important drug targets for all major disease areas, including neurodegenerative, psychiatric, metabolic, cardiovascular, cancer, and infectious diseases (Tang & Insel, 2005). Indeed, currently 30-50% of drug targets are GPCRs (Hopkins & Groom, 2002). The currently marked GPCR-targeting drugs with ~80 account for ~$50 billion in annual sales, and many have annual sales > $2 billion (Goddard III & Abrol, 2007). Identifying GPCR subtypes with specific cell and tissue has been accelerated for target evaluation, lead identification, and optimization of GPCRs. However, the clinical use as drugs for targeting GPCR have been limited by the lack of subtype selectivity or efficacy, leading to undesirable side effects.

BACKGROUND

Endogenous ligands regulate multiple GPCR subtypes. Serotonin activates 15 serotonin (5-HT) receptors. With the exception of the 5-HT_3 receptor, a ligand-gated ion channel, all other 14 serotonin receptors are GPCRs. The 5-HT_1 (1A- 1F) and 5-HT_5 (5A, 5B) receptors decrease cellular level of cAMP through coupling with Gi/ Go protein, while $5HT_4$, 5-HT_6, and 5-HT_7 receptors increase cellular level of cAMP through coupling with Gs protein. 5-HT_2 (2A– 2C) receptors increase cellular level of inositol triphosphate (IP_3) and diacylglycerol (DAG) through coupling with G_q/ G_{11} protein (Nichols & Nichols, 2008). Various biological and neurological processes were regulated through the serotonin receptors such as aggression, anxiety, appetite, cognition, learning, memory, mood, nausea, sleep, and thermoregulation. Thus, the serotonin receptors are the target of a variety of pharmaceutical drugs, including many antidepressants, antipsychotics, anorectics, antiemetics, gastroprokinetic agents, antimigraine agents, hallucinogens, and entactogens (Nichols & Nichols, 2008).

Histamine acts via four histamine receptors (HRs); H_1, H_2, H_3 and H_4. Histamine has a critical role in immumomodulation and allergic diseases. Other biological activities include cell proliferation, differentiation, hematopoiesis, embryonic development, regeneration, wound healing, aminergic neurotransmission, secretion of pituitary hormones and regulation of gastrointestinal and circulatory functions (Jutel, Blaser, & Akdis, 2005). The H_3 and H_4 HRs inhibit the cellular level of cAMP through coupling with Gi/ Go protein, while the H_2HR activates the cellular level of cAMP through coupling with Gs protein. The H_1HR increases the cellular level of IP_3 and DAG through coupling with G_q/ G_{11} protein.

Adenosine binds all 4 subtypes of adenosine receptors (ARs), denoted A_1, A_{2A}, A_{2B}, and A_3, which coupled to G proteins. Activation of the A_1 and A_3 ARs inhibit the cellular level of cAMP via Gi/ Go protein, while the A_{2A} and A_{2B} ARs activate the cellular level of cAMP via Gs protein (Olah & Stiles, 1995). ARs are involved in many of the body's cytoprotective functions. Thus, ARs are important pharmacological targets in the treatment of a variety of diseases because of their key roles in controlling numerous physiological processes. For example, many therapeutic agents under development for treatment of central nervous system disorders, inflammatory diseases, asthma, kidney failure and ischemic injuries exert their effects via interactions with ARs.

To achieve high selectivity for specific GPCR subtype, an alternative approach is the development of selective allosteric modulators of the specific receptor subtypes. There are two marketed GPCR allosteric modulators, a positive allosteric modulator of the calcium sensing receptor used to treat hyperparathy-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

roidism and Maraviroc a negative allosteric modulator of chemokine receptor 5 that inhibits HIV entry into cells and is used to treat HIV infections (Conn, Christopoulos, & Lindsley, 2009). However, in this review we will focus on the subtype selective orthosteric ligands. Several groups studied the subtype selectivity. The 3D models of all four subtypes using the crystal structure of the $hAA_{2A}R$ as a template were generated by homology modeling and applied the methodology of ligand-guided receptor optimization for ređnement (Katritch, Kufareva, & Abagyan, 2011). The crystal structures of 5-HT_{1B} and 5-HT_{2B} receptors were compared (Wang, Jiang, Ma, & Xu, 2013). The 5-HT_{2A} selectivity was discussed based on the steered molecular dynamics (MD) approach of the 5-HT_{2A} model (Isberg, Balle, Sander, Jørgensen, & Gloriam, 2011). The development of subtype selective nicotinic acetylcholine receptor ligands was discussed (Astles et al., 2002). Fine-tune ligand selectivity for the angiotensin 2 receptors AT2R subtypes through electronic control of ligand aromatic-prolyl interactions results in an AT2R high affinity (Ki = 3 nM) agonist analogue with 18,000-fold higher selectivity over AT1R(Magnani et al., 2014). More recently, the binding pocket and subtype specificity in the X-ray structures of opioid receptors (OR) were discussed (Manglik et al., 2012b). In the binding pocket of the δ-OR within 4 Å of the ligand, 11 out of the 14 residues, are identical between μ-OR and δ -OR. The three differences are at μ-OR positions $E229^{EC2}$, $K303^{6.58}$ and $W318^{7.35}$, which are Asp, Trp and Leu in the δ-OR, respectively. In particular, the point mutation $W318L^{7.35}$ markedly increases the affinity of the δ-OR selective ligands at the μ-OR. But the qualitative analysis is not done for which residues are involved in ligand subtype selectivity according to energy. The interaction energy includes the non-bonding van der Waals (vdW) and electrostatic Coulombic energy between the ligand and protein to see how much or which interaction the subtype selective residues contribute in the binding site.

MAIN FOCUS OF THE CHAPTER

Issues, Controversies, Problems

To develop subtype-selective GPCR ligands with desired molecular properties, we need much better understanding of the binding sites for ligands to GPCRs and of how the mechanism for subsequent activation is affected by the structural parameters. Particularly difficulty here is that there are often many subtypes for the same endogenous ligand (4 for histamine and adenosine, 13 for serotonin), which we can expect might have someone similar binding sites. Moreover, there is clear evidence that the GPCR structure suitable for recognizing antagonists can be quite different than those for agonists. Thus even with a crystal structure of a GPCR bound to a specific antagonist or agonist, the best GPCR conformation for binding a different agonist or antagonist might be very different. Thus to predict the proper binding site to a particular GPCR, we need to first predict the ensemble of stable apo-protein structures which might be suitable for the various ligands.

To predict the ensemble of low energy GPCR conformations, we developed the GEnSeMBLE (GPCR Ensemble of Structures in Membrane BiLayer Environment) Monte Carlo Method. GEnSeMBLE compares the sequences of any one target to those of all other GPCRs to predict the hydrophobic regions likely to span the membrane and then predicts the optimum packing of the 7 transmembrane (TM) domains into 7-helix bundles. To ensure sampling of all possible packings, GEnSeMBLE starts with templates for GPCRs obtained previously from experiment (or theory) and samples up to ~12 trillion tilts and rotations of these helices, which it reduces down to the best ~10 to 20.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Then the DarwinDock Monte Carlo Technique was performed to predict the best binding pose for each ligand to each of the 7-helix bundles in this 10-20 bundle ensemble.

These procedures, which have been validated against several X-ray crystal structures, are applied here to three systems which were compared with the X-ray studies and validated by other experiments. We consider here three successful applications of computations to predict the binding mechanism for subtype selectivity:

1. Human 5-HT_{2B} (5-Hydroxytryptamine, 5-HT) serotonin receptor ($hHT_{2B}R$), (S.-K. Kim, Li, Abrol, Heo, & Goddard III, 2011)
2. Human H_3 Histamine receptor (hH_3HR) (S. K. Kim, Fristrup, Abrol, & Goddard III, 2011) and
3. Human A_3 adenosine receptor (hA_3AR) (S. K. Kim, Riley, Abrol, Jacobson, & Goddard III, 2011)

These calculations improved understanding of how these subtype selective ligands interact with each subtype at the molecular level and would be useful to diminish undesired side effects through the cross-selectivity with other subtypes and to design novel classes of subtype selective drugs.

1. METHODS

1.1. GEnSeMBLE Monte Carlo Protocol (Abrol, Bray, & Goddard III, 2011b)

The MembEnsemb (later version of the MembStruck) techniques which were used to predict the 3D structure for the hHT2BR and hHT2CR is the earlier version of the GEnSeMBLE Monte Carlo method. For each of the 7-helix conformations selected from the BiHelix analysis we built full 7-helix bundle, scream all 7 helixes simultaneously and evaluated the energy, ScreamTot. In addition, we evaluated the membrane solvation free energy (MembSolE, Es) using a multi-dielectric (80|7|2|7|80) implicit membrane model of the total solvation free energy change associated with transfer of protein from implicit bulk water. In the GEnSemBLE method, the scoring energies are ranked 4 different ways the charged total energy, the neutralized total energy, the charged interhelical energy, and the neutralized interhelical energy. Although we did not apply the same methods for the three successful applications, we validated our previous result using our new methods.

The GEnSeMBLE method (Abrol, et al., 2011b) was used to generate the 3D structures for the ensemble conformations of GPCRs, as summarized in Figure 1. GEnSeMBLE generates a complete sampling (millions to trillions) of rotations and tilts of the helices for the ensemble of low lying structures expected to be energetically accessible for binding of ligands. This method replaced our earlier MembStruk method which sampled helix rotations helix by helix, rather than combinatorial (Vaidehi et al., 2002).

The structure prediction methodology described previously (Abrol, Bray, & Goddard III, 2011a) is summarized as follows:

1. **PredicTM:** Uses multiple sequence alignments of over 2,000 GPCR sequences using the MAFFT (Katoh, Kuma, Toh, & Miyata, 2005) program combined with the hydrophobicity scales from White and von Heijne(Wimley, Creamer, & White, 1996) to predict the TM domains for membrane protein.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

These TM domains were extended by capping rules and the secondary structure prediction using PORTER(Pollastri & McLysaght, 2005) and SSPro(Pollastri, Przybylski, Rost, & Baldi, 2002).

2. **OptHelix:** OptHelix uses molecular dynamics to predict the structure for each TM domain, which is usually helical except for kinks that may be caused by Proline residues.
3. **Homologize Helices:** When closely related X-ray structures with higher than 30% of sequence identity are available, we also use homology models to determine the helix shape. We consider the currently available X-ray structures; human nociceptin/ orphanin FQ receptor,(Thompson et al., 2012) mOPRD mouse delta opioid receptor,(Granier et al., 2012) mouse mu opioid receptor,(Manglik et al., 2012a) kappa opioid receptor,(H. Wu et al., 2012) human D_3 dopamine receptor,(Chien et al., 2010) turkey β_1 adrenergic receptor,(T. Warne, Serrano-Vega, M.J., Baker, J.G., Moukhametzianov, R., Edwards, P.C., Henderson, R., Leslie, A.G.W., Tate, C.G., Schertler, G.F.X., 2008) human adenosine A_{2A} receptor,(Jaakola et al., 2008) human β_2 adrenergic receptor,(V. Cherezov, Rosenbaum, D.M., Hanson, M.A., Rasmussen, S.G.F., Thian, F.S., Kobilka, T.S., Choi, H-J., Kuhn, P., Weis, W.I., Kobilka, B.K., Stevens, R.C., 2007) human sphingosine 1-phosphate,(Hanson et al., 2012) human Chemokine CXCR4,(B. Wu et al., 2010) human H_1 histamine receptor,(Shimamura et al., 2011) rat M_3 muscarinic receptor,(Kruse et al., 2012) human M_2 muscarinic receptor,(Haga et al., 2012) and bovine rhodopsin (Li, 2004; T. Okada, Fujiyoshi, Y., Silow, M., Navarro, J., Landau, E.M., Shichida, Y., 2002; T. Okada, Sugihara, M., Bondar, A.N., Elstner, M., Entel, P., Buss, V., 2004; Palczewski, 2000; Teller, 2001) Based on the sequence identities of the TM regions for these systems and the diversity of structures, we chose a starting template.
4. **BiHelix:** To cover all possible rotations of all 7 helices, consider 30° increments in the rotation about each TM axis (eta η angle), leading to $(12)^7 \sim 35$ million packings. The energies for all 35 million packing are estimated in by evaluating the energies of all $(12)^2=144$ interactions for each of the 12 pairs of helices in direct contact. For each of the 1,728 pairwise interactions, SCREAM(V.W.T. Kam & W.A. Goddard III, 2008) was used to optimize the side-chains. The BiHelix mean field energies for all 35,000,000 packings are used to select the best 2000. We then build the full 7-helix bundle for each of these 2,000 structures, optimize the side-chains for each using SCREAM, and neutralize the charged residues for more accurate energy scoring. The Dreiding D3 force field (D3FF)(Mayo, Olafson, & Goddard III, **1990**) was used throughout wherever energies were evaluated.
5. **SuperBiHelix(Bray, Abrol, Goddard III, Trzaskowski, & Scott, 2014):** Starting with the X-ray tilt angles we validated(Abrol, et al., 2011a) that the BiHelix analysis always identifies the experimental set of rotation angles correctly (this validates the procedure and the scoring function). However we have shown that even for closely related GPCRs, we must optimize the tilt angles: theta θ (tilting away from the z-axis) and phi φ (the azimuthal angle of the tilting from the xy plane) angle in order to get an accurate structure for a structure based on a different template (Abrol, Griffith, Bray, & Goddard III, 2012) Here we have found that starting with the best angles from the BiHelix optimization, it is sufficient to sample $\pm 10°$ for θ tilt angle while simultaneously sampling by $\pm 30°$ for both φ and η angles, leading to a total of $(3x5x5)^7 \sim 10$ trillion combinations. Generally the hydrophobic center (HPC) for each TM domain from the PredicTM analysis is placed at z=0, but we can use SuperBiHelix to optimize translation along the TM axis simultaneously with optimizing rotations.

In SuperBiHelix, The BiHelix mean field energies for all 10 trillion combinations packings are used to select the best 2000, which are then examined much more accurately by building the 7 TM bundles

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

and optimizing side chains. Our experience is that the mean field energies are sufficiently accurate that the best 7-helix bundle energies are all in the first 700 of the 2,000, indicating that analyzing the best 2,000 is sufficient.

6. **Loop Generation:** The loops and the N/C terminus including helix 8 for a new structure are modeled through homology with the template structure, and then relaxed through 10 cycles of simulated annealing between 50K and 600K each for 0.1 ps, followed by minimization. The disulfide bridge between C3.25 and Cys in the second extracellular loop (EC2), which is conserved among Class A GPCRs, is constructed. Then keeping the 7 TM bundle fixed, we first optimize the loop structures (up to1000 steps or down to 0.5 RMS force) followed by quench annealing between 50 K and 600K for 10 cycles.

The best examples of using our procedures to successfully predict mechanisms relating to activation or inactive character of GPCRs are our studies on various mutants of CB1 that were subsequently confirmed by experiment. We were able to show that mutations that strengthening the coupling of TM6 to TM2 and TM3 make the CB1 receptor totally inactive, while mutations that break this interaction are essentially totally active (Ahn, Scott, Abrol, Goddard III, & Kendall, 2013) Moreover we predicted mutations that would switch either from totally inactive to constitutively active or from totally active to constitutively active that were confirmed by subsequent experiments.

1.2. DarwinDock

The lowest energy predicted structures from BiHelix/ SuperBiHelix were used for docking several ligands, using DarwinDock. The starting structure and charges of the ligands are calculated using quantum mechanics (B3LYP with the 6-311G** basis set). Then we develop a set of conformations by LigCluster and select 10 to 20 for docking.

1. **Scanning the receptor for potential binding regions:** Using the predicted 7-helix bundle structure, we predicted putative ligands binding regions as follows. The 6 hydrophobic residues, I, L, V, F, Y, and W, were alanized for the whole protein and scanned for potential binding regions. The overall molecular surface of the protein structure was mapped with spheres representing the empty volume of the protein (currently using the Sphgen procedure in DOCK4.0 suite). The entire set of protein spheres is partitioned into ~30 to 50 overlapping cubes of 10 to 14 Å sides. For each of these 30 - 50 regions, 1,000 poses were generated.
2. **DarwinDock:** The GenMSCDock is the later version of the GenMSCDock techniques to predict the binding site for HT2B/ HT2CR agonists. The GenMSCDock procedures sampled a complete set of configurations for each conformation of the ligand. This leads to a hierarchy of families with a specified range of diversities, allowing the best to be selected at a coarse level by evaluating energies of family heads. This also leads to an ensemble of the best diversity families that are used for higher-level calculations. The GenMSCDock method does two rounds, one to ensure completeness and the other to enrich the better families. To achieve an average of 6 children in each family, we resort to obtain 0.6 Å families in the enrichment step. The steps in GenMSCDock include bulky residue alanination, diversity finder, Voronoi reclustering, side-chain refinement and neutralization. The DarwinDock method which is the later version of GenMSCDock increases the sampling

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

number for all binding configurations from 2500 to 5000 with a larger diversity parameter of 1.2 – 1.4 Å in the completeness step. In addition, we include the scoring energies of ligand strain and solvation.

DarwinDock has replaced our earlier methods, the HierDock and GenMSCDock. For each ligand conformation, DarwinDock iteratively produces a total of ~50,000 poses into the putative binding regions of the alanized protein. The poses partitions into families based on CRMS and the energy scoring of family heads and select the top 10% ordered by total energy. The 100 conformations are scored for the children of these top families for further optimization. For 100 conformations, we dealanize the protein side-chains to optimize the side chains using SCREAM. Then we neutralize the protein and ligand by transferring protons within salt bridges and protonating or deprotonating exterior ligands, followed by further full geometry minimization.

We validated DarwinDock using 3 crystal structures of ligand/ GPCR complexes: human β_2-adrenergic receptor (0.4 Å RMSD),(V. Cherezov et al., 2007) human $AA_{2A}R$ (0.8 Å RMSD),(Jaakola, et al., 2008) and turkey β_1-adrenergic receptor (0.1 Å RMSD) (T. Warne et al., 2008) This supports that we can accurately identify ligand binding sites in proteins and optimize the ligands with desirable properties.

3. **Neutralization for scoring energy:** Quantum mechanics (QM) calculations show that if an effective dielectric constant is < 8Å, the extra proton on a Lys or Arg transfers back to the negative carboxylate of an Asp or Glu.[22] Thus buried salt bridges is expected to have neutral residues. We find that neutralizing these exposed residues removes the sensitivity to details of the distances of charged residues (and counter ions) remote from the binding cavity. This neutralization leads to differential binding energies that are dominated by the local cavity interactions and leads to much smaller solvation energies.

We used the unified cavity energy as the scoring function for docking. It was calculated by the total non-bonding energy in 4 Å of ligand which is the sum of van der Waals (vdW), Coulomb, and H-bond energy (kcal/mol) in the unified cavity.

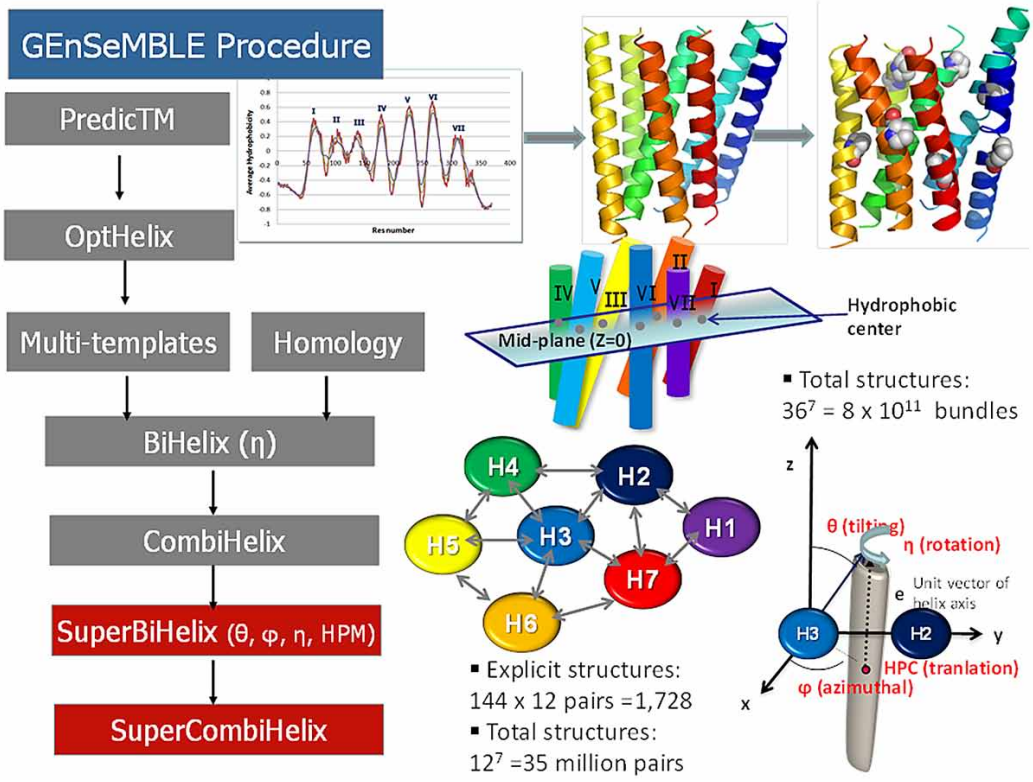
An excellent example validating our DarwinDock is the predicted binding site for the Maraviroc anti HIV drug from a selection of 8 diverse packings for the chemokine CCR5 GPCR (Abrol et al., 2014) Then we predicted 12 mutations designed to increase or decrease binding significantly. These mutations, carried out after the predictions, led to a mean error of <1 kcal/mol in the predicted correlation of relative binding energies. Interestingly, the optimum protein packing for binding Maraviroc was different than for the original wild type binding site for each of the 12 mutations.

2. APPLICATIONS

2.1. Subtype Selectivity of Antagonists for $hHT_{2B}R$ (Kim et al., 2011)

Three 3 subtypes of 5-HT_2 GPCRs are important drug targets for schizophrenia, depression, migraines, anxiety, hallucinogens, feeding disorders, perception, hypertension, and gastrointestinal dysfunctions. In particular, $hHT_{2B}R$ antagonists have a possible therapeutic treatment of pulmonary hypertension (Fredriksson, et al., 2003).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



The sequence identities of overall and TM region between $hHT_{2B}R$ and $hHT_{2C}R$ were 57.38 and 72.51%, respectively. The sequence identities of each TM region have 65.22% for TM1, 75.00% for TM2, 87.50% for TM3, 55.56% for TM4, 62.50% for TM5, 81.82% for TM6, and 80.80% for TM7. The predicted structure of $hHT_{2B}R$ has an average RMSD of 0.39 Å relative to the $hHT_{2c}R$ TM bundle (RMSD of TM1: 0.63 Å, TM2: 0.39 Å, TM3: 0.26 Å, TM4: 0.52 Å, TM5: 0.45 Å, TM6: 0.21 Å, TM7: 0.30 Å).

We compare here the binding sites and energies for two cases

- A non-selective antagonist (SB-206533 **1**:5 -methyl-1-3,5-dihydro-2H-pyrrolo[2,3-f]indole-1-carboxylic acid pyridine-3-ylamide) bound to hHT_{2B} and $hHT_{2C}R$ (serotonin) GPCR
- A selective antagonist **2** (1-methyl-1-1,6,7,8-tetrahydro-pyrrolo[2,3-g]quinoline-5-carboxylic acid pyridine-3-ylamide) bound to hHT_{2B} (serotonin) GPCR

Figure 1 shows the predicted structures(S.-K. Kim, et al., 2011) for non-selective SB-206533 **1** in cyan, to both of the $hHT_{2B}R$ and $hHT_{2C}R$. For residue numbering, we used the Ballesteros-Weinstein number; the most conserved residue in each of the 7 TM domains is taken as the reference and numbered as 50. This residue is designated x.50 where x is the number of the TM helix (Ballesteros & Weinstein, 1995) From the cavity analysis, we find similar interaction energies for this antagonist to both $hHT_{2B}R$ and the $hHT_{2C}R$. For example the hydrogen bonding (HB) interactions between the ureido-CO group and the

Figure 1. Flowchart of GEnSeMBLE (GPCR Ensemble of Structures in Membrane BiLayer Environment) Monte Carlo method

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Ser-OH side chain at S139$^{3.36}$ is conserved among 5-HT2 family receptors, 2A, 2B, and 2C. The complex is stabilized through additional hydrophobic interactions at conserved hydrophobic residues, V136$^{3.33}$, F274$^{6.51}$ (2B)/ F272$^{6.51}$ (2C), and F299$^{7.38}$/ F298$^{7.38}$. The N-methyl group in the cyclopenta-indole ring forms the hydrophobic interactions with the subtype variable residues, Non-bond energies of L132$^{3.29}$, I186$^{4.56}$, and V190$^{4.60}$ in the $hHT_{2B}R$ are -2.48, -0.10, and -0.76 kcal/mol, respectively. The corresponding amino acids, I132$^{3.29}$, V186$^{4.56}$, and I190$^{4.60}$, at the $hHT_{2C}R$ also have favorable non-bond energies. Thus, similar total cavity energies of SB-206533 **1** at the $hHT_{2B}R$ and $hHT_{2C}R$ are -42.48 and -42.28 kcal/mol, respectively. In addition, subtype-selective residues also reveal similar interactions (Table 1).

Then we studied the conformational restricted analogue **2** (1-methyl-1-1,6,7,8-tetrahydro-pyrrolo[2,3-g] quinoline-5-carboxylic acid pyridine-3-ylamide) known to bind much more strongly to 5-$HT_{2B}R$ affinity (pA2, 5-HT2B: 7.27 vs. pKi, 5-HT2C: 5.39) (Forbes et al., 1995)

Table 1. Cavity analysis of SB-206533 **1** *and* **2** *at human 5-HT2B and 2C receptors. The residues are ordered by the non-bonding energy difference (2C -2B)*

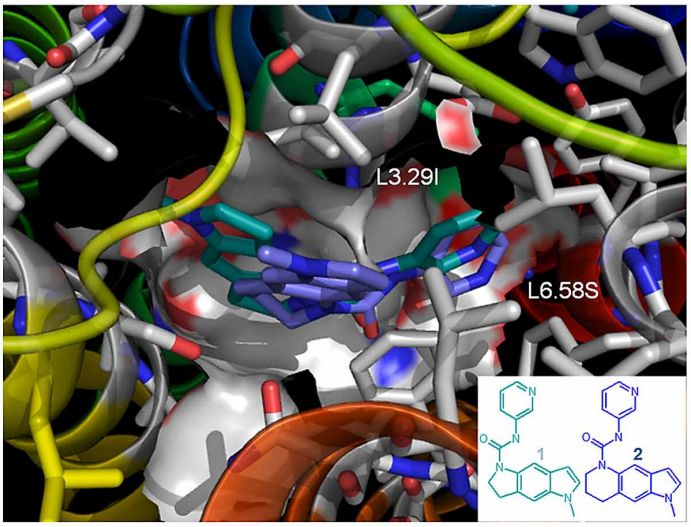
S.-K. Kim, et al. (2011)



Indeed we find that arises because the introduction of the six membered ring is clearly detrimental for $hHT_{2C}R$. The major hydrogen bond interaction is at the ureido-CO group with Ser-OH at conserved $S139^{3.36}$. Conserved hydrophobic residues, $V136^{3.33}$, $F274^{6.51}$ / $F272^{6.51}$ (2C), and $F299^{7.38}$/ $F298^{7.38}$ (2C) also stabilize the complex through hydrophobic interactions. We observed that bad contacts at $I132^{3.29}$ with unfavorable vdW interaction (+6.24 kcal/mol) result in reduced interaction at the $hHT_{2C}R$, compared with the favorable vdW interaction at the $hHT_{2B}R$ (-2.32 kcal/mol).

In addition, similar binding energies were shown at other variable residues, $V190^{4.60}$ / $I190^{4.60}$ in 2C, $L281^{6.58}$/ $S279^{6.58}$ in 2C. We find favorable interaction at $hHT_{2B}R$ (-47.53 kcal/mol) but unfavorable interaction at the $hHT_{2C}R$ (+11.47 kcal/mol), consistent with experiment (Table 1). However, $A225^{5.46}$ in 2B and $A223^{5.46}$ in 2C which were reported as specific interaction for 5-HT_{2A} selectivity(Isberg, et al., 2011) shows the similar interaction at both receptors.

The superimposition of **1** in cyan and **2** in blue in Figure 2 suggest that the *N*-methyl of the cyclohexa-indole ring of 2B selective compound **2** pointing toward the upper TM 3 leads to unfavorable interactions

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

*Figure 2. Superimposition of the predicted structures for the nonselective 5-HT2B/ 2C receptor antagonist (SB-206533 1) and the selective 5-HT2B receptor antagonist (***2***) at the human 5-HT2B receptor. The N-methyl of the cyclohexa-indole ring of* **2** *is closer to the upper part of TM3 leading to unfavorable interactions with bulkier Ile side chains in the 5-HT2C receptors (I132$^{3.29}$), while the methyl of the cyclopenta-indole ring in SB-206533* **1** *is pointing toward the upper TM 4.*
S.-K. Kim, et al. (2011)

with the bulkier Ile side chain in $hHT_{2C}R$ (I132$^{3.29}$), while the *N*-methyl of the cyclopenta-indole ring in the non-selective compound **1** directs toward the upper TM 4. In addition, the cyclohexa-indole ring is near the hydrophilic residue S279$^{6.58}$ in the $hHT_{2C}R$, while it interacts with hydrophobic L281$^{6.58}$ in $hHT_{2B}R$.

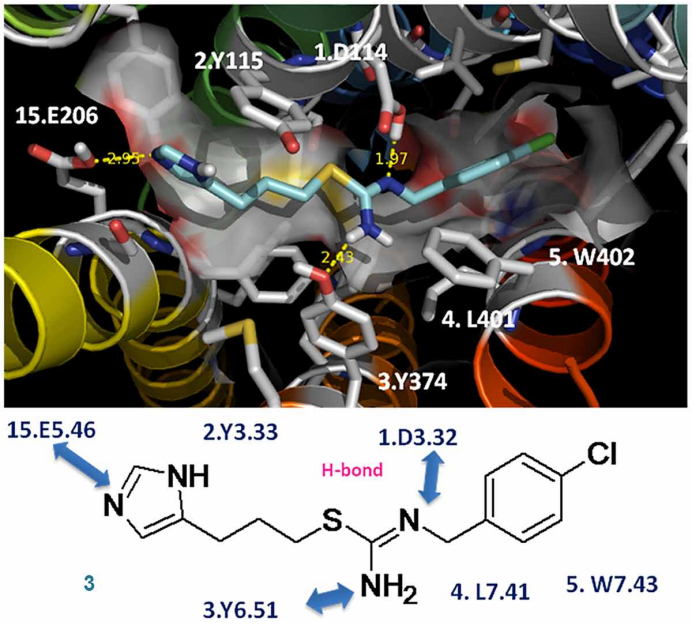
In the binding cavity of $hHT_{2B}R$, 13 out of 46 residues are variable compared with the binding cavity of $hHT_{2C}R$ with 72% sequence identity. Among them, L3.29I is the major contribution to the $hHT_{2B}R$ selectivity. L6.58S and M5.39V are the next important residues for the $hHT_{2B}R$ selectivity.

When compared with the recently published crystal structures of the partial agonist ergotamine-bound $hHT_{2B}R$ (4IB4),(Wacker et al., 2013) the predicted $hHT_{2B}R$ has a Ca RMSD of 2.49 Å relative to the $hHT_{2B}R$ crystal TM bundle. We observed the same TMs 1-2-7 networks among N1.50-D2.50-N7.49 and TMs 2-3-4 networks among S2.45-H3.42-W4.50 which is observed in the crystal structure. The H-bonding between D3.32 and Y7.43 which is conserved in most biogenic amine receptor was also observed near the binding site.

2.2. Subtype Selectivity of hH_3HR (Kim, Fristrup, et al., 2011)

HRs are major drug targets for the treatment of various diseases, such as schizophrenia, psychosis, depression, migraine, allergies, asthma ulcers, and hypertension. In particular, hH_3HR antagonists have been reported as specific therapeutic applications for the treatment of Alzheimer's disease, attention deficit hyperactivity disorder (ADHD), epilepsy, and obesity (Lorenzi et al., 2005) We report here the predicted lowest energy structure of all four human HR subtypes (H_1, H_2, H_3, and H_4), for each of which we have predicted the binding sites for H_3 selective antagonist: clobenpropit **3**, (*N*'-[(4-chlorophenyl) methyl]-1-[3-(3H-imidazol-4-yl)propylsulfanyl]formamidine).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



The hH_3HR shared 54.74% sequence identity with the hH_4HR, 32.15% sequence identity with the hH_1HR, and 33.08% sequence identity with the hH_2HR in the TM regions. The predicted structure of hH_3HR has an average RMSD of 0.04 Å for the hH_1HR, 1.03 Å for the hH_2HR, 1.01 Å for the hH_4HR, and 1.33 Å for the crystal structure of hH_1HR (3RZE) (Shimamura, et al., 2011). The predicted hH_1HR also has the same RMSD of 1.33 Å for the crystal structure of hH_1HR (Shimamura, et al., 2011).

We docked hH_3HR selective clobenpropit, to the lowest energy conformations of all four subtypes. From the cavity analysis of antagonist clobenpropit at hH_3HR, the major contributing amino acids are $Y115^{3.33}$ (-4.96 kcal/mol), $W402^{7.43}$ (-4.71 kcal/mol), and $D114^{3.32}$ (-3.73 kcal/mol) in Table 2. $D114^{3.32}$ and $Y374^{6.51}$ form the major H-bonding with the isothiourea group. The terminal imidazole ring forms additional H-bonding with at $E206^{5.46}$. Hydrophobic residues, $L401^{7.42}$ and $W402^{7.43}$ surround the *para*-chloro-benzyl group of clobenpropit (Figure 3).

To study subtype selectivity of HRs, the predicted best binding pose of the highly H_3-selective ligand clobenpropit at hH_3HR was matched into other three subtypes (H_1, H_2, H_4) of hHRs, and then SCREAM(V.W.T. Kam & W.A. Goddard III, 2008) was used to optimize the side chain position of residues in the binding cavity, followed by minimization and neutralization of the final ligand/ protein complex.

Table 2 displays predicted variable residues among four subtypes in the binding site (H_4: 29%, 8 out of 28, H_1: 57%, 16 out of 28, H_2: 68%, 19 out of 28). The corresponding amino acids of the same E5.46/ S5.43 in both of hH_3HR and hH_4HR are $N198^{5.46}$/ $A195^{5.43}$ in hH_1HR and $T190^{5.46}$/ $G187^{5.43}$ in hH_2HR (Figure 4) with weakened interactions in the cavity, resulting in a 2.2 to 2.4 kcal/mol favorable interaction in hH_3HR in Table 2. But, a similar interaction is observed at these two conserved residues E5.46/ S5.43

Figure 3. Predicted best structures of the H_3 selective antagonist clobenpropit **3** *bound to the human histamine H_3 receptor (hH_3HR). The H-bonding is represented by the arrows between the donor and the acceptor. The residues are numbered according to the order of unified cavity energy in Table 2. A schematic structure of the predicted binding site is displayed on the bottom figure.*
S. K. Kim, P. Fristrup, et al. (2011)

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

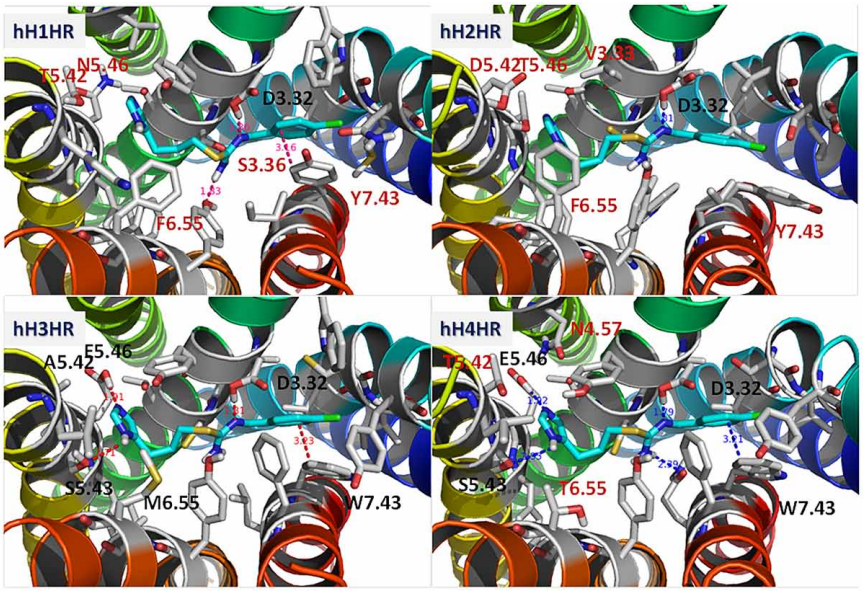


Table 2. Cavity energy of the H_3 selective antagonist clobenpropit **3** *to four human histamine receptors (HRs). Residues are ordered by total NonBond energy (H_3), which is the sum of van der Waals (vdW), Coulomb, and H-bond energy (kcal/mol) in the unified cavity. Predicted subtype residues that vary among four subtypes (H4: 29%, 8/28, H1: 57%, 16/28, H2: 68%, 19/28) are displayed in italic font. The color coding for contributions of each residue to binding of the adenosine ligand is: Dark grey: > 3 kcal/mol, Grey: 1 - 3 kcal/mol, Light grey: 0.5 - 1.0 kcal/mol. In the Ballesteros-Weinstein numbering, the most conserved residue in each of the 7 TM domains is taken as the reference and numbered as 50. This residue is designated x.50 where x is the number of the TM helix.*

Figure 4. Predicted best structures of the H_3 selective antagonist clobenpropit **3** *bound to four human histamine receptors (hH_1HR, hH_2HR, hH_3HR, hH_4HR). H-bonding is indicated by red dots, and subtype selective residues are shown in red.*
S. K. Kim, P. Fristrup, et al. (2011)

of hH_4HR. Thus, the final cavity energy leads to a substantial decrease in binding affinity (cavity sum = -34.11 kcal/mol in hH_1HR, -33.77 kcal/mol in hH_2HR) in agreement with the dramatically decreased experimental binding affinity at hH_1HR (PKi: 5.6) and hH_2HR (PKi: 5.2).

The final cavity energy shows a weakened binding affinity (-35.12 kcal/mol) for hH_4HR (PKi: 7.4) is a compared with the cavity energy (-36.94 kcal/mol) of hH_3HR (PKi: 9.4), Thus, this predicted binding energy is well correlated with the experimental binding affinity of H_3 subtype selective clobenpropit (Esbenshade et al., 2003).

In the binding cavity of hH_3HR, 7 (25%), 16 (57%), and 18 (72%) out of 28 residues are variable for hH_4HR, hH_1HR, and hH_2HR, respectively. The important residues for the hH_3HR selectivity are E5.46/ S5.43 in both of hH_3HR and hH_4HR which are $N198^{5.46}$/ $A195^{5.43}$ in hH_1HR and $T190^{5.46}$/ $G187^{5.43}$ in hH_2HR, respectively. When compared with the hH_4HR, M6.55T is the most important residue to overcome the hH_3HR selectivity.

Table 2 shows the unified cavity energy (UCav E) in all subtypes of hHRs, which are ordered by experimental binding affinity including. We find that the predicted binding energies for all four HRs are consistent with their experimental binding affinities with the r^2 values (correlation coefficients) ranging from 0.67 to 0.99.

2.3. Subtype Selectivity of $hAA_{2A}R$ and hAA_3R (Kim, Riley, et al., 2011)

ARs are targets for treatments of central nervous system disorders, inflammatory diseases, asthma, kidney failure, and ischemic injuries. Each agonist for 4 subtypes of ARs has various therapeutic applications. For example, the hAA_1R activation involves in cardioprotection, antilipolysis, type II diabetes,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

anti-arrhythmic, antiepileptic, analgesic/antinociceptive, ischemia, tachycardia, obesity, cachexia, while the hAA_3R activation involves in cardioprotection, cerebrovascular protection, prevention of stroke, anti-inflammatory, anti-asthmatic, neurological disease, ischemia, immune disorder, anticancer, and anti-arthritic. In addition, the $hAA_{2A}R$ agonists are useful for the target of antihypotensive, antipsychotic, and anti-inflammatory, while the $hAA_{2B}R$ agonists are useful for the target of anti-asthma cystic fibrosis, anti-inflammatory, septic shock, cardiac disease, diarrhea, impotence, and angiogenesis. The only other adenosine agonist currently in clinical use is non-selective adenosine itself, for the treatment of supraventricular tachycardia and as an aid in cardiac imaging. But the $hAA_{2A}R$-selective agonist Lexiscan (regadenoson, CV Therapeutics, Palo Alto, CA, USA), CVT-3146, recently approved for cardiac imaging in patients (K.A. Jacobson, A.M. Klutz, D.K. Tosh, A.A. Ivanov, D. Preti, & P.G. Baraldi, 2009). Selective hAA_3R antagonists are especially interesting as potential anti-glaucoma agents (Yang et al., 2005). Moreover, such selective hAA_3R agonists as IB-MECA (N^6-(3-Iodobenzyl)-5'-*N*-methylcarboxamidoadenosine) and Cl-IB-MECA (2-Chloro-N^6-(3-iodobenzyl)-5'-*N*-methylcarboxamidoadenosine), are now in Phase II clinical trials for treatment of liver cancer (K.A. Jacobson, A.M. Klutz, D.K. Tosh, A.A. Ivanov, D. Preti, & P.G. Baraldi, 2009). Thus, the development of the subtype selective ligand is critical for the specific treatment of human diseases.

To map out the binding site of A_3 subtype selective agonist, we predicted the ensemble of the 20 most stable structures for each of the four ARs. Here we used the high-resolution X-ray structure of $hAA_{2A}R$(Jaakola, et al., 2008) as the template. Because this crystal structure has $hAA_{2A}R$ bound to an antagonist, it provides little information about the structural changes involved in activation by agonist binding.

Then we predicted the binding of the above two A_3 selective agonists all 20 structures from this ensemble for each of the human adenosine subtypes (A_1, A_{2A}, A_{2B}, and A_3). In addition, we predicted the high hAA_3R selectivity for the agonist, Cl-IB-MECA and the high $hAA_{2A}R$ selectively for the endogenous agonist adenosine, validating the models for understanding the subtype selectivity. In addition we predicted binding sites for several A_3 selective antagonists to these structures for hA_3 and hA_{2A}.

The sequence identities of overall and TM region between hA_3AR and $hA_{2A}AR$ were 31.31 and 51.01%, respectively. The sequence identities of each TM region have 44.44% for TM1, 56.14% for TM2, 47.37% for TM3, 48.00% for TM4, 57.14% for TM5, 52.94% for TM6, and 51.04% for TM7. The predicted structure of hA_3AR has an average RMSD of 0.49 Å relative to the $hA_{2A}AR$ TM bundle (RMSD of TM1: 0.50 Å, TM2: 0.32 Å, TM3: 0.50 Å, TM4: 0.56 Å, TM5: 0.55 Å, TM6: 0.53 Å, TM7: 0.48 Å).

1. **$hAA_{2A}R$ selective adenosine:** We selected adenosine because of ~ 30 fold higher selectivity to $hAA_{2A}R$ than hAA_3R. The endogenous agonist adenosine was docked to the ensemble of 25 low-lying structures of apo-$hAA_{2A}R$.

All adenosine agonists show similar ribose moieties, except for the amide substitution at the 5'-position. Indeed an intact furanose moiety is present in most potent adenosine agonists previously reported (Jacobson et al., 2000). Table 3 shows the cavity analysis of the adenosine bound to $hAA_{2A}R$. Three major contributing amino acids are $N253^{6.55}$ (-7.22 kcal/mol), $F168^{EC2}$ (-6.33 kcal/mol), and $E169^{EC2}$ (-5.13 kcal/mol), based on non-bonding energies as the sum of vdW, electrostatic Coulomb with 2.5 dielectric constant and H-bond energies.

In the binding site of adenosine-$hAA_{2A}R$, the exo-cyclic amino group of the adenine ring interacts with $N253^{6.55}$ and $E169^{EC2}$ as the X-ray structure of $hAA_{2A}R$ also interacts with the amino group in the

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Table 3. Cavity energy of the endogenous agonist adenosine 4 bound to the human adenosine A_3 (AA_3R) and A_{2A} receptors ($AA_{2A}R$) () Residues are ordered by total NonBond energy (A_{2A}), which is the sum of van der Waals (vdW), Coulomb, and H-bond energy (kcal/mol) in the unified cavity. Subtype residues that are predicted to vary between A_{2A} and A_3 are displayed in bold face. The main interactions leading to subtype selectivity (underlined) in the predicted structure are E169 in A_{2A} vs. V169 in A_3, and V84 in A_{2A} vs. L90 in A_3. The color coding for contributions of each residue to binding of the adenosine ligand is: Dark grey: > 3 kcal/mol, Grey: 1 - 3 kcal/mol, Light grey: 0.5 - 1.0 kcal/mol.

tri-cyclic ring of ZM241385 (Doré et al., 2011). We also observed an additional H-bonding interaction (-2.82 kcal/mol) between the 2' and 3'-OH group of the nucleoside ring and the side chains of the double protonated basic $H278^{7.43}$, which forms the H-bonding with $E13^{1.39}$. The mutation of $N253^{6.55}$ to alanine reports loss of binding for agonist and antagonist, while the $H278E^{7.43}$ mutation displays substantial decrease of binding for agonist and antagonist except in the case of N^6-substituted agonists (S.-K. Kim et al., 2003)

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Later this adenosine-bound $hA_{2A}AR$ was compared with the crystal structures of the agonist UK43207-bound structure (3QAK)(Xu et al., 2011) and the agonist adenosine-bound structure (2YDO) (Lebon et al., 2011) and has a Ca RMSD of 1.61 and 1.69 Å relative to the $hAA_{2A}R$ crystal TM bundle, respectively. After the TM alignment, the adenosine conformation has a RMSD of 1.33 Å relative to the crystal structure.

The predicted ligand binding structure from $hAA_{2A}R$ to hAA_3R was then matched, leading to common interactions at $N250^{6.55}$ (-5.82 kcal/mol), $F168^{EC2}$ (-4.52 kcal/mol), and $H272^{7.43}$ (-4.03 kcal/mol). However, the $V169^{EC2}$ in hAA_3R (corresponding amino acid of $E169^{EC2}$ in $hAA_{2A}R$) results in unfavorable interactions in hAA_3R because of the different loop geometry of EC2 as well as loss of the interaction with the terminal amino group (Table 3 and Figure 5A and 4B). The result is a dramatic reduced binding affinity (cavity sum = -37.56 for $hAA_{2A}R$ vs. -28.92 for hAA_3R), which agrees with the dramatically decreased experimental binding affinity of endogenous adenosine at both rat ARs ($rAA_{2A}R$ estimated K_i: 30 nM vs. rAA_3R estimated K_i, 1,000 nM) (Jacobson, et al., 2000).

Figure 5. Predicted binding sites (A) adenosine 4 to the adenosine A_{2A} receptor ($AA_{2A}R$), (B) adenosine to the adenosine A_3 receptor (AA_3R), (C) A_3 selective agonist Cl-IB-MECA **5** *at $AA_{2A}R$, (D) A_3 selective agonist Cl-IB-MECA at AA_3Rs. The high selectivity of Cl-IB-MECA for AA_3R relative to $AA_{2A}R$ is due to the salt-bridge between E169 and H264 (red circle in (C)) in AA_3R. In $AA_{2A}R$ we have V169 but there is no residue corresponding to H264 because of the gap in $AA_{2A}R$. H-bonding is indicated by red dots, and subtype selective residues are shown in red.*
S. K. Kim, L. Riley, et al. (2011)

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

2. **hAA$_3$R selective Cl-IB-MECA agonist:** We docked A$_3$ subtype selective Cl-IB-MECA to the lowest energy conformation of hAA$_3$R. From the cavity analysis of Cl-IB-MECA at hAA$_3$R, the major contributing amino acids are F168^{EC2} (-9.79 kcal/mol), N250$^{6.55}$ (-4.44 kcal/mol), L246$^{6.51}$ (-4.28 kcal/mol), and H272$^{7.43}$ (-3.35 kcal/mol) in Table 4. The hydrophobic residues, V169^{EC2} and I253$^{6.58}$, surround the terminal benzyl group of Cl-IB-MECA (Figure 5D). The N^6-bulky benzyl group forms an additional interaction between EC2 and upper TM6, stabilizing the complex.

To study the origin of subtype selectivity, the predicted best binding pose of the highly A$_3$-selective ligand Cl-IB-MECA was matched to the hAA$_{2A}$R predicted structure, and then SCREAM(V.W.T. Kam & W.A Goddard III, 2008) was used to optimize the side chains in the binding pocket, after which the final ligand/protein complex was neutralized and minimized. In hAA$_{2A}$R, the interactions between protein and ligands were hampered by the conformationally restricted loop between E169^{EC2} and H264^{EL3} through a salt-bridge (Figure 5C). The corresponding amino acids of I253$^{6.58}$, V169^{EC2}, and Q167^{EC2} in hAA$_3$R are T256$^{6.58}$, E169^{EC2}, and L167^{EC2} in hAA$_{2A}$R with weakened interactions, resulting in a 7.31 kcal/mol favorable interaction in hAA$_3$R (Table 4). This predicted binding mode is in parallel with the experimental binding affinity of A$_3$ subtype selective Cl-IB-MECA (AA$_3$R Ki: 1.4 nM vs. AA$_{2A}$R Ki, 5,360 nM) (Jeong et al., 2007). The docking result also agrees with reported observations, where modification of the N^6-amine moiety (where large hydrophobic groups tend to produce AA$_1$R and AA$_3$R selectivity) and the C2 position (where large hydrophobic groups tend to produce AA$_{2A}$R selectivity) increase the subtype selectivity of adenosine derivatives as AR agonists for each subtype (K. A. Jacobson et al., 2009).

From the docking studies of the subtype selective antagonists, I253$^{6.58}$ and V169^{EC2} in hAA$_3$R are involved in hydrophobic interactions with the N^6-bulky group in the A$_3$ selective ligands, while E169^{EC2} in hAA$_{2A}$R (which is the corresponding amino acid of V169^{EC2} in hAA$_3$R) stabilizes the exocyclic amino group of the A$_{2A}$ selective ligands through additional H-bonding. Thus this predicted structure explains the increase of A$_3$ selectivity for the additional N^6-bulky substituent at hAA$_3$R. However, Q167^{EC2} in hAA$_3$R is located in the proximity of the C2 substituent which is oriented toward the extracellular loop 2 (EC2) in the docking model. The corresponding amino acid L167^{EC2} in hAA$_{2A}$R could explain the hA$_{2A}$AR selectivity for large hydrophobic C2 substituents which are observed in most A$_{2A}$ selective antagonists (K. A. Jacobson, et al., 2009).

From 27 residues in the binding site of hA$_3$AR, 14 residues are conserved with 52% sequence identity with the hA$_{2A}$AR. For the hA$_{2A}$AR selectivity, E169V in EC2 (Val in hA$_3$AR) is the most important residue which could form an extra H-bonding interaction. V3.32L is also important for the hA$_{2A}$AR selectivity. However, for the hA$_3$AR selectivity, Q167L (Leu in hA$_{2A}$AR) can increase the hA$_3$AR binding. T3.29A can also add a hydrophilic interaction compared with the hA$_{2A}$AR.

3. EXECUTIVE SUMMARY

The GEnSeMBLE Monte Carlo Technique was used to generate an ensemble of the 10 to 20 low energy packing of the 7-helix bundles for all subtypes of hHT$_2$Rs, hHRs and hARs to understand the origin of subtype selectivity for several subtype selective antagonists of hHT$_{2B}$R, hH$_3$HR and hA$_3$AR. Then the DarwinDock Monte Carlo Technique was performed to predict the best binding pose to each of the structures of this ensemble the

Table 4. Cavity energy of the A_3 selective Cl-IB-MECA **5** *bound to the human adenosine A_3 (AA_3R) and A_{2A} receptors ($AA_{2A}R$). The residues are ordered by the total NonBond energy (A_3), which is the sum of van der Waals (vdW), Coulomb, and H-bond energy (kcal/mol) in the unified cavity. Subtype residues that vary between A_{2A} and A_3 are displayed in bold face. The main interactions leading to subtype selectivity are I253 in A_3 vs. T256 in A_{2A}, V169 in A_3 vs. E169 in $A_{2A,}$ and Q167 in A_3 vs. L167 in A_{2A}, leading to 3.85 of the predicted 7.31 differential binding. The other major differences, involving conserved residues are for F168, S273, M174 favoring A_3 and N250, I268 favoring A_{2A}, leading to a differential of 2.16 of the predicted 7.31 differential binding. The color coding for contributions of each residue to binding of the adenosine ligand is: Dark grey: > 3 kcal/mol, Grey: 1 - 3 kcal/mol, Light grey: 0.5 - 1.0 kcal/mol*

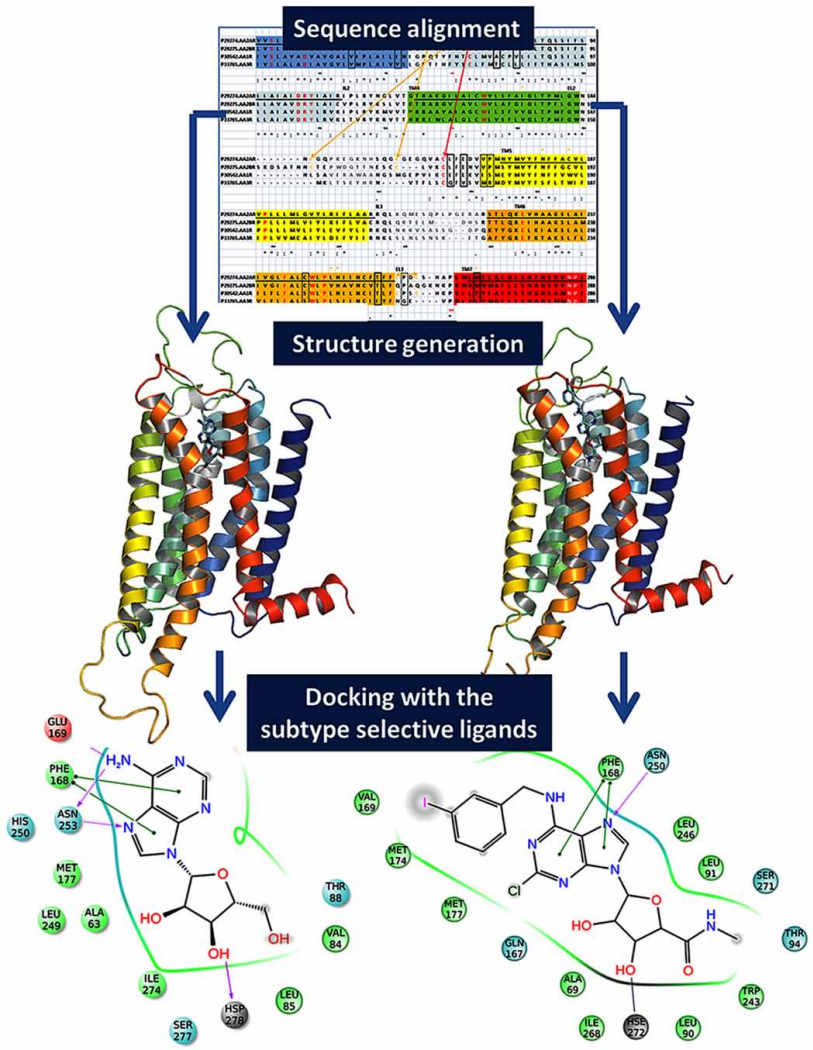
1. We found that the antagonist **2** is selective to HT_{2B} because of favorable vdW interaction at $L132^{3.29}$ and $L281^{6.58}$ in $hHT_{2B}R$, while become unfavorable at $I132^{3.29}$ and $S279^{6.58}$in $hHT_{2C}R$.
2. We found that clobenpropit **3** binds selective to both hH_3HR and hH_4HR because of the additional H-bonding to E5.46/ S5.43, whereas the corresponding amino acids $N198^{5.46}$/ $A195^{5.43}$ in hH_1HR and $T190^{5.46}$/ $G187^{5.43}$ in hH_2HR lead to a loss in these hydrophilic interactions.
3. We found that the A_3 selective ligand, Cl-IB-MECA **5**, has favorable vdW interactions of the N^6-bulky group with $I253^{6.58}$ and $V169^{EC2}$ in hAA_3R while $E169^{EC2}$ in $hAA_{2A}R$ (the amino acid corresponding to $V169^{EC2}$ in hAA_3R) instead interacts with the free amino group of the A_{2A} selective endogenous ligand adenosine **4** through additional H-bonding.

SOLUTIONS AND RECOMMENDATIONS

Although GPCRs are the most fruitful targets for marketed drugs, the success of developments of highly selective subtype drug candidates have been hampered by difficulty in achieving high selectivity for individual GPCR subtypes. After lead or target discovery, management of drug cross-reactivity is a crucial part in the lead-optimization process. Since a major problem of drug is cross-reactivity across members of a single GPCR subfamily because of high conservation of the orthosteric binding sites, development of subtype selective GPCR agonists or antagonists through the aid of molecular modelling is the first step of understanding for the structural requirements for subtype selectivity and the molecular properties required for activation or inactivation.

FUTURE RESEARCH DIRECTIONS

While high resolution 3D structures of $hAA_{2A}R$, hH_1HR, and $hHT_{2B}R$ represent an excellent template for homology modeling for other subtypes, the developments of subtype selective ligands has yet to be shown. Direct comparison of binding modes of subtype selective ligands at other subtypes was applied to rational design of novel subtype-selective ligands without side-effects. The non-conserved residues in the binding cavity which serve as determinants of ligand selectivity will affect overall protein conformation, leading to the different local environments in the binding cavity. Analysis of the subtype-speciđc ligand receptor interactions allowed identiđcation of the major determinants of ligand selectivity, which may facilitate discovery of more efđcient drug candidates. Application of these computational approaches is advancing the understanding of structure-function relationships among individual types, subtypes, and other family of GPCRs. Site directed mutagenesis experiments are also an effective tool to investigate the amino acid properties of specific residues for determining the subtype-selectivity. However, the issue in GPCR targeted drug discovery is the presence of multiple conformations. GPCRs exhibit several distinct low-energy conformations, each of which might favor binding to different ligands and/or lead to different downstream functions, understanding their function requires the various ensembles of low-energy configurations that might play a role in this pleiotropic functionality. Thus take-home message in this review is the activation conformation might be various among the subtypes which were regulated by different G protein, in which might be the one of the major causes of attrition in drug discovery. Accounting for 28% of cases was the lack of systemic drug efficacy because of lack of information of GPCR activation. In addition, the existence of functional dimers or larger oligomeric complexes through homo- or



EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

heterodimerization makes it more difficult to interpret the experimental data. Despite all of problems, we expect that the improved understanding of the microscopic interactions at the various binding site of the various low energy conformations of the GPCRs will guide dramatically in the development of novel subtype selective ligands. Since GPCRs are important as physiological and pharmacologic targets, such results from computational predictions validated by experiment should likely provide useful new insights of broad biological and medical importance.

CONCLUSION

The availability of high resolution X-ray structures has provided new insights into the structures of GPCRs, however for distinguishing between the GPCR conformations favored by the various ligands it is

Figure 6. Diagram of rational drug design for the subtype selective GPCR ligands

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

essential to determine the low energy packings of the GPCR that might be favored by different ligands for different subtypes. The GEnSeMBLE methodology provides the means to predict these low lying structures, but the accuracy of GEnSeMBLE has been dramatically improved by the availability of the many new X-ray structures. We studied the subtype selectivity of GPCRs using molecular modeling. As summarized in Figure 6, we generated the 3D-structures from the sequence alignment and docked the subtype-selective ligands. Finally, the comparison of binding site at each subtype gives the information which residues are directly involved in the subtype selectivity and how much subtype selective residues are energetically affected by ligands through the cavity analysis. This information will be the best tools for understanding the binding mechanism of each subtypes and further developing the subtype selective ligands through rational drug design to minimize the undesirable side effects because of non-specificity. Thus the computation and experiment working together can provide the information required for determining the optimum packing and binding pose for various ligands to various subtypes.

KEY TERMS AND DEFINITIONS

BiHelix: To cover all possible rotations of all 7 helices, consider 30° increments in the rotation about each TM axis (eta η angle), leading to $(12)^7 \sim 35$ million packings.

GEnSeMBLE: GPCR Ensemble of Structures in Membrane BiLayer Environment) Monte Carlo method.

GPCR: G protein-coupled receptors.

Subtype Selectivity: The requirement to gain control of receptor selectivity.

SuperBihelix: To cover all possible rotations of all 7 helices, optimize the tilt angles: theta θ (tilting away from the z-axis) and phi φ (the azimuthal angle of the tilting from the xy plane) angle in addition to the rotation about each TM axis (eta η angle) leading to ~12 trillion packings.

Chapter 26
Role of Molecular Docking in Computer-Aided Drug Design and Development

ABSTRACT

Molecular Docking is widely used in CADD (Computer-Aided Drug Designing), SBDD (Structure-Based Drug Designing) and LBDD (Ligand-Based Drug Designing). It is a method used to predict the binding orientation of one molecule with the other and used for any kind of molecule based on the interaction like, small drug molecule with its protein target, protein – protein binding or a DNA – protein binding. Docking is very much popular technique due to its reliable prediction properties. This book chapter will provide an overview of diverse docking methodologies present that are used in drug design and development. There will be discussion on several case studies, pertaining to each method, followed by advantages and disadvantages of the discussed methodology. It will typically aim professionals in the field of cheminformatics and bioinformatics, both in academia and in industry and aspiring scientists and students who want to take up this as a profession in the near future. We will conclude with our opinion on the effectiveness of this technology in the future of pharmaceutical industry.

1. INTRODUCTION

Computer aided drug designing or CADD, is a strategy that harnesses state of the art technology to expedite the drug development process. Traditionally the drug development /discovery (that includes random screening, serendipitous discovery and process optimization) takes nearly a decade to complete with an

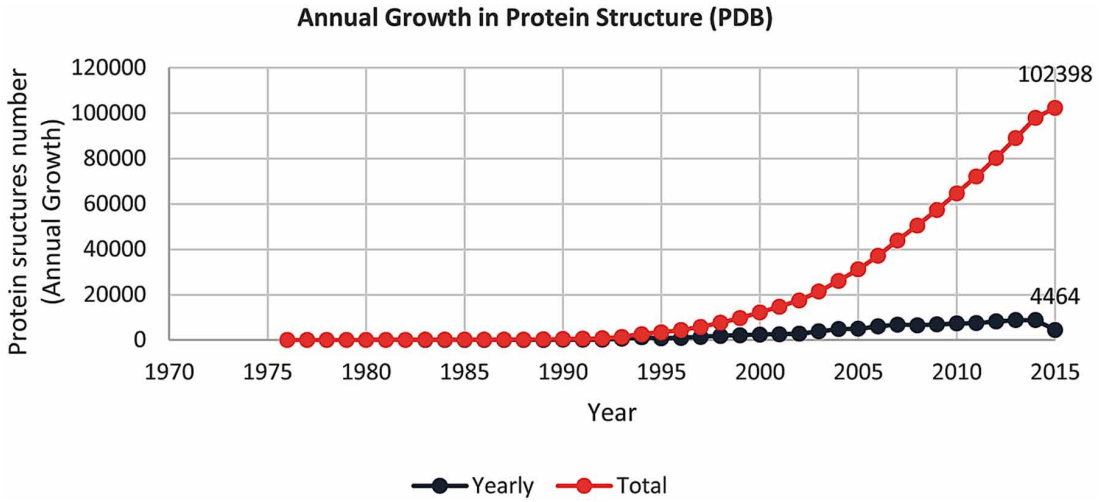
average expense of ~300 million dollar. CADD tends to curtail this expenditure and timeline by providing a holistic view of a drug discovery project and enables a SWOT (strength-weakness-opportunity-threat) analysis to evaluate the viability of the program.

Molecular docking is one of the fundamental pillars of CADD. It analyzes the binding interaction between a target protein and small molecules (Lengauer & Rarey, 1996). These small molecules also referred as ligands are the potential drug candidates that are being developed against the phenotypes and the therapeutic model for which the protein in the CADD is the target (Sliwoski, Kothiwale, Meiler, & Lowe, 2014).

2. HISTORY OF CADD



The evolution of CADD began in 1900s when Emiel Fischer (in 1894) and later Paul Ehlrich (in 1909) propagated the concept of receptors and lock and key mechanism (Fischer, 1894). Lock and key concept explains the interaction of a drug and its receptor. Just as there are innumerable pairs of lock and key, where each key inserts into a specific lock to open it, drugs are designed to be tailor made for a particular receptor. Depending on the perfection of the design, the drugs its binding capacity of the drugs with the receptor excels. But just as duplicate keys can be made for a single lock, which makes the lock vulnerable, there is a chance that multiple drugs can work on single receptor thereby giving rise to undue side effects. Additionally one drug can also interact with multiple receptors again giving rise to undue side effects. It was Paul Ehlrich, who proposed the concept of "magic bullet" the elusive drug that only bind to the chosen receptor thereby exhibiting no side effects (Elrich P, 1909,1957).

Figure 1. Flowsheet of the operations in CADD

Figure 2. PDB protein structure growth per annum graph that displays the number of searchable protein structures per year

Nearly 70 years later with the advent of quantitative structure activity relationship (QSAR), CADD took its next leap towards advancement. At that time only 2-dimentional medchem properties were considered and it was much later that the 3-dimentional properties came into the picture. Gradually, with the evolution of the concepts of molecular biology, protein X-ray crystallography (refer Figure 1) and multidimensional nuclear magnetic resonance spectroscopy (NMR), CADD too evolved into a more reliable and viable strategy in drug discovery.

Advancements in high performance computing, availability of 3-dimensional structure of important pharmaceutical targets, has opened new possibilities for computational drug design. An article in Fortune magazine entitled "Next Industrial Revolution: Designing Drugs by Computer at Merck" (Sliwoski et al., 2014; Van Drie, 2007) clearly postulated the beginning of a new era for drug discovery methods involving a bevy of computational approaches.

3. COMPUTER AIDED DRUG DESIGN (CADD)

Computer Aided Drug Designing (CADD) broadly focuses on two major verticals; 1) Ligand Based Drug Designing (LBDD) and 2) Structure Based Drug Designing (SBDD). These two methods depend on the information available about the protein structure and the ligands binding to them. Ligand based drug designing involved structure activity relationship studies where structure of the receptor (mostly proteins) is unknown. Ligands were tested for their activity and pharmacophore generation. Ligand based drug discovery propagates that similar ligands are assumed to bind to similar proteins and thus to have similar biological activities.

In general LBDD involved four major steps:

1. Prefiltering in virtual screening: it involves Lipinski's Rule of Five (Lipinski, 2004; Lipinski, Lombardo, Dominy, & Feeney, 2001) to find out compounds with drug likeliness features

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

   a. A molecular weight of less than 500 g/mol
   b. A calculated lipophilicity (log P) of less than 5
   c. Fewer than five H-bond donors
   d. Fewer than 10 H-bond acceptors
   e. Number of rotable bonds is less than 10 or one of the four rules can be violated.
2. *In silico* Absorption, Distribution, Metabolism, Elimination, and Toxicity (ADMET)
3. Similarity searches: achieved by following the principle of "similar structure- similar property"
4. Development of pharmacophore model by 3D structure alignment.

On the other hand SBDD or Structure based drug design is applied only when the 3D structure of the target of interest is known, either from X-ray crystallography, NMR spectroscopy or homology modeling. Here the known or predicted shape of the binding site is used to optimize the ligand to best fit the receptor. Existing algorithms for structure-based design can be categorized into two classes: *de novo design methods*, which builds ligands tailored to fit the target (Examples of *de novo* design include Lewis (Lewis et al., 1992) and Miranker (Miranker & Karplus, 1995) and the program LUDI (Böhm, 1992a, 1992b), and the *docking methods*, which searches for existing compounds with good complementarity to the target. In both the methods receptors are usually treated as a rigid body single conformation. There are two types of *de novo* design methods 1) *outside-in method* (Lewis & Leach, 1994), the binding sites is first analyzed to determine where specific functional groups might bind tightly. These groups were then connected together to transform into real molecules. 2) *inside-out approach* where molecules are allowed to grow inside binding site using appropriate search algorithm evaluating the each suggestion by energy functions.

4. MOLECULAR DOCKING

Molecular Docking is the central part of the structure based drug designing and is widely used for CADD applications. Fitting a ligand from a 3-D structure database into the binding site of a target protein is called docking. The docking process involves identification of "true" pose (conformation and orientation) of ligand inside receptor binding site and assessment of the binding affinity. Docking methods can be illustrated using a combined approach of search strategy and scoring function. Most docking methods generated large number of possible structures and hence require a parameter to rank the structure using scoring functions. The docking problem is linked with the generation and evaluation of structures of intermolecular complexes. To tackle docking problem, many algorithms has been developed. All the docking methods can be characterized by number of degree of freedom. An overview of docking programs is given in Table 1.

Before ligands can be docked against an enzyme or receptor, usually the binding site has to be discovered first. To minimize the search space on the receptor surface and thus minimize the degrees of freedom that has to be searched. This information can be obtained from crystal structures of ligand-bound receptors or can be predicted using binding site detection programs or online servers, e.g. GRID (Goodford, 1985; Kastenholz, Pastor, Cruciani, Haaksma, & Fox, 2000), POCKET (Levitt & Banaszak, 1992), SurfNet (Laskowski, 1995), PASS (Brady & Stouten, 2000) and MMC (Mezei, 2003). Binding site information significantly increases the docking efficiency. Generally, the largest cavity on a protein surface is considered as an active site, but this is not a universal fact.

5. TYPES OF MOLECULAR DOCKING

Based on conformational flexibility of the ligand, molecular docking can be either rigid, flexible can be divided into two sub categories rigid and flexible docking.

Rigid Docking is the simplest algorithm that considers both the receptor and ligand as rigid entities. It explores only six degrees of translational and rotational freedom. Rigid docking approaches were being used in the initial docking algorithms for docking small molecules into the binding sites of proteins and DNA. DOCK is an excellent example of rigid docking methods (Kuntz, Blaney, Oatley, Langridge, & Ferrin, 1982). It works on identifying the small molecules with high degree of shape complementarity to the receptor binding site. The DOCK algorithm uses a geometric matching algorithm to superimpose the ligand onto a negative image of the binding pocket. The receptor spheres generated inside the binding sites of the ligand atoms is viewed in a negative image of the active site, ligand shape can be identified by looking at the negative image of the active site. Rigid docking involved docking with rigid ligands and mostly used pre-generated ligand conformers. This reduced the computational burden however was not the best docking solution provider.

Flexible Docking can be done where either ligand or receptor is flexible or both are flexible. Generally the active site or the surrounding residues of the receptor active site are made flexible rather than the whole receptor. This is done because the docking takes place in the active site or nearby active site residues. Flexible docking strategies do not require any prior knowledge of the conformation of the ligand. Hence the search space consists of 6+N translational, rotational and conformational variables. Flexible docking is useful if there is no conformational information about the ligand. Four different strategies are applied, they are a) Monte Carlo; b) in-site combinatorial search; c) Ligand building; d) site mapping and fragment assembly.

Distance geometry can also be used to perform molecular docking, however incremental construction of the ligand within binding sites is used by a number of programs.in this method a series of conformations would be generated by systematically varying dihedral angles between 0° and 360°.This involves the grid search, where all base fragments were identified within the ligand. Base fragments will be docked into the binding site and clustered to remove duplicate orientations. Each docked orientation of the base fragment then represents the starting point for the conformational analysis of the rest of the ligand.

Genetic algorithms, molecular dynamics approaches can also be used to perform molecular docking. The ideal docking method would allow both ligand and receptor to explore their conformational degrees of freedom. However such calculations are computation intensive and are more useful for refinement of docked structures.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

6. SCORING FUNCTIONS

The binding of ligand and receptor are quantum mechanical in nature, but due to computational limitations and biological complexities quantum theories becomes impractical and are not always accurate. The strength of ligand receptor interaction can be measured experimentally and is often reported as the dissociation constant, K_d or by the concentration of ligand inhibiting activity by 50% (IC 50). Most of the methods attempt to estimate binding free energy of the ligand binding to receptor, which can be given by:

$$\Delta G_{\text{bind}} = \Delta G_{\text{complex}} - (\Delta G_{\text{ligand}} + \Delta G_{\text{receptor}}) \quad (1)$$

The relationship between the binding free energy ΔG and the experimentally determined K_d or IC_{50} is defined in Equation 2

$$\Delta G_{\text{bind}} = -RT \ln K_{\text{eq}} = -RT \ln K_d = -RT \ln 1/\text{IC50} \quad (2)$$

With Equation (2) it is possible to calculate the binding free energy where K_d is defined with respect to standard state (Atkins, De Paula, & Walters, 2006). The pressure,1 atm, and the activity of the solutions, namely 1M, define standard state.

Molecular docking have played an increasing role in the functional study of proteins and structure-based drug design with the increase in experimentally determined three-dimensional protein structures. However, one important problem is the development of scoring function that can heuristically and precisely describe the protein and ligand interaction. Scoring function plays major role in ascertaining three major applications. Firstly, defining the binding mode and ligand site on a protein. For a target molecule like protein, molecular docking generates numerous putative ligand binding orientations/conformations at the active site around the protein. A scoring function is used to rank these ligand orientations/conformations by evaluating the binding tightness of each of the putative complexes. Gold standard for scoring is to rank the experimentally determined binding mode most highly. Another application is linked to first application and it involves prediction of absolute binding affinity between protein and ligand, which is very much important for lead optimization. Lead optimization is used to improvise the binding of low-affinity hits or lead compounds. An idle scoring function can significantly increase the optimization efficiency and prevent costs of ligand synthesis and experimental testing. Structure-based drug design is another important application of scoring functions and is used to screen potential drug hits (leads) for a receptor (protein target) by searching a large ligand database this is also known as virtual screening. Scoring function is commonly used for ranking known binders most highly according to their binding scores during virtual screening (Huang, Grinter, & Zou, 2010).

Large number of poses are generated by docking algorithms, few got rejected because of high-energy clash with the protein. Scoring functions will be used further to assess the left out poses. Scoring function is required to rank the ligand molecules (if using database of molecules for screening against a receptor) relative to each other. Moreover, scoring functions are essential to identify the docked orientation that could be the real representation of 'true' structure of the intermolecular complex or docking mode.

Molecular docking is used to predict how a ligand will interact with the receptor binding site. The ligand is mostly a small molecule but can be a protein also. Likewise, receptor is mostly a protein of pharmacological significance however it could be a DNA or RNA molecule as well. The next step in docking is consists of scoring functions which will distinguish among the generated binding modes and

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

the optimal solution that is fairly matches to actual binding. The most promising predicted protein-ligand complex is considered to be the biologically relevant one. A large number of different scoring functions have been developed to model protein-small molecule docking which can be divided into three types or classes: 1) Force-field based 2) empirical and 3) knowledge-based scoring functions.

Force-field Scoring Functions: Force field (FF) based scoring tries to quantify internal ligand energy as well as ligand-receptor binding energy. Molecular mechanics force fields based scoring functions are based on different parameter sets, like AutoDock is based on the AMBER force field (Kitchen, Decornez, Furr, & Bajorath, 2004).

The ligand-receptor binding interactions can be best described by using van der Waals (VDW), electrostatic energy terms, bond stretching/bending/torsional energies, etc. Intermolecular forces are calculated using "6-12" Lennard-Jones potential functions representing van der Waals interactions however the interactions between atomic charges can be calculated using Coulomb's equation. Examples of force field based scoring functions include D-Score, G-Score, GOLD, AUTODOCK, DOCK. Following equations shows the use of distance-dependent dielectric constant ε (*rij*) force field scoring function in DOCK:

$$\Delta G_{bind} = \sum_{i}^{lig} \sum_{j}^{rec} \left[\frac{A_{ij}}{r_{ij}^{12}} - \frac{B_{ij}}{r_{ij}^{6}} + \frac{q_i q_j}{\varepsilon(r_{ij}) r_{ij}} \right] \tag{3}$$

where *rij* stands for the distance between protein atom *i* and ligand atom *j*, *Aij* and *Bij* are the VDW parameters, and *qi* and *qj* are the atomic charges. *ε* (*rij*) is usually set to *4rij*, reflecting the screening effect of water on electrostatic interactions.

Force field scoring functions is widely used but faces some challenges which involves the explanation of solvent effect and entropy effect.

Empirical Scoring Functions: Emperical scoring functions uses weighted energy terms to estimate the binding affinity of a complex. Ludi empirical scoring functions conceptualized that binding energies can be estimated by addition of individual unrelated terms.

These unrelated terms can be obtained from receptor-ligand crystal structure or training the binding constants of thousands of protein-ligand complexes. In empirical scoring function simple scalable contributions like hydrogen bonds, metal ligations, hydrophobic effect rotable bonds evaluated for estimating the energetics of ligand- receptor binding.

$$\Delta G_{bind} = \Delta G^{0} + \Delta G_{HB} \sum_{HB} f(\Delta r) f(\Delta 1\alpha) + \Delta G_{met} \sum_{met} f(\Delta r) + \Delta G_{lipo} \sum_{lipo} f(\Delta r) + \Delta G_{tot} N'_{rot} \tag{4}$$

Or it can also be given as,

$$\Delta G = \sum_{i} Wi \,.\Delta \mathrm{G_i} \tag{5}$$

In Equation 5 (Huang et al., 2010), ΔG_i represents different energy terms such as Van Der Waal energy, electrostatic energy, hydrogen bond, desolvation, entropy, hydrophobicity, etc. Here, *Wi* are determined by fitting the binding affinity data of a training set of protein–ligand complexes with known three-dimensional structures.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Because of their simple energy terms, empirical scoring functions are much more faster in binding score calculations compared to force field scoring functions.

LUDI, F-score, Chemscore, Score, x-score are some examples of empirical based scoring function.

Knowledge based scoring functions: Knowledge based scoring functions (also referred to as statistical-potential based scoring functions). Knowledge based scoring functions recruits energy potentials directly derived from structural information of experimentally determined atomic structures. Knowledge based scoring functions for protein- ligand complex are modelled using simple atomic interaction-pair potentials. This scoring functions is based on the potential of mean force, which is defined by the inverse Boltzmann relation. The GOLD fitness function is a measure of Chemscore or GOLD score, represented by $\sigma_{o,}$ which is measure of water contribution $\sigma_{1,}$

Is loss in the entropy of the water molecule and σ_w is the intrinsic binding affinity of the water.

$$\text{Fitness} = \sigma_o + \sum_w O\left(w\right)\left(\sigma \mathrm{p} + \sigma \mathrm{i}\left(w\right)\right) \tag{6}$$

Drugscore, ITScore, DFIRE, GOLD/ASP,Kscore, PMF and SMoG, BLEEP, MScore are examples of knowledge based scoring functions.

Compared to the force field and empirical scoring functions, the knowledge-based scoring functions provide more balanced option between precision and heuristics. Because the potentials in Equation (6) are extracted from the structures rather than from attempting to reproduce the known affinities by fitting, and because the training structural database can be large and diverse, the knowledge-based scoring functions are quite robust and relatively insensitive to the training set (Huang et al., 2010).

7. APPLICATIONS OF MOLECULAR DOCKING

Molecular docking has been one of the most extensively used technique in CADD (Computer Aided Drug Designing) and is the central dogma of Structure-Based Drug Designing (SBDD). SBDD is applied when the structure of target macromolecules generally, protein is known. The main aim of the SBDD is to identify the molecules which favorably interact with the target protein at its binding site. Molecular docking fulfills this objective by predicting the binding orientation of one molecule with the other in 3D space thereby identifying the lowest free energy complex structures. Another aim of the SB-CADD is the lead identification in the drug discovery process. In general, lead identification is done by two methods: High Throughput Screening (HTS) and Virtual High Throughput Screening (vHTS). HTS is the traditional technique which is slow and expensive compared to vHTS. In vHTS, a database containing large number of small molecules are screened against a protein target using molecular docking techniques and then ranked hits for lead generation. Previously, molecular docking was also used in SBDD pipeline for screening large compounds database and to identify the binding orientation with the target. With the advancement of the docking methodologies, presently molecular docking is used for various other applications viz. identification of differential binding of a ligand to different target biomacromolecules, de novo design for lead generation, adverse drug reaction prediction in the drug development and in some cases molecular docking is also used for non drug related projects like identification of putative pollutants for biodegradative enzymes. This exhibits the diversity of application of molecular docking.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

In the following section we will discuss major applications of molecular docking along with case studies.

7.1 Virtual Screening

Virtual screening is a tool to screen large compound libraries against a drug target that can be a protein or an enzyme or any other biomacromolecules. It is used to find the compounds from a large library which exhibited good binding interaction with the drug target. It is one of the most useful technique in the drug development process.

Case Study (Virtual Screening): Identification of BCR-ABL Tyrosine Kinase Hits Using Molecular Operating Environment (MOE) Software

In this case study (Rahul & Ashutosh, unpublished) we discuss how virtual screening is performed using MOE (Molecular Operating Environment (MOE), 2015). We screened an in-house database of ~2000 compounds against BCR-ABL tyrosine kinase, durg target for chronic myeloid leukemia (CML) treatment. The crystallographic co-ordinates of BCR-ABL is available on Protein Data bank (Berman et al., 2000) (PDB ID: 3OXZ, (Zhou et al., 2011)). The coordinates pdb file was downloaded and prepared using MOE Strucuture preparation wizard (Molecular Operating Environment (MOE), 2015). During struture prepration the hydrogens was added to the protein structure (Note: at times the pdb file has some missing side chains or missing residue which could be fixed by various tools like MOE (Molecular Operating Environment (MOE), 2015) or chimera (Pettersen et al., 2004)). Appropriate charges were added and water molecules which were more than 4.5 A^0 apart from the receptor were removed. Finally the energy was minimized using MMFF94x forcefield (Halgren, 1996) (There are various other force field are available like Amber (Cornell et al., 1995), OPLS (Jorgensen & Tirado-Rives, 1988), CHARMM (MacKerell et al., 1998) etc. with different versions here we are using the default).

In order to prepare the ligands the conformations of the 2000 compounds structure database were generated using MMFF94x forcefield (Halgren, 1996). A limit of 4.5 kcal/mol strain energy was imposed with a 500 conformation limit for each molecule. Duplicate conformations were removed with a heavy atom RMSD tolerance of 0.6 A^0 (0.75 A^0 for conformations with strain greater than 3.5 kcal/mol). The fact that a ligand was already bound at the active site of the protein, enabled us to define the active site. Next step involved generation of possible poses from the various ligand conformations. Diverse placement methods are available viz. Alpha Triangle, Alpha PMI, Flex, GOLD, Proxy Triangle, Template Forcing, Template Searching, Triangle Matcher. Here we used the default triangle matcher for the placement step. Next rescoring, refinement and again rescoring took place using London DG methods (other methods such as ASE, Affinity dG, Alpha HB, Electron Density, GBVI/WSA dG are also available). Further refinement is done using forcefield method and again rescoring was done using GBVI/WSA dG method. Finally 30 poses were kept and total 46,129 conformations were generated which were docked into the active site of BCR-ABL tyrosine kinase. MOE (Molecular Operating Environment (MOE), 2015) gave an output in form of a table having 10 fields which are depicted in Table 2 and the output of top 10 compounds on the basis of final score S was given in Table 3. These 10 compounds having score in order of (-9.2595) to (-8.8398) were obtained. All the top 10 compounds were docked into active site, the results are shown in Figure 3. These compounds could be used further for invitro assays.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

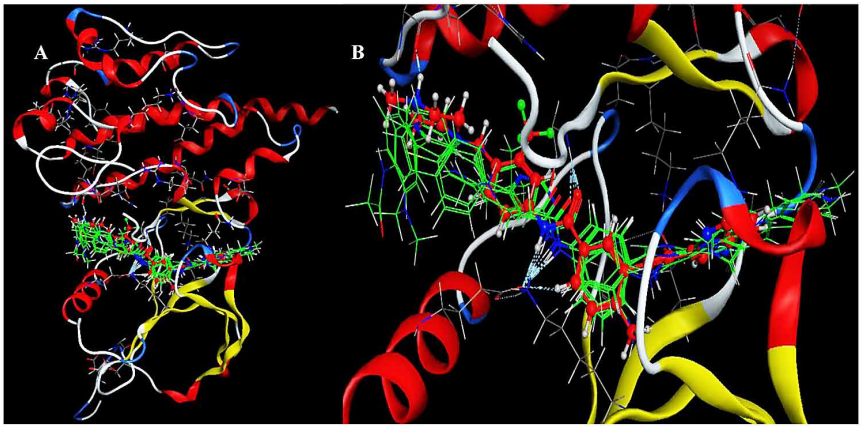

Table 2. Fields with description of MOE output (Molecular Operating Environment (MOE), 2015)

Field(s)	Description
Mol	An output pose.
receptor	The receptor after the refinement stage.
Rseq	The receptor sequence number.
Mseq	The molecule sequence number.
S	The final score, which is the score of the last stage that was not set to None.
Rmsd	The root mean square deviation of the pose, in Å, from the original ligand. This field is present if the site definition was identical to the ligand definition.
rmsd_refine	The root mean square deviation between the pose before refinement and the pose after refinement.
E_conf	The energy of the conformer. If there is a refinement stage, this is the energy calculated at the end of the refinement. Note that for Forcefield refinement, by default, this energy is calculated with the solvation option set to Born.
E_place	Score from the placement stage.
E_score1 E_score2	Score from rescoring stages 1 and 2.
E_refine	Score from the refinement stage, calculated to be the sum of the van der Waals electrostatics and solvation energies, under the Generalized Born solvation model (GB/VI).

Case Study (Virtual Screening): Identification of BRD4(1) Inhibitors Using Protein-Ligand Docking and Structure-Guided Design.

Bromodomains (BRDs) are recently discovered as a potential new drug targets for cancer, inflammation, diabetes and cardiovascular therapeutics. BRD-containing proteins choses epigenetics route for binding against acetylated lysines (KAc) on chromatin structures. Duffy et al., in 2015 employed a virtual screening & X-ray crystallography along with other cheminformatics techniques to identify several scaffold

Figure 3. 3D view of bound ligands with the BCR-ABL protein. A) Full view of the BCR-ABL protein with ligand. B) zoomed view of the ligands present into the active site of BCR-ABL protein. Red is the ligand already present in crystal structure while green are the top 10 compounds which are screened using docking studies.

clustershits binding to BRD4(1) (Duffy et al., 2015). Database of approx 25 million compounds from various publicly available sources were filtered on the basis of common drug-like property. Approximately 230,000 filtered compounds were selected through multiple rounds of random selections followed by diversity confirmation *via* 2-D atom-pair similarity calculations. These were docked against two X-ray crystal structures of BRD4(1) with different co-crystallized ligand using Glide (Richard A. Friesner et al., 2004). The binding pose was considered if potential hydrogen bond is present with the Asn140 sidechain amide, that mimics the native histone acetylated lysine binding location. Finally, 153 available compounds were selected on the basis of hydrogen bond requirements & Glide score. These compounds represented 82 scaffolds and were purchased from commercial vendors and evaluated in vitro screening. These 153 compounds were tested by HTRF binding inhibition to BRD4(1) and BRD2(2) at 50 μM concentrations. Compounds having 50% or more binding to BRD4(1) were submitted for dose-response testing and IC_{50} calculations, while hits in the 30–49% binding range at 50 μM were grouped by scaffold. The compound showing highest activity was retest for IC50 calculation and also co-crystallized in BRD4(1) to identify the actual binding pose. A small series of compounds analogs of the highest active compound were prepared and tested. The most active compound in this series, shows greater activity. The molecular docking with other experimental method process allowed to identify BRD4(1) inhibitors also helps in improving the activity of a compound in BRD4(1) inhibition.

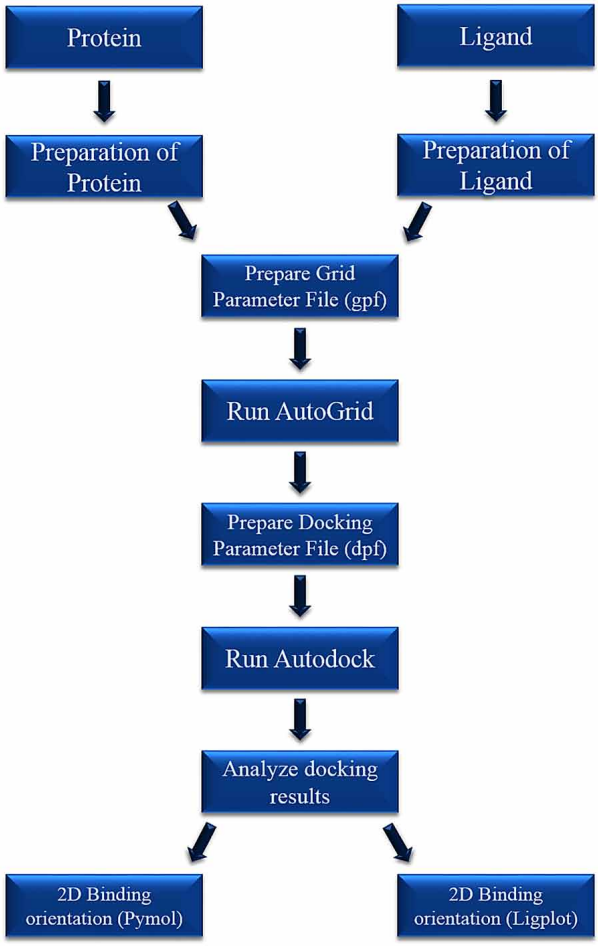
7.2 Identifying the Binding Orientation ('True' Pose) of Ligand with the Drug Target

Molecular docking can be used as a tool for virtual screening if screening against ligand database or if single or few ligands are searched for identification of true pose inside receptor binding site. This information is extremely advantageous to identify the binding sites or groups which are involved in binding. This will also help in designing the new potent compounds by knowing the binding pattern of the existing compounds. There are two steps involved in identifying the binding orientation of ligand withn the drug target. They are preparation of the protein and the liagnd and then the final docking. Preparation of the protien involves the searching the protein structure in PDB database for the availability of their crystal structure. If the protein crystal structure is not available then the protein structrue is modelled using bioinformatics methods. While the preparation of ligand involves the generation of energy minimized 3D structure of the lignad.

The docking depends on individual cases which is depicted below.

Case Study: True Pose Identification of Acarbose with α-Glucosidase Enzyme

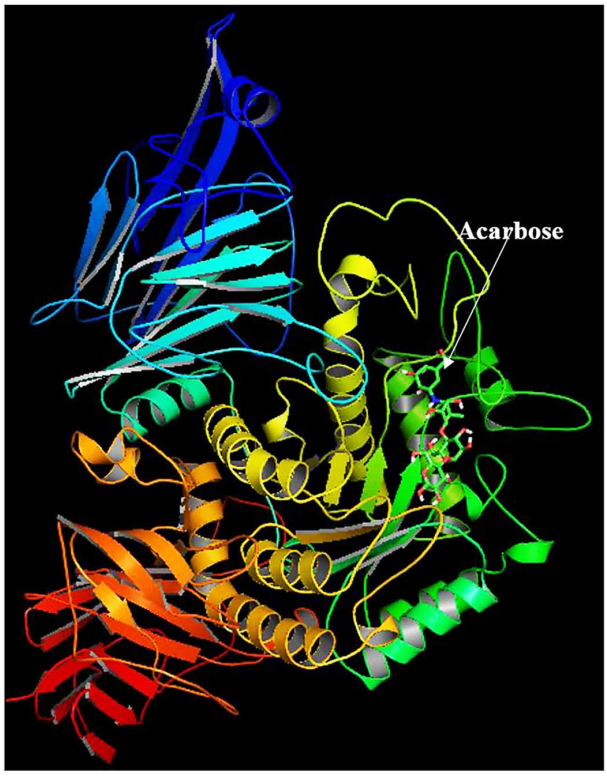
This study which was conducted in our lab (unpublished results), involved the step wise procedure to identify the binding orientation of Acarbose with α-Glucosidase enzyme. In this example α-Glucosidase protein model was built using I-Tasser (Yang et al., 2015) while docking analysis was done using Autodock (Morris et al., 2009). α-Glucosidase is a proven drug target for Diabetes. α-Glucosidase inhibitors decrease the absorption of carbohydrates from the digestive tract, thereby lowering the aftermeal glucose levels. Crystal structure of α-Glucosidase enzyme is not available on PDB (Berman et al., 2000). So, α-Glucosidase protein structure was modelled using bioinformatics methods. Modelling of the protein structure involved few steps and primarily depends on the identity of sequence similarity with the template sequence. Here we had 44% sequence identity with two human maltase-glucoamylase templates



EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

(PDBID: 2QLY and 3L4T) with query coverage 90% each. On this sequence identity we used threading method to model the protein. I-Tasser (Yang et al., 2015) was applied to model α-Glucosidase protein structure. The modelled protein structure was validated through ramachandran plot. Since there was no ligand bound to the protein we identified the active site residues in the protein structure *via* centroid co-ordinates of the complex ligands in the crystal structure (PDB ID: 3L4T). Finally docking was performed using Autodock program (Morris et al., 2009). It is one of the widely used freely available docking tool. The docking procedure for this molecule is shown in Figure 4.

After successful execution of autodock program docked log file (dlg) was generated in which the docked conformation co-ordinates of ligand with their binding energy were present. Total 10 docked conformation were obtained and the best conformation is having -4.45 Kcal/mol binding energy. This docked acarbose with protein target can be visulized using pymol (The PyMOL Molecular Graphics System) as shown in Figure 5 and save as complex pdb file. This complex pdb file is used to analyze the 2D and 3D binding orientation of Acarbose with protein using Ligplot as shown in Figure 6 & 7 resp.



The major limitation of this case study is the quality of the alpha-glucosidase protein structure because the whole docking is depends on the receptor structure. While performing docking studies using predicted structure one have to ensure that the modelled protein structure quality is upto the mark or not.

Figure 4. The procedure followed to perform this study

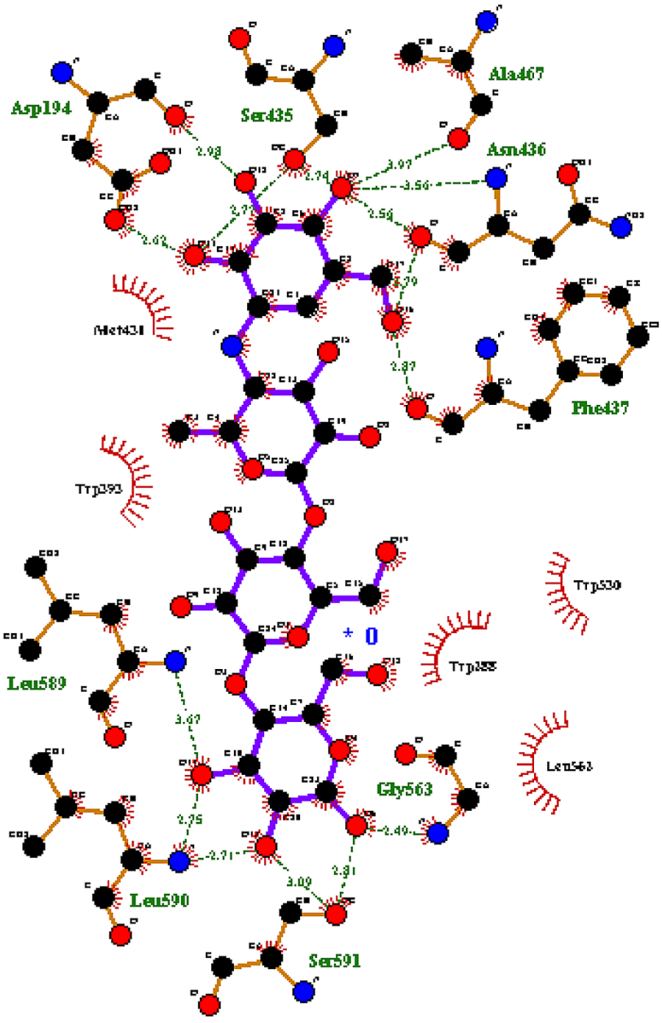
Figure 5. Full view of the Acarbose docked in the modelled alpha-glucosidase active site. Acarbose are shown as sticks model while the protein are shown as cartoons.
This image is viewed using Pymol (The PyMOL Molecular Graphics System).

7.3 Hydrated Docking



Hydrated docking involved docking of protein-ligand in presence of water molecules. Water molecules play an important role during protein-ligand interaction. Forli & Olson in 2012 developed a force field with discrete displaceable water and desolvation entropy for studying hydrated ligand docking (Forli & Olson, 2012). Autodock tool provided a script for implementing hydrated docking.

Case Study: Identification of Noncamptothecin Topoisomerase I (Top1) Inhibitors Using Hydrated Docking

Taliani et al. in 2013 used hydrated docking to identify the binding orientation of their noncamptothecin Topoisomerase I (Top1) inhibitors (Taliani et al., 2013). To begin with, the binding pose of HTOP1 (human topoisomerase 1) with inhibitor Topotecan (inform the readers about Topotecan) was observed from X-ray diffraction technique and Autodock docking method (Morris et al., 2009) (as shown in Figure 8 below). Here, hydrated docking between HTop1 and Topotecan provided useful information about the binding pattern of the compound in presence of water molecules. This information was used to design novel compounds with diverse architectures that resulted in the improvement of Top1 inhibitory activity.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 6. 2D interaction of modelled alpha glucosidase with the Acarbose inhibitor. Acarbose is majorilly interacted with Asp194, Ser435, Asn436, Phe437, Ala467, Gly563, Leu589, Leu590, Ser591.
Image is created by Ligplot (Wallace, Laskowski, & Thornton, 1995).

The problem with hydrated docking is the difficulty in comparing the results with the crystal complex having water interactions which is not able to distiguish whether water is really involved or it is apart of crystal effect.

7.4 Reverse Docking

Reverse docking is a technique that identified the target proteins of known biological active compounds. In this method small compounds or ligands are docked into the active sites of multiple drug targets, their binding orientation were analysed and ranked on the basis of their binding interaction strength. It is very useful when target information is unknown.

Case Study: Identification of Targets which are binding to Dioscin

Recently Yen et al. described a workflow in which they coupled reverse docking with other bioinformatics methods to predict drug targets, biological activities, signal pathway and regulating networks of Dioscin that could be implemented on other available biological active compounds (Yin et al., 2015). Dioscin is a natural steroidal saponin present in many Chinese medical herbs (like, Dioscorea nipponica Makino, Dioscorea zingiberensis) and known to posses many medical pharmacological properties including anti-tumor, anti-hyperlipidemic, anti-fungal and antivirus activities. Yen et al. screened the available potential protein targets from humans (71), rats (7) and mice (8). The reverse docking indicated that most probable targets of dioscin were cyclin A2, calmodulin, hemoglobin subunit beta, DNA topoisomerase I, DNA polymerase lambda, nitric oxide synthase and UDP-N-acetylhexosamine pyrophosphorylase, etc. The workflow used by (Yin et al., 2015) is depictedin Figure 9.

7.5 Adverse Drug Reaction Prediction

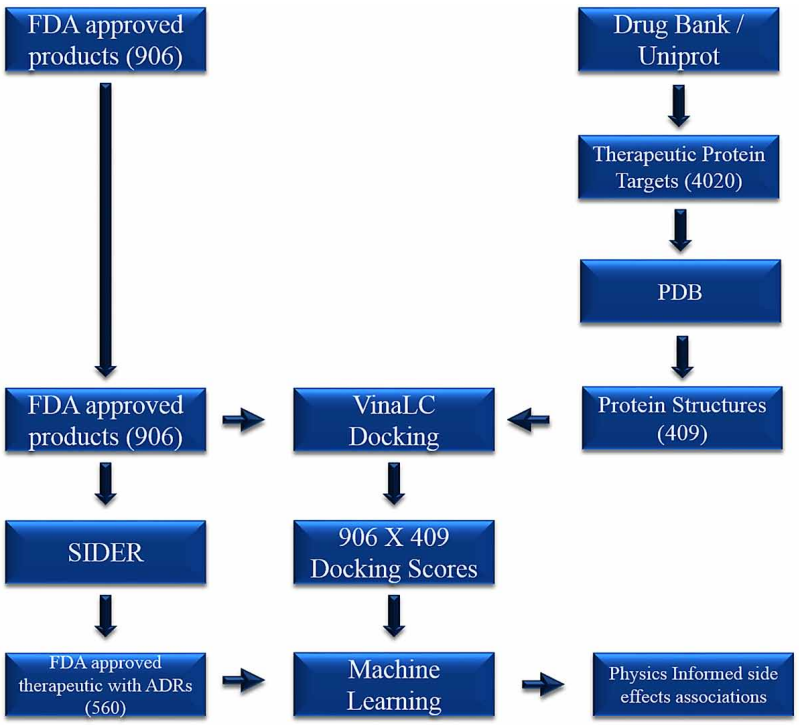
Prediction of Adverse drug reactions (ADRs) is essential for a pharmacologically active small molecules because adverse drug reaction produces effect which could be extremely harmful,unusual and could alter

Figure 9. The analysis process of the prediction of drug targets, biological activities, signal pathway and regulating networks
Source:(Yin et al., 2015).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

the biochemical pathways (LaBute et al., 2014). Nearly hundred thousand fatalities are reported in US every year because of ADRs. Prediction of adverse drug reactions (ADRs) by lead compounds is very useful in drug discovery process.

Case Study: Adverse Drug Reaction Prediction Workflow



In 2014, LaBute et al. developed a computation process that enabled prediction of ADRs using molecular docking and known ADR information from DrugBank and SIDER. The workflow is shown in Figure 10.

The drug target information were obtained from Uniprot (Consortium, 2015). Nearly four thousand proteins were identified and extensive search of their crystal structure led to the discovery of 409 of them in Protein Data Bank (PDB) (Berman et al., 2000). They were used as a virtual panel. All 906 FDA-approved drugs (till date) were docked in this virtual panel using the VinaLC program (Zhang, Wong, & Lightstone, 2013). Side effect of 560 compounds were present in SIDER database which were used for building logistic regression models for ADR prediction.

This type of study immensely helped in drug development process by which the lead ADRs is accessed at earlier stage of drug discovery and could be dropped or redesigned.

This study depends on the machine learning methods which may provide various false positives and false negatives.

Figure 10. Data integration/analysis workflow scheme

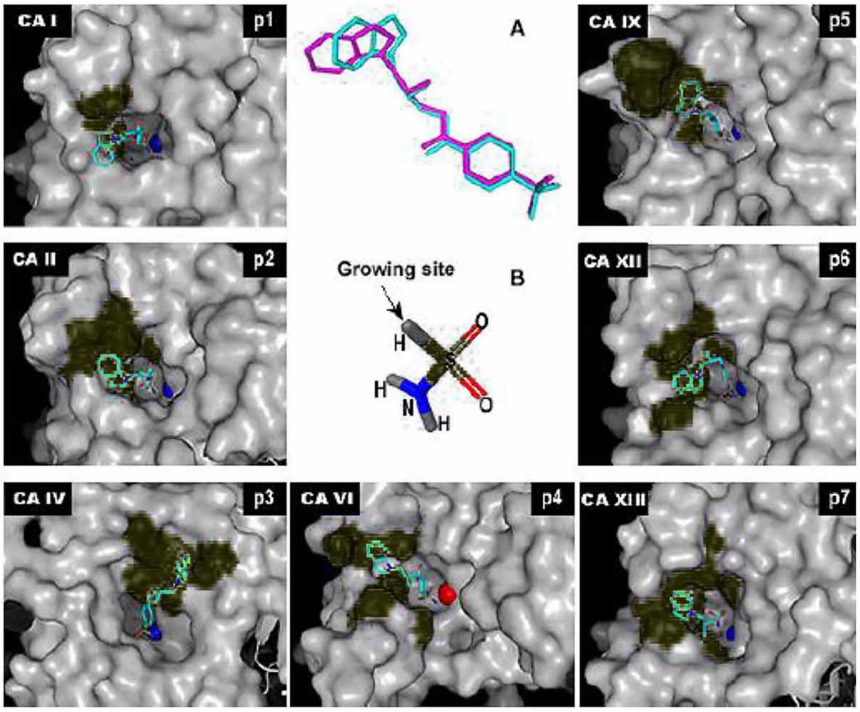
7.6 De-Novo Drug Design

De novo drug design is generally used to generate new drug-like compounds by linking fragments. De novo design uses library of building blocks that also contain single atoms, functional groups, and small molecular fragments. De novo drug design is widely used in the drug development process to generate new novel and potent compounds by using the drug target active site information.

Case Study: De Nove Design



Xiang et al. used this approach to discover the isozyme-selective inhibitor scaffolds of human carbonic anhydrases (CAs) (Xiang, Xiang, Fang, Zhang, & Li, 2014). CAs are known drug targets for the treatment or prevention of disease like altitude sickness, epilepsy, glaucoma, obesity, tumor, acid–base disequilibria, and other neuromuscular diseases. Experimental procedure included the alignment of available 9 PDB structures of CAs where one of them was complexed with SBR ((R)-N-(3-indol-1-yl-2-methyl-propyl)-4-sulfamoyl-benzamide). The ligand (SBR) was docked to all 9 structures using Autodock Vina (Trott & Olson, 2010). POCKET module of LigBuilder (Yuan, Pei, & Lai, 2011) was used to identify the interaction residues and molecules were constructed for the target protein using GROW module. GROW module required a seed structure on which fragments were added to generated new hit compounds. Figure 11 depicted the interaction of SBR ligand with different CAs and seed struture with growing site. Total 200 top candidates were selected after Lipinski filter of maximal molecular weight and logP value being 500 and 5, respectively. Further top hits having multiple rings were used for further docking analysis. These four molecules are naphthalenesulfonamide, N-sulfonamide-phthalimide, 3-sulfonamide-acridan, and fluorenesulfonamide derivatives, these scaffold structures can be the potential isozyme-selective inhibitors against CA II, IV, and IX.

8. CHALLENGES OF MOLECULAR DOCKING

Identification of binding pattern between proteins and small molecules face substantial challenges. Majority of the docking programs are sensitive enough to predict known protein bound poses with averaged accuracies close to about 1.5–2 Å and with reported success rates in the range of 70 – 80%. However, significant improvement beyond this range seems for now unachievable. One of the fundamental challenges are scoring in which various assumptions are used in order to make calculations computationally more efficient but by using these assumptions, some very important aspects of molecular recognition like solvent effect and entropy effect got neglected. Along with this the incorporation of water molecules in the active site having interaction with ligand and receptor is also a challenge. Molecular docking process also facing limitations on the availability of the crystallographic structure of the protein. Besides all these limitations and challenges molecular docking is still a method of choice and widelly used for the prediction of ligand-receptor pose.

9. CONCLUSION

Herein we have provided a complete overview of diverse docking methodologies that are used in drug design and development. Our discussion typically aimed at professionals in the field of cheminformatics and bioinformatics, both in academia and in industry and aspiring scientists and students who want to take up this as a profession in the near future. We discussed several case studies, pertaining to each method. In few cases we provided step wise information to conduct the experiments. This discussion highlighted various application of molecular docking in drug discovery. We apprehend that in the years to come molecular docking in conjunction with variety of state of the art techniques *viz.* molecular biology, computer graphics and protein x-ray crystallography will be an indispensable tool in drug discovery.

Chapter 27
Molecular-Docking-Based Anti-Allergic Drug Design

Anamika Basu
Gurudas College, India

Piyali Basak
Jadavpur University, India

Anasua Sarkar
Jadavpur University, India

ABSTRACT

Allergens are foreign proteins that when come in contact of part(s) of human body stimulate the production of immunoglobulin types of proteins (antibodies). These allergens react with antibodies (immunoglobulin type E or IgE) produces allergic reactions, also known as immediate-type hypersensitivity reactions. As much as 20% of the general population may be affected by grass pollen as a major cause of allergic disease. EXPB class of proteins are known in the immunological literature as group-1 grass pollen allergens Molecular docking method can be used to identify the predicated the interaction of pollen allergen EXPB1 (Zea m 1), a beta-expansin and group-1 pollen allergen from maize with IgE molecules of human. The World Health Organization recognised allergen immunotherapy, as therapeutics for allergic diseases. RNA Interference (RNAi) is a biological process in which RNA molecules e.g. Small Interfering RNAs (siRNAs) inhibit gene expression, by cleavage and destruction of specific mRNA molecules. Use of Small Interfering RNA (siRNA) is a novel method in the induction of RNA Interference (RNAi), which is a potent method for therapeutics of allergic reactions. Due to various effects of STAT 6 proteins during hypersensitivity reactions caused by pollen allergens, mRNA of STAT6 gene is selected as target gene for allergy therapeutics via Post-Transcriptional Gene Silencing (PTGS). Using molecular docking study a specific sense siRNA is identified as anti allergic drug to treat allergic asthma during immediate type of hypersensitivity reaction, caused by Zea m 1 pollen allergen.

INTRODUCTION

Allergens are foreign proteins that when come in contact of part(s) of human body stimulate the production of immunoglobulin types of proteins (antibodies). These allergens react with antibodies (immunoglobulin type E or IgE) produces allergic reactions, also known as immediate-type hypersensitivity reactions (Kay, 2008). As much as 20% of the general population may be affected by grass pollen as a major cause of allergic disease. An evolutionary conserved protein in plant developmental biology, expansins play an important role in cell wall expansion by slippage or rearrangement of matrix polymers during plant cell growth (Basu, 2013). But among the four classes of expansin protein family, EXPB class of proteins are known in the immunological literature as group-1 grass pollen allergens (Anderson, 2003). These EXPBs proteins cause hay fever and seasonal asthma in humans (Ball, 2005). Allergy symptoms are caused by these proteins when these allergens come into contact with the moist surface of the human respiratory tract (Knox, 1996). Molecular docking method can be used to identify the predicated the interaction of pollen allergen EXPB1 (Zea m 1), a beta-expansin and group-1 pollen allergen from maize with IgE molecules of human. Antibodies, expressed on the surface of B –cell of human immune system, recognize antigenic determinants, also called epitopes on their antigen. The interacting part of the antibody involved in the antigen-antibody interaction, is called the paratope (Stave, 2013). Paratope is formed in combination of different amino acids in the complementarity Determining Regions (CDRs) of antibody or immunoglobulin (Collis, 2003).

At present drugs such as antihistamines, leukotriene receptor antagonists, and corticosteroids are used for symptomatic treatment, but they do not prevent the allergic response (Natt, 2011). The World Health Organization recognised allergen immunotherapy, as therapeutic vaccines for allergic diseases, also known as desensitisation or hyposensitisation. The use of chemically altered allergens, allergoids, recombinant allergens, and relevant T-cell epitope peptides are some common approaches for immunotherapy.RNA interference (RNAi) is a biological process in which RNA molecules e.g. small interfering RNAs (siRNAs) and microRNAs (miRNAs) inhibit gene expression, by cleavage and destruction of specific mRNA molecules. Small interfering RNAs (siRNAs) are 21-25 nucleotide single-stranded RNAs containing 2 nucleotide 3′ overhangs produced by cleavage of longer double-stranded RNAs by the enzyme Dicer. After cleavage by Dicer the 21-25 nucleotide double-stranded product is loaded into an Argonuate protein (humans contain 4 Argonautes) and rendered single-stranded.

Small interfering RNAs (siRNAs) can regulate eukaryotic gene expression when transcribed endogenously or preformed, synthetic siRNA introduced into cells. Among two strands of siRNA, the guide strand pairs with a complementary sequence in a messenger RNA molecule and induces cleavage of mRNA molecule with the help of catalytic component of the RNA-induced silencing complex (RISC) complex. The siRNA component guides RISC to mRNA molecules containing a homologous antisense sequence, resulting in cleavage and degradation of that mRNA. RISC is composed of dicer protein, the double-stranded RNA binding protein TAR RNA Binding Protein (TRBP), and Argonaute2 (AGO2) and does not required ATP for its activity. Dicer protein converts long double-stranded RNAs into siRNAs by the endonuclease activity and Argonaute protein performs the cleavage of the mRNA. At first the process of RNA interference is initiated through Dicer protein by converting double-stranded RNA into small interfering RNA (siRNA). Then the siRNA guide strand after binding with the Argonaute protein in RISC recognizes its complementary sequence in mRNA and targets mRNA for its cleavage.

RNA interference or RNA silencing occurs due to endonucleolytic cleavage of the mRNA specifically by AGO2 protein, when RISC complex binds with a perfectly complementary mRNA (Kandeel, 2013).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

The 'minimal RISC' complex composed of AGO2 bound to a short interfering RNA (siRNA). Among two domains of AGO2, The PIWI domain may perform RNA cleavage by a mechanism similar to that of RNase H and the PAZ domain is an RNA-binding module (Song, 2003). It has been already established that PAZ domain of AGO2 protein in RISC anchors the 2-nucleotide 3'-overhang of the siRNA duplex causing two types of effects (Lingel, 2004). The first effect is the binding the 7-nucleotide phosphodiester backbone of the overhang-containing strand and the second one is the capping the 5'-terminal residue of the complementary strand in a sequence-independent manner. In RISC, PAZ acts as an anchoring site for the 3'-end of guide RNA within silencing effector complexes. Similarly the PAZ domain of AGO2 serves as a siRNA-end-binding module for siRNA transfer in the RNA interference method.

Use of small interfering RNA (siRNA) is a novel method in the induction of RNA interference (RNAi), which is a potent method for therapeutics of allergic reactions (Bantounas, 2004). Effect on human immune system can be modulated by siRNAs in immunotherapy of pollen allergen Zea m1. Structures of Zea m1 allergen (PDB ID 2HCZ), human immunoglobulin E (PDB ID 4J4P) and human Argonaute2 protein (PDB ID 4OLA) have been extracted from RCSB PDB web server. Protein- protein molecular docking between pollen allergen Zea m 1 and human immunoglobulin E was done using PatchDock protein- protein docking server. In our present work we propose a strategy for vaccine preparation for Plant pollen allergen Zea m 1 by RNA Interference by using In Silico approaches such as molecular docking and designing siRNA. Analyzing the docking results for pollen allergen Zea m1 with human immunoglobulin E protein, we can identify the paratopes present in that specific antibody, which is essential for preparation of vaccine for that pollen allergen. Findings from the molecular docking study of AGO2 protein with siRNAs would help us to guide the future design of modified siRNA analogues as anti allergic drug in immunotherapy of pollen allergen Zea m 1.

BACKGROUND

Zea m 1 as Pollen Allergen

Allergens from various sources (e.g. pollen, house dust mites, pets, moulds, food and insects) and are mainly proteins or glycoproteins (Valenta, 2008). When allergen comes in contact to human body the production of allergen-specific IgE antibodies increases and that bind to their receptors on immune cells. That binding causes allergic inflammatory response. Cross-linking of IgE antibodies that are bound to the high-affinity receptors for IgE (i.e. FcεRI) on mast cells and basophils causes degranulation within a few minutes.The release of inflammatory mediators, proteases and pro-inflammatory cytokines after degranulation is known as immediate hypersensitivity reaction and that is the cause for the majority of allergic symptoms.

Inhaled pollen allergens encounter antigen presenting cells (APC) that are present in the lining of respiratory tract. After recognition as antigen allergenic proteins are presented by APC, leads to cell differentiation of naive T cells into TH2 cells. Activated TH2 stimulate the formation of IgE by B cells. IgE molecules bind to IgE receptors located on mast cells. The cross linking of mast-cell-bound IgE by allergens leads to the release of biologically active mediators (histamine, leukotrienes) by means of degranulation and, so, to the immediate symptoms of allergy as shown in Figure 1. Mast cells also release chemotactic factors that contribute to the recruitment of inflammatory cells, particularly eosinophils, whose proliferation and differentiation from bone marrow progenitors is promoted by IL-5.There are

several other protein factors are involved in airflow obstruction, bronchial hyperresponsiveness, and airway inflammation.These are some important symptoms of immediate type of hypersensitivity reaction, caused by pollen allergens.

Molecular docking study with Zea m1 allergen (PDB ID 2HCZ) and human immunoglobulin E (PDB ID 4J4P) using PatchDock web server (Duhovny 2002; Schneidman-Duhovny, 2005) with clustering RMSD 4.0 and score 10504 is shown in Figure 3. PatchDock is an algorithm for molecular docking. The algorithm has three major stages:

- Molecular Shape Representation

Figure 3. Molecular docking structure of Zea m1 with human IgE

- Surface Patch Matching
- Filtering and Scoring

After refinement of docking results with FireDock web server (Andrusier, 2007; Mashiach, 2008) the following figure is obtained as shown in figure 4. The FireDock web server solves the refinement problem of protein-protein docking solutions. The method simultaneously targets the problem of flexibility and scoring of solutions produced by fast rigid-body docking algorithms. Here the candidate solutions for FireDock are generated by rigid-body docking method, such as PatchDock as shown in table 2. Each result from PatchDock is subsequently refined by restricted interface side-chain rearrangement and by soft rigid-body optimization. The side-chain flexibility is modelled by rotamers and the obtained combinatorial optimization problem is solved by integer linear programming. Following rearrangement of the side-chains, the relative position of the docking partners is refined by Monte Carlo minimization of the binding score function. The refined candidates are ranked by the binding score. The binding free energy is the change in the free energy of the system, which occurs upon complex formation, which combines the free energy of the receptor-ligand complex and the free energies of the uncomplexed receptor and ligand, respectively. The desolvation free energy is estimated by the ACE potential. The electrostatic contribution is approximately calculated by the atomic pair-wise partial Coulomb energy. The torsion energy, contributions of the hydrogen bonds, disulfide bonds, van der Waals interactions and Π-Stacking and aliphatic interactions are also considered to calculate binding score (Andrusier,2007). Interacting amino acid Thr 12 of Zea m1 with heavy and light chains of human immunoglobulin E are shown in Figure 4. Molecular docking result proves that Zea m 1 allergen binds with human IgE and causes immediate-type hypersensitivity reaction and allergic symptoms.

- **Attractive and Repulsive VdW:** The contribution of the van der Waals forces to the global binding energy.
- **ACE:** The contribution of the atomic contact energy (ACE) to the global binding energy. The ACE (Atomic Contact Energy) function is a statistical contact potential for all (non-hydrogen) atom pairs less than 6 Å apart,
- **HB:** The contribution of the hydrogen bonds to the global binding energy.

Antiallergic Drug Design for Pollen Allergen Zea m 1

Compounds, Histamine, Prostaglandins and Leukotrienes are involved in allergic reactions in human as shown in Figure 2. Nowadays drugs such as antihistamines, leukotriene receptor antagonists, and corticosteroids are used for symptomatic treatment, but they do not prevent the allergic response. In order to eradicate allergic reaction due to any allergen, allergen specific immunotherapy can be applied. Allergen-specific immunotherapy is based on the repeated lower dose administration of disease-causing allergens to modify the allergen-specific immune response in patients so that higher doses of the allergen can be tolerated during hyper sensitivity reaction. (Valenta, 2012) reviewed several approaches for

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

allergen specific immunotherapy using T-cell epitope-containing peptides, Recombinant hypoallergens and chemically modified allergens. In first method allergen-derived synthetic peptides containing T-cell epitopes are used to treat sensitivity reactions. Because these peptides which are synthesized from linear sequences of small allergen fragments, that are epitopes of T cells. These peptides can bind with the receptor of allergen-specific T cells and show no reactivity with IgE antibodies of B cells. The T-cell epitope-containing peptides can be used to reduce the IgE-mediated allergic reactions for that allergen. In second method recombinant hypoallergenic allergens, developed in Escherichia coli, by introducing mutations into the allergen sequence, are used to reduce IgE reactivity. Combination of allergens with DNA sequences containing CpG motifs as immunomodulatory components are used to activate the innate immune system through toll-like receptors (TLRs).This method is applied to inhibit Th2 immune responses and finally later stages of hypersensitivity reaction.

RNA interference (RNAi) technologies (Ball, 2004) are very new approach in the development of allergy therapeutics via post-transcriptional gene silencing (PTGS). From one mRNA molecule about 5,000 copies of that protein can be produced. So, it is a wise decision to target mRNA molecules related to allergic reaction rather than blocking different proteins involved in hypersensitivity reactions. (Popescu, 2005) identified different types of protein molecules as target for potential anti-mRNA drugs in asthma and other allergic disorders. They are shown in Table 2.

Miller et al (1998) suggested that the regulation of class switching to IgE by cytokines is mediated by STAT transcription factors, by analyzing the cytokine signalling in patients with extrinsic asthma and hyper immunoglobulin E. IgE production in asthma and hyper immunoglobulin E usually is associated with elevated levels of IL-4in the peripheral blood. The protein encoded by STAT6 is a member of the STAT family of transcription factors. In response to cytokines and growth factors, STAT family members are phosphorylated by the receptor associated kinases, and then form homo- or heterodimers that translocate to the cell nucleus where they act as transcription activators. This protein plays a central role in exerting IL4 mediated biological responses. Walford and Doherty (2013) elaborately discussed about the various functions of STAT6 protein, which play crucial roles in the pathogenesis of allergen-induced airway inflammation, mucus production, and airway hyper responsiveness (AHR). In asthma patients different structural cells (airway epithelium, smooth muscle, and fibroblasts) and immune cells

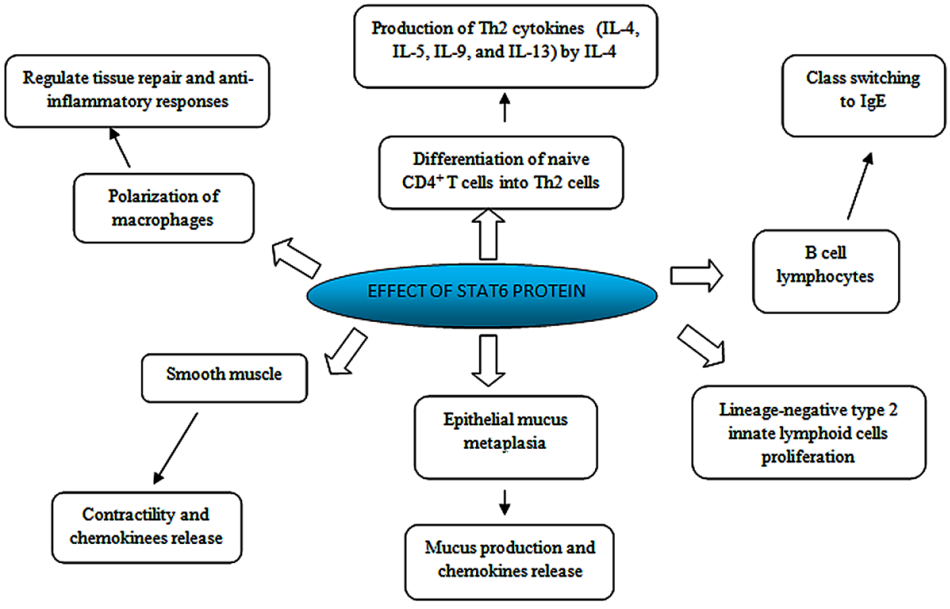
Table 2. Different types of protein molecules as target for potential anti-mRNA drugs in asthma and other allergic disorders

Serial Number	Type of Protein Molecule	Examples
1.	Cell surface receptors	adenosine A1 receptor, high-affinity receptor Fc-ε RI-α, cytokine receptors
2.	Adhesion molecules and ligands	ICAM-1, VLA-4
3.	Ion channels	calcium-dependent chloride channel-1
4.	Cytokines and related factors	IL-4, IL-5, IL-13, SCF, TNF-α, TGF-β1
6.	Intracellular signal transduction molecules	tyrosine-protein kinases (Syk, Lyn, Btk),
7.	Serine/threonine-protein kinases	p38 α MAP kinase, Raf-1
8.	Non-kinase signaling proteins	RasGRP4
9.	Transcription factors involved in Th2 differentiation and allergic inflammation	STAT-6, GATA-3, NF-κB

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

(B and T cells, macrophages, dendritic cells, and innate lymphoid cells) are involved in many pathological conditions e.g. Th2 cell differentiation and production of cytokines (IL-4, IL-5, IL-9, and IL-13), IgE production from B cells, airway eosinophilia, epithelial mucus production, change in contractility of smooth muscle. Effects of STAT6 protein on different types of cell are summarized in Figure 5.

Due to various effects of STAT 6 proteins during hypersensitivity reactions caused by pollen allergens, mRNA of STAT6 gene is selected as target gene for allergy therapeutics via post-transcriptional gene silencing (PTGS). For drug designing using siRNA for STAT6 mRNA, following steps are performed:



- Search for siRNA for signal transducer and activator of transcription 6, interleukin-4 induced (STAT6) for human.
- Comparative modelling of siRNA 3D structures.
- Secondary structure determination of siRNAs.

Search result for siRNA for signal transducer and activator of transcription 6, interleukin-4 induced (STAT6) for human in NCBI, shows six siRNA sequences as shown in Table 3.

Using ModeRNA (Rother, 2011) a program for comparative modelling of RNA 3D structures, three dimensional structure for all six siRNAs can be elucidated. But this program requires a pairwise sequence alignment and a structural template to generate a 3D structural model of the target RNA sequence. But template finding results for those six siRNAs show that only fifth and sixth sequences have structural templates with PDB Ids (shown in Table 4) and their models were built using ModeRNA server (Rother, 2011).

Secondary structure determination of Probe|16741853| sense and antisense siRNAs was carried out using RNAstructure, Version 5.7 (Mathews, 2014) which is a complete package for RNA secondary structure prediction and analysis including facility to predict base pairing probabilities. Results from

RNAstructure for Probe|16741853|SIRNA_SENSE siRNA sense sequence (without overhang) and Probe|16741853|SIRNA_ANTISENSE siRNA antisense sequence (without overhang) shown in Figure 6. Predicted 3D secondary structures of two siRNAs can be visualized as shown in Figure 7 by using UCSF Chimera software (Petersen, 2004). UCSF Chimera is a highly extensible program for interactive visualization and analysis of molecular structures and related data e.g. molecular docking results.

Since the 'minimal RISC' complex composed of AGO2 bound to a short interfering RNA (siRNA), a docking server for nucleic acid and protein was identified. NPDock (Nucleic acid-Protein Dock) is a web server (Tuszyńska, 2015) for modelling of RNA-protein complex structures. It combines (1) GRAMM for global macromolecular docking, (2) scoring with a statistical potential, (3) clustering of best-scored structures, and (4) local refinement. PDB files for sense and antisense siRNA obtained from RNAstructure (Mathews, 2014) and AGO2 (PDB ID 4OLA) were used as input files. Using NPDock web server (Tuszyńska, 2015) 'minimal RISC' structures for sense and antisense siRNAs with AGO2 proteins are built and visualized by UCSF Chimera software (Petersen, 2004) as shown in Figure 8 where sense and antisense siRNA were shown in green colour. The distance and orientation-dependent knowledge-based potentials (DARS-RNP and QUASI-RNP) were generated for both sense and antisense RNAs when bound with AGO2 protein using reverse Boltzmann statistics.

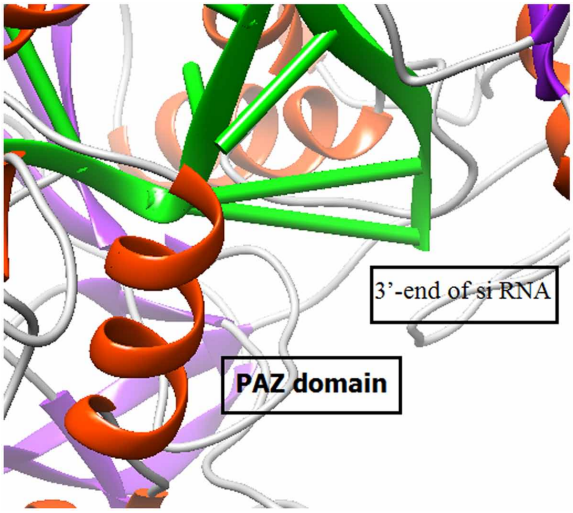

Figure 8. Binding structures of siRNAs with AGO2. a. For sense strand b. For antisense strand.

From the best scored docking results, after visualizing with UCSF chimera software (Petersen, 2004), it can be concluded that both sense and antisense siRNA strands bind with PIWI domain of AGO2. PIWI domain is present in AGO2 protein from 517-818 amino acids sequence. Since binding energy score was more negative for sense siRNA, so it has been selected among two binding structures for sense and antisense siRNAs with AGO2 protein.

In RISC, PAZ acts as an anchoring site for the 3'-end of guide RNA within silencing effecter complexes. For sense siRNA the 'minimal RISC' complex composed of AGO2 bound to a siRNA as shown in Figure 9 where PAZ domain of AGO2 protein shown in red and sense siRNA in green.

STAT6 Gene as Target Gene for Allergy Therapeutics

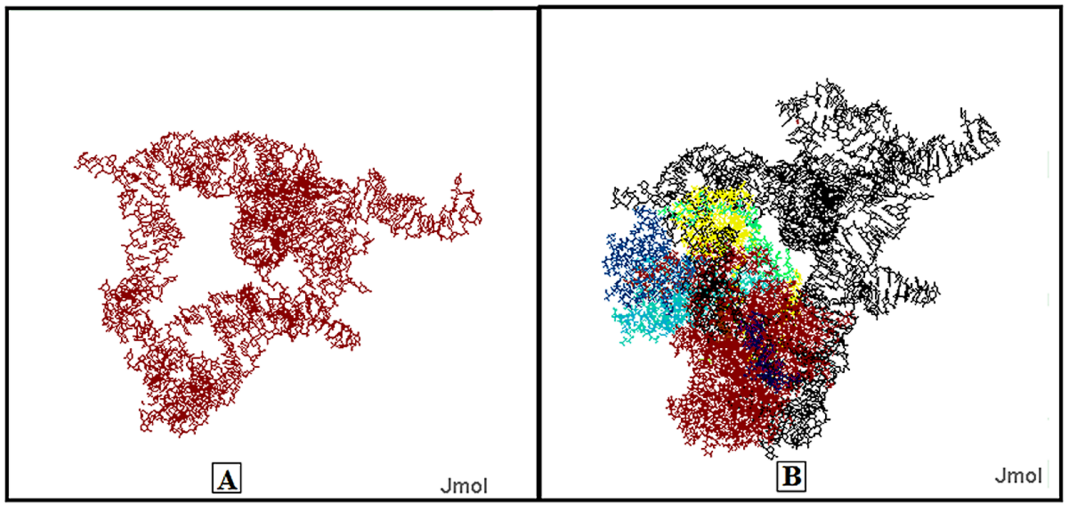
After retrieving gene sequence from NCBI for Homo sapiens STAT6 mRNA for signal transducer and activator of transcription 6 nirs variant 2, complete cds (GenBank Accession number AB103089.1) containing 2022 bp, mRNA sequence was obtained from Transcription and Translation Tool (www.attotron.com/cybertory/analysis/trans.htm). From RNAfold web server (Gruber, 2008), which can predict secondary structures of single stranded RNA sequences, Minimum free energy (MFE) secondary structure of that mRNA molecule was built. The MFE structure of an RNA sequence is the secondary structure that contributes a minimum of free energy (Zuker, 1981). The optimal secondary structure of STAT6 mRNA for human was modelled with minimum free energy -1584.20 kcal.mol using RNAfold web server (Gruber, 2008). For molecular docking study required three dimensional structure of the same molecule was formed from 3dRNA web server (http://biophy.hust.edu.cn/3dRNA/3dRNA.html) as shown in Figure 10 and visualized with UCSF chimera software (Petersen, 2004).

Using web server LigandRNA (Philips, 2013) molecular docking was performed with 'minimal RISC ' complex (formed between AGO2 protein and sense siRNA, shown in Figure 4a) and mRNA of STAT6 transcript2 gene (shown in Figure 10). Since this mRNA is 2022 nt long, its 3' end was selected (red coloured molecule in Figure 11 A). The molecular docking study results in following conformer with LigandRNA score -61.34, shown in Figure 11 B. In this figure mRNA molecule shown in black, different domains of AGO2 protein in red, blue, cyan, yellow colour and sense siRNA bound with AGO2 protein in dark blue colour. From the Figure 11 B it is clear that minimal RISC complex (AGO2 and sense siRNA) interacts with STAT6 mRNA through PIWI domain of AGO2 protein (red in colour) and may perform RNA cleavage by a mechanism similar to that of RNase H. Similarly in RISC, PAZ acts as an anchoring site for the 3'-end of guide RNA within silencing effecter complexes. Similarly the PAZ domain of AGO2 serves as a siRNA-end-binding module for siRNA transfer in the RNA interference method. RNA interference or RNA silencing occurs due to endonucleolytic cleavage of the mRNA specifically

Figure 10. 3D structure of mRNA of STAT6 transcript2 gene

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

by AGO2 protein, when RISC complex binds with a perfectly complementary mRNA. Finally it can be concluded that the sense siRNA can act as antiallergic drug to treat allergic asthma during immediate type of hypersensitivity reaction, caused by Zea m 1 pollen allergen.



CONCLUSION

Molecular docking is an important technique in computational biology. By using this technique we first of all identified Zea m 1 as allergen after analyzing the binding mode of Zea m1 allergen (PDB ID 2HCZ) and human immunoglobulin E (PDB ID 4J4P). Resulting immediate-type hypersensitivity reaction and allergic symptoms can be treated with the concept of RNA interference (RNAi) technologies. In this work Homo sapiens STAT6 mRNA was selected as target gene for allergy therapeutics. Drug designing for allergy was done by selecting, modelling and binding of sense siRNA with STAT6 mRNA in presence of AGO2 protein. Molecular docking study reveals that in RISC, PAZ acts as an anchoring site for the 3'-end of guide RNA within silencing effecter complexes and RNA silencing occurs due to endonucleolytic cleavage of the STAT6 mRNA specifically by AGO2 protein. Thus crucial roles of STAT6 proteins in the pathogenesis of allergen-induced airway inflammation, mucus production, and airway hyper responsiveness (AHR) can be avoided by using siRNA of STAT6 mRNA.

FUTURE RESEARCH DIRECTIONS

For future work plan we propose the study on 'off target binding' of that specific sense siRNA, which is essential for rational therapeutic use of this siRNA in allergic reaction.

KEY TERMS AND DEFINITIONS

Argonaute Proteins: Argonaute proteins (AGO) play a central role in RNA silencing processes, as essential catalytic components of the RNA-induced silencing complex (RISC). Argonaute proteins bind different classes of small non-coding RNAs, including microRNAs (miRNAs), small interfering RNAs (siRNAs) and Piwi-interacting RNAs (piRNAs). Small RNAs guide Argonaute proteins to their specific targets through sequence complementarity (base pairing), which then leads to mRNA cleavage or translation inhibition.

RISC: The RNA-induced silencing complex, or RISC, is a multiprotein complex, specifically a ribonucleoprotein. RISC complex is responsible for the gene silencing phenomenon known as RNA interference (RNAi), which incorporates one strand of a double-stranded RNA (dsRNA) fragment, such as small interfering RNA (siRNA) or microRNA (miRNA).

Small Interfering RNA (siRNA): siRNA is a class of double-stranded RNA molecules, 20-25 base pairs in length. siRNA interferes with the expression of specific genes with complementary nucleotide sequences in RNAi or RNA interference technique. siRNA functions by cutting mRNA into pieces after transcription, resulting in no translation.

STAT Protein: Signal Transducers and Activators of Transcription (STAT) family proteins contains transcription factors that are specifically activated to regulate gene transcription when cells encounter cytokines and growth factors; hence they act as signal transducers in the cytoplasm and transcription activators in the nucleus. STAT proteins play a critical role in regulating innate and acquired host immune responses.

Chapter 28
Molecular Docking Technique to Understand Enzyme-Ligand Interactions

Kailas Dashrath Sonawane
Shivaji University, India

Maruti Jayram Dhanavade
Shivaji University, India

ABSTRACT

Molecular docking has advanced to such an extent that one can rapidly and accurately identify pharmaceutically useful lead compounds. It is being used routinely to understand molecular interactions between enzyme and ligand molecules. Several computational approaches are combined with experimental work to investigate molecular mechanisms in detail at the atomic level. Molecular docking method is also useful to investigate proper orientation and interactions between receptor and ligand. In this chapter we have discussed protein-protein approach to understand interactions between enzyme and amyloid beta (Aβ) peptide. The Aβ peptide is a causative agent of Alzheimer's disease. The Aβ peptides can be cleaved specifically by several enzymes. Their interactions with Aβ peptide and specific enzyme can be investigated using molecular docking. Thus, the molecular information obtained from docking studies might be useful to design new therapeutic approaches in treatment of Alzheimer's as well as several other diseases.

BACKGROUND

Large numbers of three-dimensional structures of biomolecules are being uploaded in the various structural databases. These 3-D structures along with molecular models may be used in the docking process to understand proper interactions between receptor and ligand molecules. Molecular docking method is useful to investigate proper orientation and interactions between protein-protein, protein-ligand and DNA-protein molecules. In this chapter we have discussed protein-protein approach to understand interactions between human cathepsin B and *Aβ* peptide a causative agent of Alzheimer's disease with the help of AutoDock. Docking methodology and procedure has been discussed with proper figures.

INTRODUCTION

Molecular docking has become a useful technique in structure-based drug design (Sousa, 2006). We can predict the preferred orientation of receptor and ligand bound to each other to form a stable complex (Lengauer & Rarey, 2006). The molecular docking is a multistep process which starts with the representation followed by docking algorithms to identify best matched conformation to receptor structure. The docking algorithms complemented by scoring functions which is used for evaluation of interactions between ligand and receptor based on shape and electrostatic complementarities (Kitchen, et al., 2004). The two main features of molecular docking technique are conformation search algorithm and scoring function estimates the binding affinity between molecules. There are three types of docking such as protein-protein (Sonawane & Barage, 2004; Tseng, et al., 2007; Barage, et al., 2014), protein-ligand (Jalkute, et al., 2014; Jalkute, et al., 2015) and DNA-protein (Parulekar, et al., 2013) which may apply depending upon the receptors and ligands used in the docking experiments. There are two types of docking approaches used such as rigid docking and flexible docking. In rigid docking approach both the protein and ligand are considered as rigid bodies whereas in the flexible-ligand docking, receptor and ligand kept flexible. Most of the molecular docking programs treat protein as a rigid molecule and ligand as a flexible molecule. For molecular docking studies several docking programs such as AutoDock (Morris, et al., 2009), HEX (Macindoe, et al., 2010), PatchDock (Duhovny, et al., 2002; Schneidman-Duhovny, et al., 2005), Ludi (Böhm, et al., 1992), Glide (Halgren, et al., 2004), etc. are being used with appropriate docking algorithms and scoring functions.

In this chapter to understand the protein-protein docking we have taken an example of docking between cathepsin B from human with *Aβ* peptide (Musil, et al., 1991; Crescenzi, et al., 2002; Dhanavade, et al., 2013; Dhanavade, et al., 2014). Amyloid plaque formation is the pathological hallmark in the Alzheimer's disease (Hardy & Selkoe, 2002; Glenner & Wong, 1984). The Aβ peptides (1–42) are the main constituent of amyloid plaques in Alzheimer's disease (Gouras, et al., 1998; Masters et al., 1985; Tanzi, et al., 2005). There are various enzymes such as IDE, NEP, ECE, ACE, MMP-9, and plasmin are known to degrade Aβ peptides (Iwata, et al., 2001; Qui, et al., 1998; Tucker, et al., 2000; Yin, et al., 2006; Zou, et al., 2007; Cimerman, et al., 1999). Similarly, certain bacterial enzymes like aminopeptidase from *Streptomyces grieus* KK565 (SGAK), Nattokinase from *Bacillus subtilis* Natto, and Angiotensin Converting Enzyme (ACE) from *Stigmatella aurantiaca* has potential to degrade Aβ peptide (Jalkute, et al., 2015; Yoo, et al., 2010; Hsu, et al., 2009). The Aβ peptide degradation is well studied experimentally but their cleavage mechanism is yet to be understood properly. Hence, in such situation molecular docking studies between respective enzyme and ligand plays an important role to understand molecular mechanism in detail at the molecular level. The detailed procedure of docking is explained and then the results are analyzed to understand the degradation of Aβ peptide by cathepsin B from human. Finally the importance of molecular docking studies is discussed.

MATERIALS

Downloading AutoDock and AutoGrid

Download freely available version of AutoDock and AutoGrid software (Morris, et al., 2009) for Windows operating system from the AutoDock webpage (http://autodock.scripps.edu/downloads/autodock-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

registration/autodock-4-2-download-page/). Install the AutoDock and AutoGrid as per the installation instructions.

Downloading the AutoDock Tools (Version 1.5.4, Version 3)

The AutoDock Tools (ADT) (mgltools_win32_1.5.6) is a tool required for the preparation and visualization of molecules along with AutoDock and AutoGrid. This mgltools_win32_1.5.6 has been made for Windows which can be downloaded from link: http://mgltools.scripps.edu/downloads. After downloading it can be installed as per the installation instructions (Morris, et al., 2009).

Other useful software for molecular docking studies:

- **MODELLER 9v7:** This software is developed by Sali and Blundell in 1993 (Sali & Blundell, 1993) and being used routinely to predict three-dimensional structures of proteins using homology modeling technique.
- **AutoDock:** This is developed by Morris and coworkers in 2009 (Morris, et al., 2009) and being used in the docking studies.
- **RasMol:** This is useful to visualize and analyze the 3D structures. This software is developed by Roger Sayle and coworkers in the year 1995 (Sayle, & Milner-White, 1995).
- **Chimera:** The Chimera is developed by the Pettersen and coworkers in the year 2004 (Pettersen, et al., 2004) and is useful for the structure visualization, analysis of models as well as to prepare attractive images of docked complex.

The above discussed software's are freely available and may be used for the basic study of molecular docking but besides this various online servers are also available for homology modeling process.

METHODS

- **Homology Modeling:** In order to start molecular docking process, three dimensional structures of receptor and ligand must be downloaded from RCSB and PUBCHEM respectively. If the 3D structure of receptor is not available then it has to be modeled by using MODELLER 9V software. In this current chapter we have considered human Cathepsin B (Musil, et al., 1991) as a receptor. Its 3-D structure (2IPP.pdb) has been directly extracted from RCSB Protein Data Bank (Musil, et al., 1991). For protein-protein docking, the amyloid beta protein, 1IYT.pdb (Macindoe, et al., 2010) has been taken as a ligand and retrieved from RCSB. If ligand is a chemical compound then its structure may be extracted from NCBI PUBCHEM.
- **Virtual Screening:** If receptor is an enzyme and its 3-D structure data available in Protein Data Bank (PDB) then one can use structural information of active site residues of receptor to search suitable drug molecules from ZINC database (Irwin, et al., 2005) which can bind effectively to the receptor. Dockblaster program has a flexible-ligand sampling algorithm which superimposes atoms of the docked molecule as per the supplied binding site which represent positions to bind ligand atoms (Irwin, et al., 2009). Basically the selection of ligand was performed by bin size; distance tolerance up to 2.0 Å, each ligand configuration was scored for electrostatic, van der Waals

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

interaction complementarity and corrected for ligand desolvation. The screening of ligand is done in ZINC database of commercially available molecules, which contains 3 million compounds available ready to dock (Irwin, et al., 2005).

Molecular Docking

Molecular docking study mainly aims to predict the intramolecular interactions formed between two or more molecules. Molecular docking has been described as a useful tool in structure-based drug design and discovery (Sousa, et al., 2006). Earlier, significant amount of work has been made in the molecular modeling and drug discovery (Blaney & Dixon, 1993; Jones & Willet, 1995; Lybrand, 1995; Rosenfeld, et al., 1995; Gschwend, et al., 1996; Lengauer & Rarey, 1996). Molecular docking is a method to predict preferred orientation of receptor and ligand interacting to each other to form a stable complex (Lengauer & Rarey, 1996). Docking method considers only translational and orientational degrees of freedom of the ligand with respect to receptor (Kuntz, et al., 1982). However, the molecule's geometry may change upon binding into the active site of an enzyme, so now most of the method considers ligand as a flexible molecule. Proteins are not rigid structures therefore ideally it should be flexible during the docking simulations. However, introducing flexibility in the macromolecular proteins during docking procedure is quite difficult because of the requirement of the huge computational power for such processes. Hence, docking studies are performed using a flexible ligand and a rigid receptor protein.

Docking is multistep process which starts with molecular representation followed by docking algorithms to identify best matched conformation of receptor and ligand complex. The docking algorithms based on shape and electrostatic complementarities with scoring functions are used to evaluate the interactions between receptor and ligand (Kitchen, et al., 2004). The AutoDock (Morris, et al., 2009) was used to predict protein-protein and protein-ligand interactions with an appropriate docking algorithms and scoring functions. The search algorithms are classified into three types such as systematic, stochastic and deterministic search algorithms (Brooijmans & Kuntz, 2003). The grid value for all degrees of freedom in molecule can be explored by systematic algorithms in a combinatorial way. The incremental construction and conformational search are carried out by some systematic search algorithms (Halperin, et al., 2002). The random changes to single ligand or to the population of ligand can be done by stochastic search algorithm operations. The algorithms such as Monte Carlo methods, genetic algorithms and tabu search are included in stochastic algorithms. The deterministic search algorithms started with known initial state up to the state of lesser energy at which the termination criteria is met (Halperin, et al., 2002). Monte Carlo methods, Genetic algorithms and Lamarckian genetic algorithms have been adopted in AutoDock, a flexible docking program (Morris, et al., 2009).

Molecular Docking Procedure

The molecular docking methodology can be divided into three steps: file preparation, docking, and analysis. Before preparing the receptor, the bound ligand and water molecules must be deleted from the crystal structure. Firstly, the addition of polar hydrogen's, computing the partial charges, and assigning of AutoDock atom types has to be performed. After that two files such as rigid.pdbqt and flexible.pdbqt are generated from the receptor file. The flexible.pdbqt file is generated by keeping the active site residues of receptor as flexible residues while remaining residues are taken as a rigid in rigid.pdbqt file. Then the parameter file must be prepared to run the AutoGrid. The docking grid should be specified to

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

constrain the search area for the docking. The grid parameter file (gpf) will be generated to show the macromolecule location, size and atoms types to compute grid map. While running AutoGrid, the parameters will be taken from the gpf file and generated grid map will be used further in AutoDock. AutoDock will generate a docking parameter file (dpf) for the ligand and then modified with the parameters for Lamarckian genetic algorithm. When all the files such as rigid.pdbqt, flexible.pdbqt and ligand.pdbqt which are needed for the docking process are generated, then one can start actual docking process. The time required for docking depends on various factors like size and number of rotatable bonds in the ligand, the docking grid size, the genetic algorithm parameters, and the number of runs. After the completion of docking process, AutoDock will give output in docking log file (dlg) which contains docked structures and binding free energies. The pose of the ligand, structural coordinates, cluster size and binding free energies can be obtained after analyzing the dlg file. The docked complex can be further converted into pdb file format and analyzed by different 3D structure visualizing software such as RasMol (Sayle & Milner-White, 1995) and Chimera (Pettersen, et al., 2004). In order to understand structural stability of docked complex molecular dynamics (MD) simulations can be carried out using available packages such as GROMACS (Spoel, et al., 2005), CHARMM (Brooks, et al., 2010) and AMBER (Case, et al., 2005).

Preparing the Macromolecule

For the preparation of macromolecule the stepwise procedure is given below.

- **Start AutoDock Tools:** Open the macromolecule structure in ADT: Click on File-----Read Molecule and then get your interested molecule e.g. 2IPP.pdb in the working area of ADTviewer.

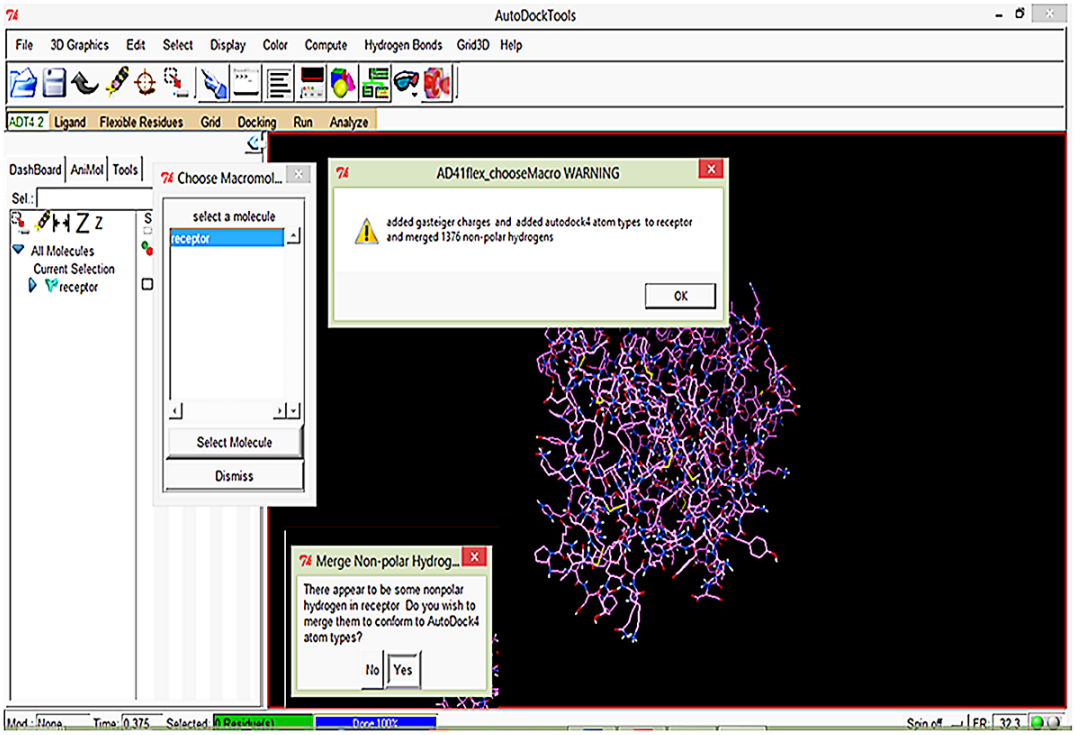
Add hydrogens to the receptor file: Click on Edit-----Hydrogens-----Add. This will add hydrogen atoms in your interested PDB file. Then save pdb file with hydrogen atoms in the same folder; File-----Save-----Write PDB-----Receptor.pdb.

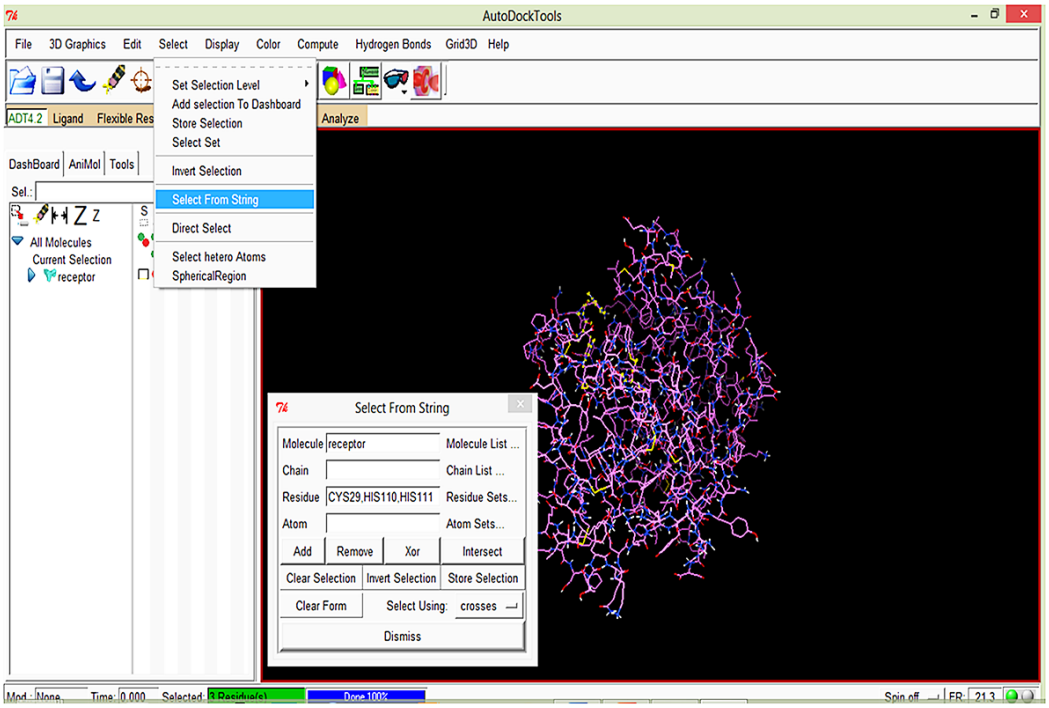
- **Preparing the Rigid and Flexible Residue File:** In this part the rigid and flexible residue files are prepared which has to be saved in the PDBQT file format. The active site residues of receptor are kept as flexible residues while the other residues are considered as rigid; Click on Flexible Residues-----Input-----Choose Macromolecule. A window will appear then select Receptor.pdb-----Select Molecule (Figure 1). This will compute Gasteiger partial charges, assigning AutoDock4 atom types to receptor and merged nonpolar hydrogens (Figure 1).
- **Selecting and Saving Flexible Residues:** The information about the active site residues are required to prepare the flexible residues file. The active site residues are considered as flexible residues.

Flexible Residues-----Input-----Choose Macromolecule. Then the receptor is selected. Then select flexible residues by clicking on Select-----Select From String-----Molecule List in which we have to select molecule (Receptor) then in the Residue column enter the names of active site residues (CYS29, HIS110, HIS111) then click on Add and then Dismiss (Figure 2). After that for setting torsions, click on Flexible Residues-----Choose Torsions in Currently Selected Residues. This will give the information about the torsion count in a separate window (Figure 3). Finally, the Flexible residue file (Flexible.pdbqt) and rigid residue file (Rigid.pdbqt) are saved as;

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 1. Selecting the receptor molecule





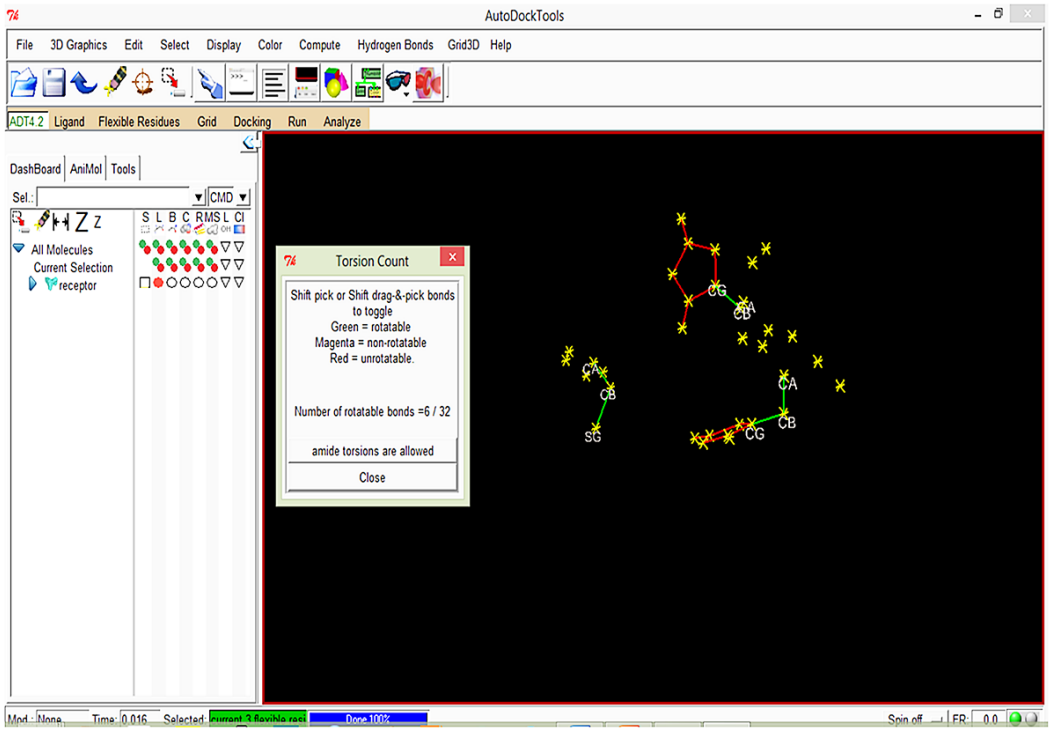


Figure 2. Selecting the active site residues

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 3. Choose torsions in active site residues

Flexible Residues-----Output-----Save Flexible PDBQT and
Flexible Residues-----Output-----Save Rigid PDBQT (Figure 4).

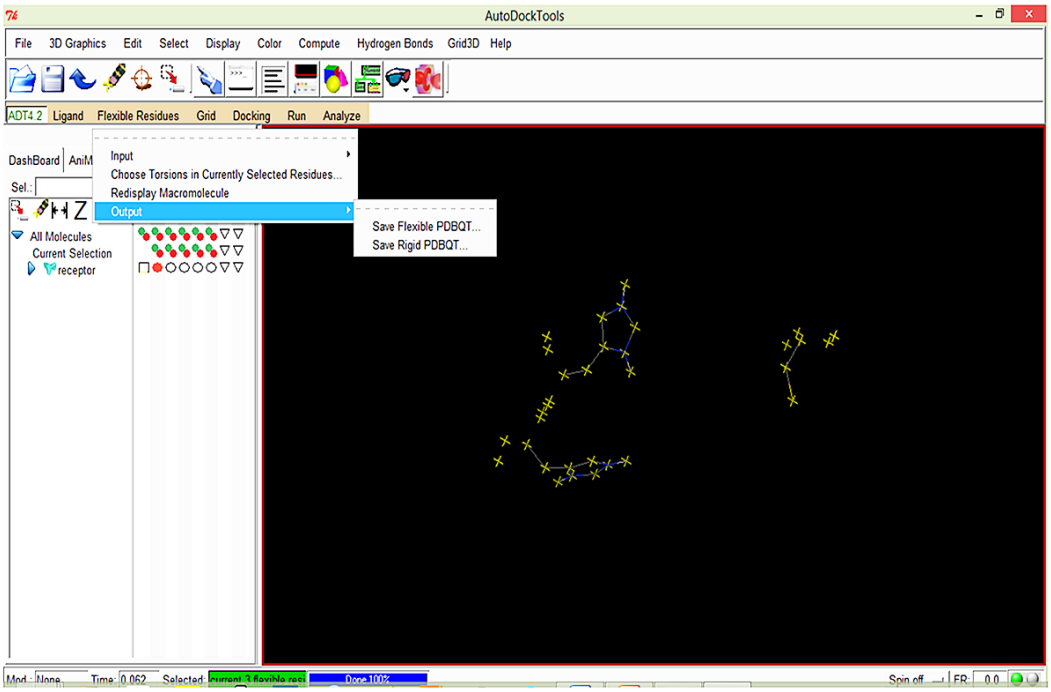
- **Preparing the Ligand File for AutoDock:** In AutoDock the ligand files are written in special keywords which can be recognized by AutoDock. The keywords such as ROOT, ENDROOT, BRANCH, and ENDBRANCH establish a "torsion tree" object or *torTree* which has a *root* and *branches*. The root is nothing but the rigid set of atoms, whereas the branches are rotatable groups of atoms connected to the rigid root. The keyword TORSDOF signals the number of torsional degrees of freedom in the ligand. The TORSDOF for a ligand is the total numbers of possible torsions in the ligand minus the number of torsions that only rotate hydrogens. TORSDOF is mainly used during calculation of the change in free energy caused due to the loss of torsional degrees of freedom upon binding. In the current example the ligand which is a patch of Aβ peptide (1IYT.pdb) is used for the docking. For the preparations of ligand.pdbqt following steps can be performed.

Click on Ligand-----Input-----Open to choose ligand PDB file i.e. IYT.PDB as shown in Figure 5. After choosing ligand.pdb click on Select Molecule for AutoDock4. Then the window will appear, in which the summary for ligand.pdb will be displayed with the ligand information as can be seen in Figure 5 and then click on OK.

Then following steps are carried out to detect root.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 4. Save rigid and flexible files



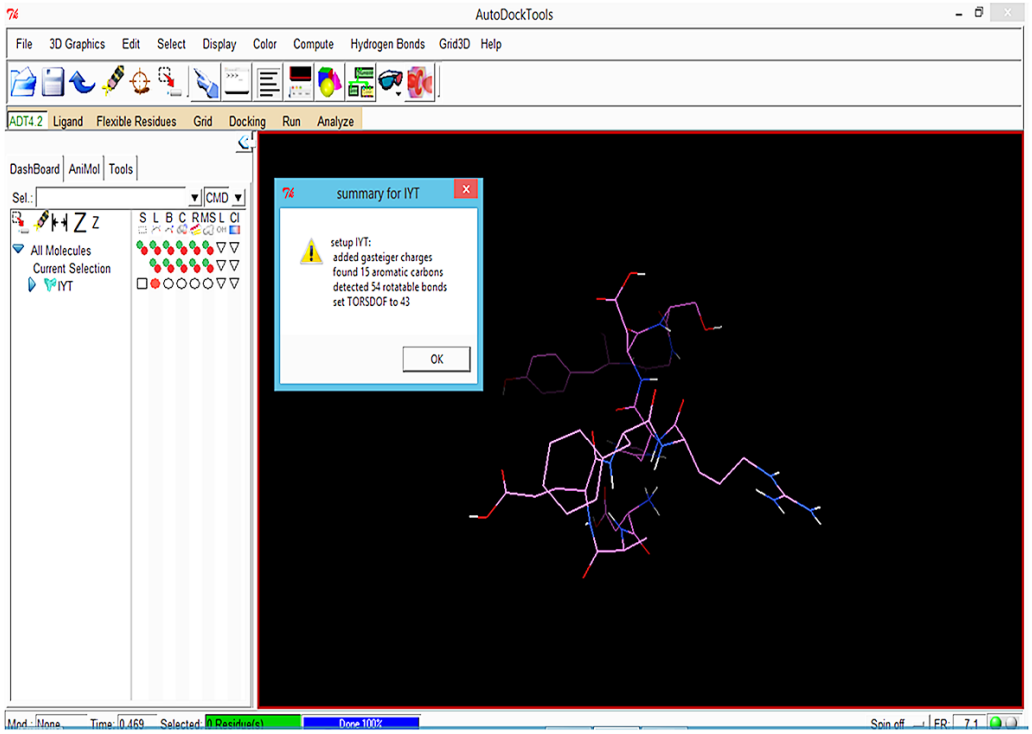


Figure 5. Selecting the ligand Molecule

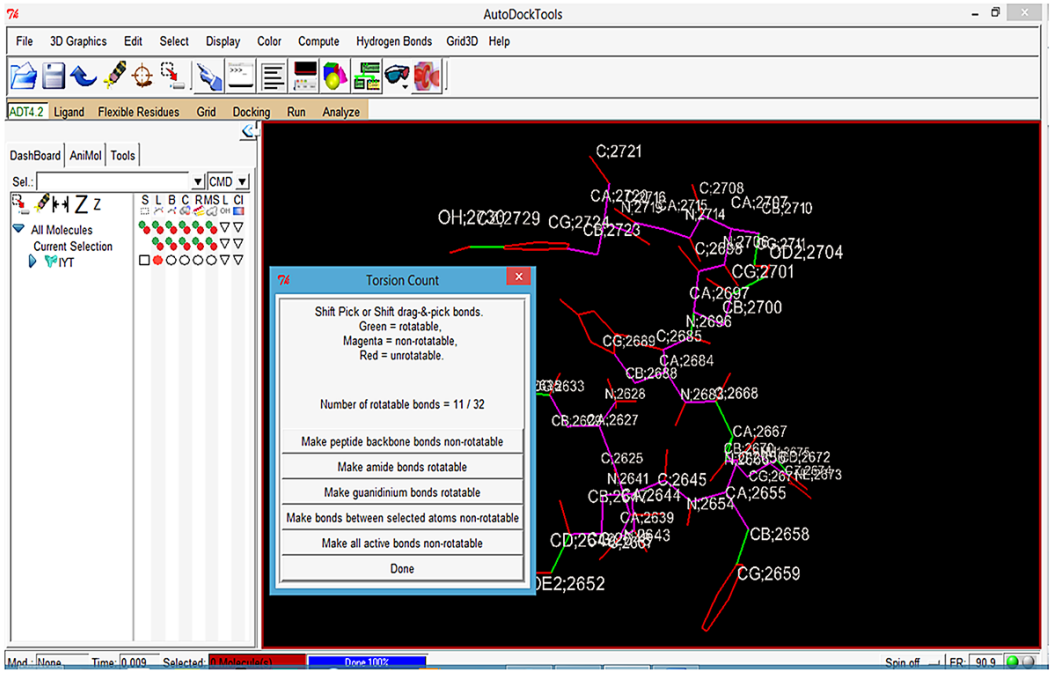
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Ligand-----Torsion Tree-----Detect Root

Ligand-----Torsion Tree-----Hide Root Expansion

Ligand-----Torsion Tree-----Show/Hide Root Marker



ADT determines the atom which fits its idea of the best root and mark it with a green sphere. This best root is nothing but the atom in the ligand having small largest subtree.

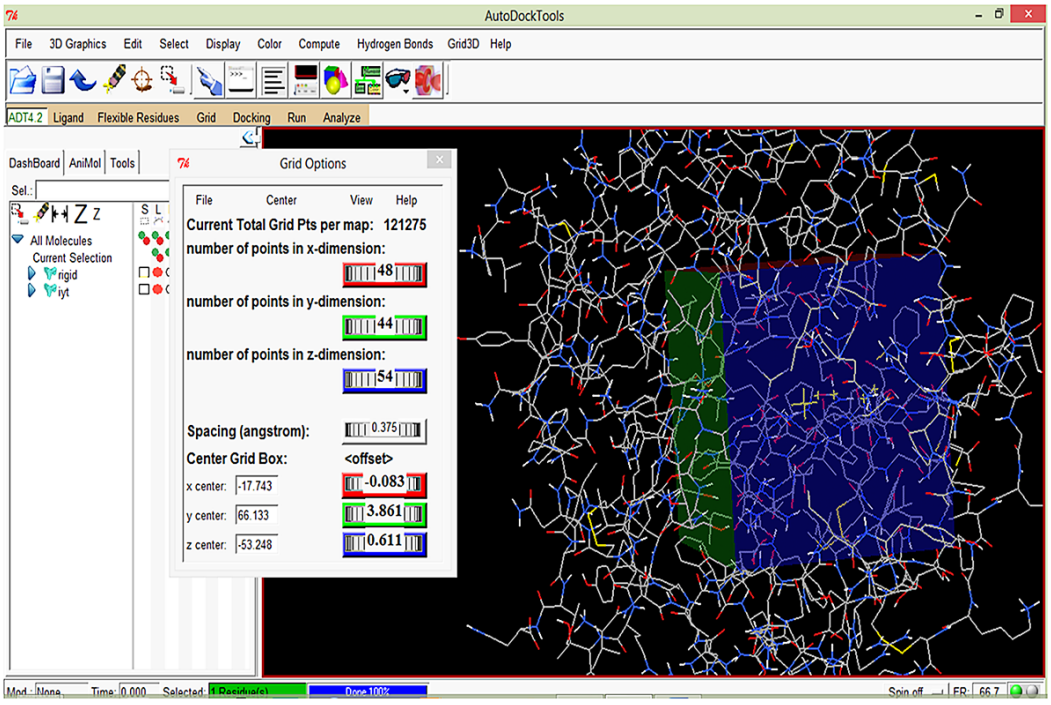
Ligand-----Torsion Tree-----Choose Torsions

These operations will open the Torsion Count widget which displays the number of currently active bonds showing; Red-non rotated bonds, Purple-currently marked as inactive, Green- Currently active. Those bonds which are in cycles cannot be rotated. ADT determines the bonds which could be rotated ('possibleTors'). In ADT one can see rotatable bonds ('activeTors') by inactivating the other bonds. We can also toggle the activity of a bond or group of bonds by picking them in the viewer. Alternatively, buttons on this widget let you toggle the activity of a type of bonds like 'peptide bonds', 'amide bonds', 'bonds between selected atoms' or 'all rotatable bonds'. To do this we can click on Make all active bonds non-rotatable then click on Make all rotatable bonds rotatable. It also states that 11 out of 32 bonds on the ligand are rotatable. Click on Done in the Torsion Count window to exit (Figure 6).

- **Saving the Ligand PDBQT (IYT.pdbqt):** To save ligand PDBQT file go to Ligand-----Output-----Save as PDBQT----- ligand.PDBQT. After these steps a ligand is prepared for the further docking procedure. This ligand.PDBQT file is then used for the actual docking process.
- **Preparing the Grid Parameter File:** Grid parameter file (gpf) is required to compute the types of maps, the location and extent of those maps as well as specific pair-wise potential energy parameters using AutoGrid. One map is calculated for each element present in the ligand with an electrostatic map. The following steps are performed for the preparation of gpf file.

Figure 6. Choose Torsion count in ligands

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



- **Open the Macromolecule File RIGID.PDBQT in ADT:** Click on File-----Read Molecule. This will open a file browser in the directory where ADT was started. Select the file, RIGID.PDBQT, and click on Open. Then Click on Grid-----Choose Molecule-----Choose the RIGID.PDBQT file. After choosing the RIGID.PDBQT a window will appear asking to preserve input receptor charges instead of adding Gasteiger charges. Then Click on Yes to keep the charges. Also a WARNING box will then pop-up, showing the initialization of the pdbqt file, stating that the autodock_elements and gasteiger charges have already been added. Then click on OK.
- **Selecting the Ligand and Generate Maps:**

Click on Grid-----Set Map Types-----Open Ligand-----ligand.PDBQT.

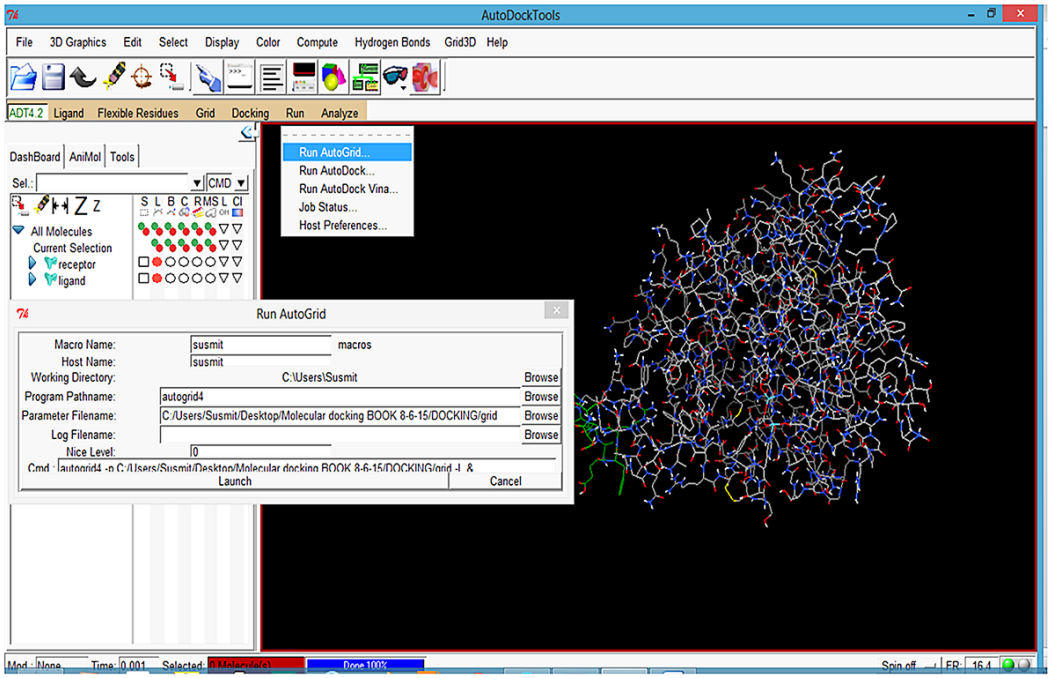
Then Grid-----Set Map Types-----Choose Ligand. Choose Ligand window will appear. Click on ligand.PDBQT and click on Select Ligand (assuming the ligand file is already open). After selecting the ligand, the gpf will specify AutoGrid to generate maps for atom types present in the ligand.

- **Specify the Grid Box Dimensions, Spacing and Center:** The grid box can be constructed by using this step; Click on Grid-----Grid Box. The window will appear with Grid Options. Specify the grid box center where ligand is located and the grid Box size such as the active site residues should be in the box. In the Grid Options window, click on the Center tab and select Center on ligand. In the current window the grid box center is now located with dimensions such as -17.743, 66.133, -53.248. The size of the grid box, as shown in Fig 19, is 48 × 44 × 54 using a 0.375 Å resolution grid. For saving the modified grid option parameters, click on file and select close saving current (Figure 7).

Figure 7. Specifying the grid box dimensions

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Save the grid parameter file (grid.gpf): Click on-----Grid-----Output-----Save GPF. A file browser will appear in which file name like grid.gpf should be saved.



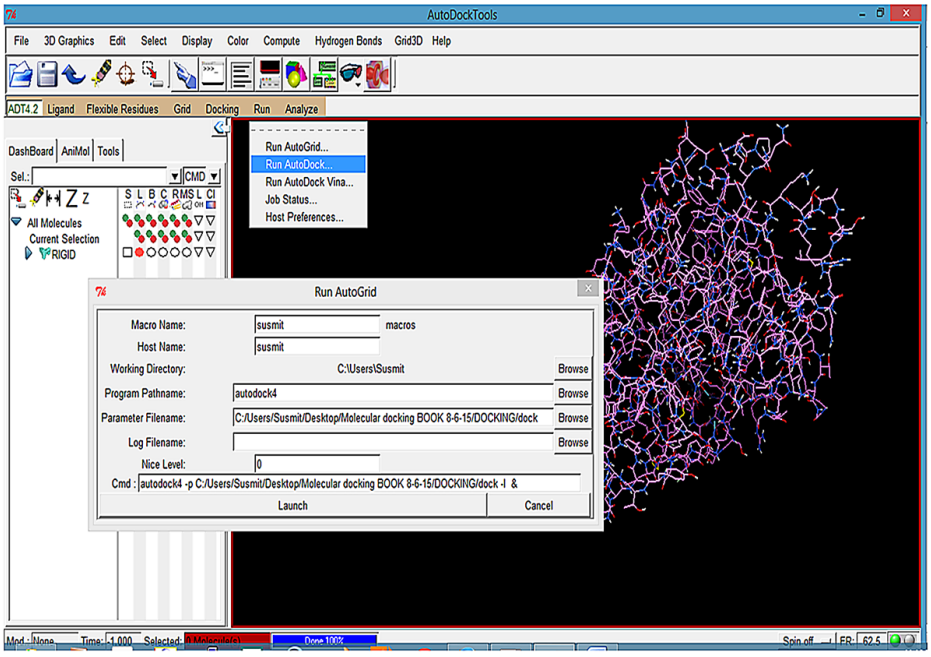
Edit the grid parameter file in a text editor. The Edit option is used to change required parameters of gpf file.

- **Running AutoGrid to Create Grid Maps:** To create the grid map for macromolecule run the AutoGrid: The AutoGrid must run in the same directory in which the ligand, macromolecule and grid parameter files are located. AutoGrid can be accessed by using ADT or command line. For running in ADT, click on

Run-----Run AutoGrid. After that a window will appear. The Macro Name and Host Name will specify your local machine by default. The location of AutoGrid executable must be specified by the program Pathname. The grid parameter file (gpf) specifies the parameter filename. The Log Filename is specifying the grid log file for the AutoGrid run. By default the name of the log file will be same as the grid parameter file, except with the extension.glg. The nice level for the remote jobs is also specified. The commands can be executed by running in cmd for windows. Click on Launch to start the job. We can see the status of job in the AutoDock Process Manager window which will appear after running the job. Alternatively, AutoGrid can be run via command line by typing: autogrid4 –p grid.gpf –l grid.glg& (Figure 8).

After completion of AutoGrid, the grid maps will be created for each specified atom type, electrostatic potential and desolvation energies. Also, other files created such as xyz file which specifies the grid box size, and the fld file which has other information about grid. The summary from the AutoGrid run is given in a grid log file (glg).

Figure 8. Running AutoGrid command



EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

- **Creating the Docking Parameter File and Running AutoDock:** The docking parameter file (dpf) is necessary to run the final docking step. The files such as ligand.pdbqt, rigid.pdbqt and flexible.pdbqt are needed for docking should be placed in same directory. To prepare docking parameter file (dpf) firstly open all the files required for docking in ADT.

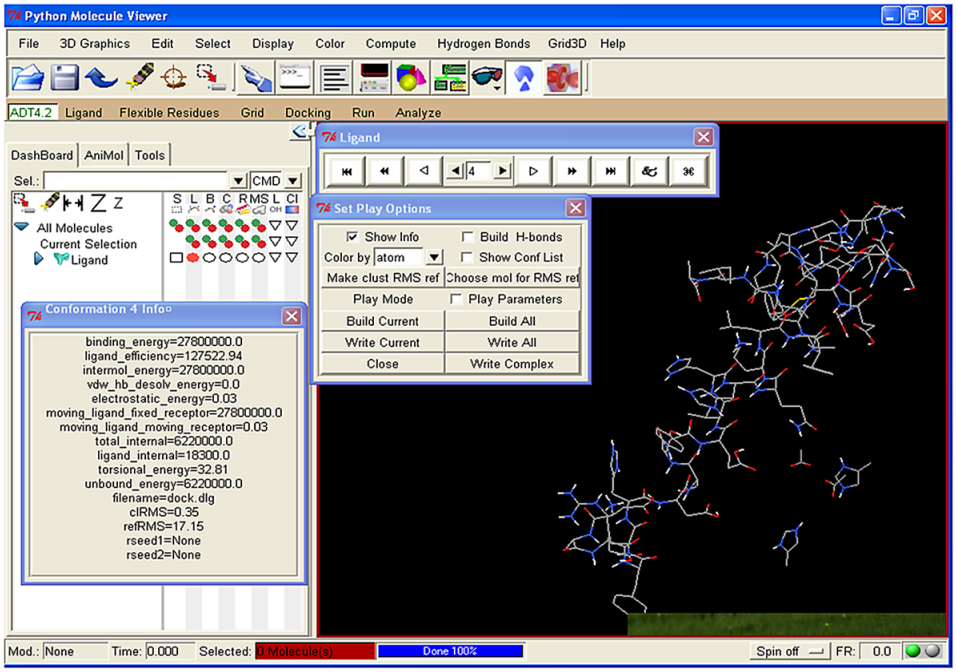
Click on-----Read Molecule-----Select RIGID.PDBQT-----Open.
Click on-----Read Molecule-----Select FLEXIBLE.PDBQT-----Open.
Then for selecting the rigid and flexible files for docking
Click on Docking-----Set Rigid Filename
Click on Docking-----Set Flexible Residue Filename
Finally open the ligand in the ADT
Click on Docking-----ligand-----Open
The search parameters are selected as;
Docking-----Search Parameters-----Genetic Algorithm
The default docking parameters are used
Docking-----Docking Parameters-----Use Defaults-----Accept
Finally saving the docking parameter file (dpf)
Docking-----Output-----Lamarckian GA (4.2) -----dock.dpf
Save the docking parameter file (dock.dpf) in the same directory where all other files are generated.

- **Run the AutoDock:** AutoDock can be accessed by using ADT or command line. For running in ADT, click on Run-----Run AutoDock (Figure 9). Alternatively, AutoDock can also be run via command line by typing: autodock4 –p dock.gpf –l dock.dlg&

Figure 9. Running AutoDock command

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

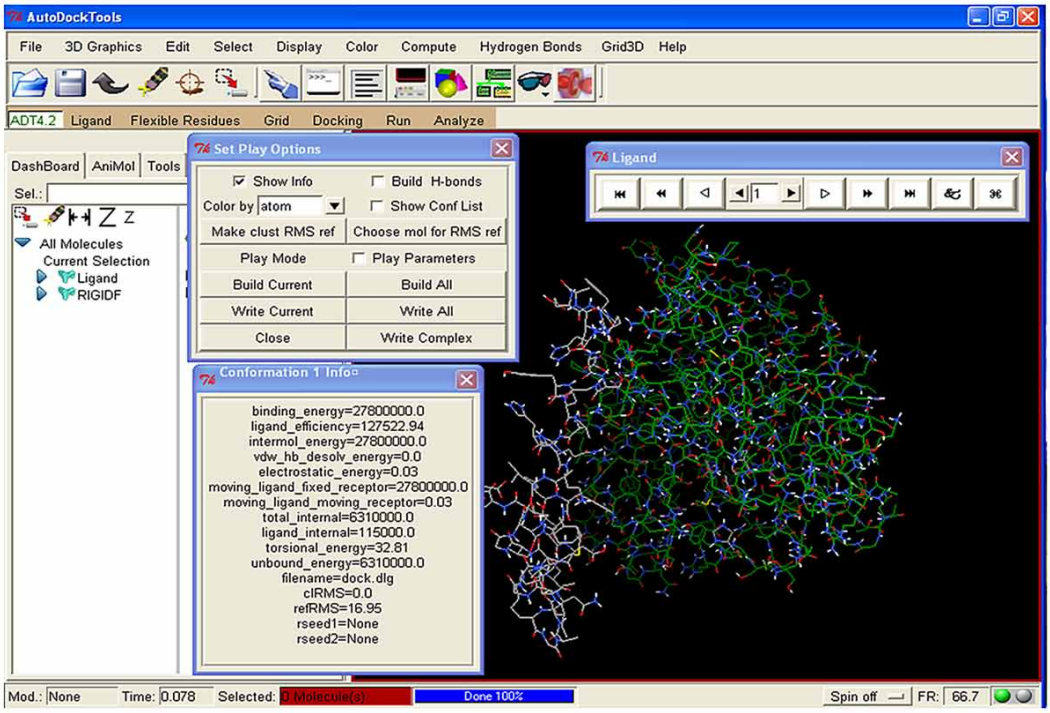
- **Analyzing Docking Results:** In AutoDock the docking results will be written in the docking log file (dlg).
  Firstly open the docking log file (dlg) in the ADT.
  Click on Analyze-----Docking-----Open-----dock.dlg. This will open the docking file.
  Open macromolecule in ADT
  Click on Analyze-----Macromolecule-----Open-----RIGID.PDBQT.
  Selection of lowest energy conformation



The lowest energy conformation must be selected from generated docked complexes. In this current procedure we have carried out 10 runs in which 10 different docked conformations were generated so we can see the energy of each conformation and then select the lowest energy conformation (Figure 10).

Click on Analyze-----Conformation-----Play

When this operation is performed a Conformation Player (CP) gets opened in which one can examine the docked conformations. The Conformation Player has a current conformations list (its sequence) and a current ID list. The sequence list consists of all the docked conformations, ordered by run. The ID list is [0, 1, 2, 3…10]. Then select the conformation on the basis of energy.

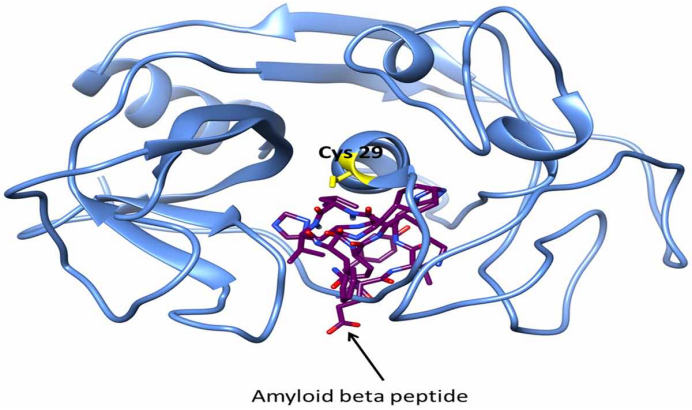


- **Saving the Docked Complex:** Finally, the docked complex with lowest energy can be saved by clicking on Write complex, and then the browser window will appear. After that select the location to save the docked complex and also change the file type and save the file in pdb file format as Docked.pdb (Figure 11). Similarly, other ligand types such as DNA and chemical compounds can

Figure 10. Selection of the lowest energy conformation

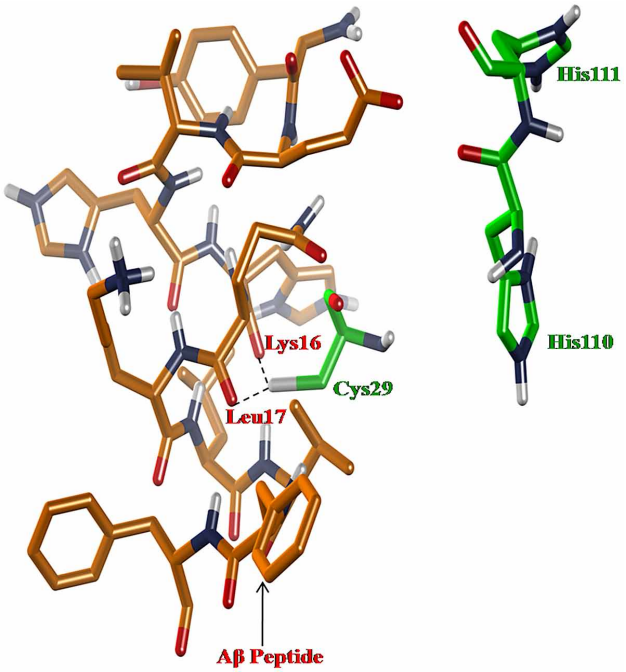
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 11. Saving the docked PDB file



be used for molecular docking studies as per the same procedure as explained above. The detailed methodologies for such docking studies have been given in (Sonawane, & Barage, 2014; Tseng, et al., 2007; Barage, et al., 2014; Jalkute, et al., 2014; Jalkute, et al., 2015; Parulekar, et al., 2013; Dhanavade, et al., 2013, Dhanavade, et al., 2014).

- **Visualizing the Docked Complex in Various Visualizing Software:** The docked complex can be visualized in the different visualizing software such as Chimera and RasMol. The images can be saved in the different image formats like TIFF, JPEG and PNG etc. The final docked complex between Cathepsin B and amyloid beta peptide which is a causative agent of Alzheimer's disease can be seen in the Figure 12. Then the docked complex can be taken further for MD simulation study to understand structural stability as explained in earlier studies (Dhanavade, et al., 2013).
- **Analyzing the Final Docked Complex:** For the analysis of docked complex various software having molecular graphics such as RasMol (Sayle & Milner-White, 1995), Chimera software (Pettersen, et al., 2004), etc. can be used. The interactions between the receptor and ligand can be investigated which would be helpful to make final conclusions. In this chapter we have considered a case study done by Dhanavade and coworkers in 2013 (Dhanavade, et al., 2013) in which docking has been carried out between cathepsin B (receptor) with *Aβ* peptide (ligand) as an example. The receptor cathepsin B (2IPP.pdb) which is a human enzyme has ability to degrade Aβ peptide. Hence, the molecular docking was carried out between the cathepsin B (receptor) with Aβ peptide (ligand) to find the active site residues of cathepsin B (receptor) involved in the interactions with the Aβ peptide (ligand).



EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 12. The docked complex between Cathepsin B and amyloid beta peptide

Finally, on the basis of interactions it is easy to find the active site residues of cathepsin B (receptor) which take part in the cleavage of Aβ peptide. The docked complex was analyzed by using Chimera (Pettersen, et al., 2004) and the results revealed that there is strong hydrogen bonding between the cathepsin B (receptor) with Aβ peptide (ligand) (Figure 13) (Dhanavade, et al., 2013). This hydrogen bonding between active site residue Cys 29 of cathepsin B with Lys 16 and Leu 17 of Aβ peptide indicate that cathepsin B can cleave Aβ peptide in between Lys 16-Leu 17 (Dhanavade, et al., 2013). There is experimental report available which confirm the degradation of Aβ peptide by human cathepsin B (Mueller-Steiner, et al., 2006). Hence, to study the exact cleavage mechanism of Aβ peptide (ligand) by cathepsin B the

Figure 13. Showing the hydrogen bonding between the cathepsin B (receptor) with Aβ peptide (ligand)

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

molecular docking technique has been found useful. Likewise, interactions between protein-protein, protein-ligand or drug, and protein-DNA can be studied using molecular docking technique.

CONCLUSION

The docking procedure and methodology discussed in this chapter would be useful for beginners to get into the field. The molecular modeling studies along with experimental findings could be useful to understand exact cause of several diseases in detail at the molecular level. Such studies might be useful to discover new lead molecules to combat neurological and several other diseases.

Future Work

The docking results must consider as a good starting point for further experimental design. MD simulations studies are must to check the stability and dynamic behavior of docked complex. Then binding free energy calculations of docked complex might be useful to get exact idea about the interacting residues. The continuous increase in computational power can be helpful to expand the practical applications of molecular models. These results are then compared with experimental findings. In future, experimental studies coupled with docking and MD simulations would be more promising to discover new lead molecules.

ACKNOWLEDGMENT

KDS is thankful to University Grants Commission, New Delhi for providing financial support. KDS is also gratefully acknowledged to Department of Science and Technology, New Delhi for providing financial grants. MJD is thankful to DST for providing fellowship as research assistance under the scheme DST-PURSE. Authors are thankful to Computer Centre, Shivaji University, Kolhapur for providing the computational facility.

Chapter 29
Molecular Modelling, Dynamics, and Docking of Membrane Proteins: Still a Challenge

Nanda Kumar Yellapu
Vector Control Research Centre, India

ABSTRACT

Computational tools and techniques are now most popular and promising to progress the research at rapid rate. Molecular modelling studies contribute their maximum role in wide variety of disciplines especially in proteomics and drug discovery strategies. Molecular dynamics and molecular docking algorithms are now became an essential part in daily research activities of every laboratory throughout the world. These strategies are now well established and standardised to study any specific protein of interest and drug molecule. But still there exist considerable drawbacks in a special concern with membrane proteins as the presently available tools and methods cannot be applied directly to them. Modelling, dynamics and docking studies of membrane proteins need a special care and attention as several challenges are to be crossed with an intensive care to produce a reliable result. This chapter is aimed to discuss such challenges and solutions to handle membrane proteins.

INTRODUCTION

Membrane Proteins

Cell membranes are the most indispensable attributes of any living organisms that safeguard the integrity of a cell by wrapping around. It acts as a potential barrier to perform several physiological functions by offering complex molecular machineries. These multifarious functions and mechanisms of membranes are facilitated and regulated by an inimitable group of proteins called as membrane proteins which are

of both surface and integral types (Figure 1). They play a vital role as channels for the transport of ions and molecule to meet the regular demands of biochemical functions (Cooper, 2000).

The structural and functional characterization of membrane proteins is typically a thorny task as the difficulties are associated with providing membrane environment that limits the purification and crystallization. Recent advancement in the technologies has led to the structural and functional characterization of several membrane proteins by providing their experimental structural information (Tatulian, 2000). But still it is not meeting the required demand as presently only *2%* of membrane protein structures were solved. Such demanding situations paved a spectacular way for the construction of membrane protein models through computational modelling methods (Arinaminpathy et al., 2009). There exist very narrow traditions to construct the protein models but providing an immense support to the structural biologists (Lacapère et al., 2007). Such ways even relies on the experimental data of pre-existing proteins (Ash et al., 2004). Such methods are incredibly known as homology modelling methods; nevertheless homology modelling also fails many times with membrane models as the availability of experimental data for them is very limited. Construction of such models remains as a challenge when the subject of protein is very demanding and necessitous. This chapter is going to describe how such situations will overcome. Stepwise recurrent methodologies with unequivocal and particularized algorithms can be followed where the propensities of amino acids can be utilized to construct the membrane protein models where *de novo* modelling is one of the methods comes under this technology. Even, this also never solve the problem entirely, as this idea works out well with the small proteins and still leavening the challenge unsolved as the membrane proteins usually bigger in size. This chapter will further deals, how the larger size membrane protein models are constructed. The constructed models must represent or resemble a natural conformation so as to mimic the experimental model. How it can be made? Still another chal-

Figure 1. Membrane and membrane proteins; their significant role as transporters and signal transducers

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

lenge remnants, whether the protein model fits into the membrane structure in line or aligns properly in the lipid bilayer. What would be thickness of the membrane for a specified protein? This chapter will explain detailed procedural solutions for all these challenges to obtain an ideal theoretical model for any membrane protein irrespective of its size.

A membrane structure with its phospholipid bilayers and component proteins resembles a disordered environment. Several types of interactions such as electrostatic, hydrophobic, covalent and hydrogen bonding etc., contribute to the dynamic moments and functions of membrane proteins. Such interactions will drive the proteins to function dynamically. Characterization and monitoring of such behaviour of channels is really challenging task through experimental techniques but can make easy by *in silico* means applying molecular dynamics (MD) simulation studies. Beyond the static conformation of a membrane protein, addition of membranes, orientation of model in the membrane and finally providing the membrane like environments can be done so as to mimic the *in vivo* environment. Simulation of such atomic models plays a vital role in shaping the perfect view to characterize the function of a membrane protein (Chang et al., 2005). Molecular dynamics simulations, irrespective of theoretical or experimental structures, offer a distinctive direction for the interpretation and correlation of structures with their function (Lindahl & Sansom, 2008). The most essential physiological functions of membrane proteins such as molecular recognition, ion regulation and energy transduction are regulated by their dynamic moments which are offered by the internal dynamic folding and orientation of several conformations of the proteins. Inspection, characterization and interpretation of such dynamic motions are highly convoluted and challenging task through experimental means and further are solved by computational simulations. Such characterizations works well with small and cytosolic proteins and when come to large and membrane proteins it will prone to several challenges. The membrane proteins will behave differently when they are present in lipid environment as they are embedded in lipid bilayer their folding is majorly influenced by the membrane. The dynamic motions of the membrane can be monitored in presence of simulated peripheral forces that duplicate some aspect of the environment, such as its voltage and surface tension. This chapter deals with the challenges associated with the membrane protein dynamics especially how the simulation of ions/molecules conductance works out which is the most challenging exertion in computational studies of membrane proteins because of the complexity of the potential energy surface, alternate hydrophilic and hydrophobic environments that finally makes the passage of ions/molecules more specific.

Membrane Proteins as Transporters/Ion Channels

The small molecules and ions possessing charge cannot pass through the cell membrane on their own and they require transport proteins that are available in the membranes. The transporter proteins in the transmembrane regions are of two types (1) Channel proteins that functions as selective pores that opens and closes in response to an electro-chemical gradient and (2) Carrier proteins that use energy processes for the translocation of a substrate against concentration gradient (Saier, 2000). Human cell membranes contain several kinds of transporters for transporting glucose, amino acids, ions, neuro transmitters etc. Some transporters are also involved in the multi drug resistance. Such multi drug resistance is the particular limitation in the cancer chemo therapy and antibiotic treatments. Hence the drug molecules that inhibit drug efflux transporters are required to use as a complement to the existing therapy in order to overcome multidrug resistance (Dantzig et al., 2003). Usually drugs show their effect on transport

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

system by binding to transporter proteins and either inhibits their activity so as preventing the passage of ions/molecules or by acting as false substrate for the transport process.

So far only a few transporter proteins from some bacterial species have been crystallized to determine their structure. There is only less structural data is available on the membrane transporter proteins that limits the development of new leads that could interfere with the structure and functions of transporter proteins. Such situations demand the molecular modelling studies for the bio computation of alternative methods for the structural studies of membrane transporters (Dahl et al., 2004). However, these methods depend both on the computational studies and experimental interference for the perfect molecular modelling studies.

Membrane Proteins as Potential Drug Targets to Discover New Drugs

The three dimensional information of a membrane structure and its interaction with a specific drug reveals several critical factors about the topology of the complex and their interacting surfaces between the membrane proteins and drug molecules (Klebe, 2006). Such information provides several possible ways for the virtual screening experiments and helps to develop novel potential lead molecules that specifically bind with a defined target membrane protein (Blundell et al., 2002). Several docking softwares can be utilised to obtain the orientation and binding affinities of the drugs against a membrane protein. This information will help a chemist to optimize the potential lead molecule by incorporating several functional groups in different orientations finally getting an improved molecule with high potency and selectivity (Hajduk & Greer, 2007).

Several drugs came into existence into the market in the present days which are developed based on the concept of structure based drug design. Some of them include HIV drugs Agenerase and Viracept developed based on the structure of HIV proteinase (Tomasselli & Heinrikson, 2000; Stoffler et al., 2002), Flu drug Zanamivir developed based on the structure of neuraminidase (Monto et al., 1999) and the inhibitors of angiotensin-converting enzyme (Cushman et al., 1987; Fournie et al., 1996). The structural information obtained from molecular and biophysical studies when combined with bioinformatics and computational approaches followed by the amalgamation of knowledge from synthetic chemistry will paves a pivotal role in the discovery of potential drug molecules which could be effective and safer.

The structural information of the membrane proteins which are involved in the cellular networking is very essential to understand the cellular machineries. The information about the structure of membrane proteins, their regulation and interacting partners forms an important basis to discover new therapeutic targets. Membrane proteins play a crucial role as transporters and also acts as co-players in the cellular metabolic activities. Such membrane transporter proteins can be targeted for the development of novel drugs.

Most of the protein targets where the drugs are supposed to bind are classified into four different types such as (1) Receptors, (2) Enzymes, (3) Ion channels and (4) Transporters. Majority of these targets includes the membrane integral proteins only rather than the cellular components. Such membrane integral proteins are involved in wide variety of metabolic networks and processes and represent themselves as plethora of molecular targets for pharmacological interference. The structural information of such membrane proteins with high resolution in the cell membranes is highly significant to develop novel drugs with high potential and specificity. Such information also provides an insight into the understanding of molecular mechanisms involved in cellular networks and functions.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Therefore the structural biology concepts such as theoretical predictions and three-dimensional structural information are becoming more significant criteria in present days.

Drugs and Membrane Proteins

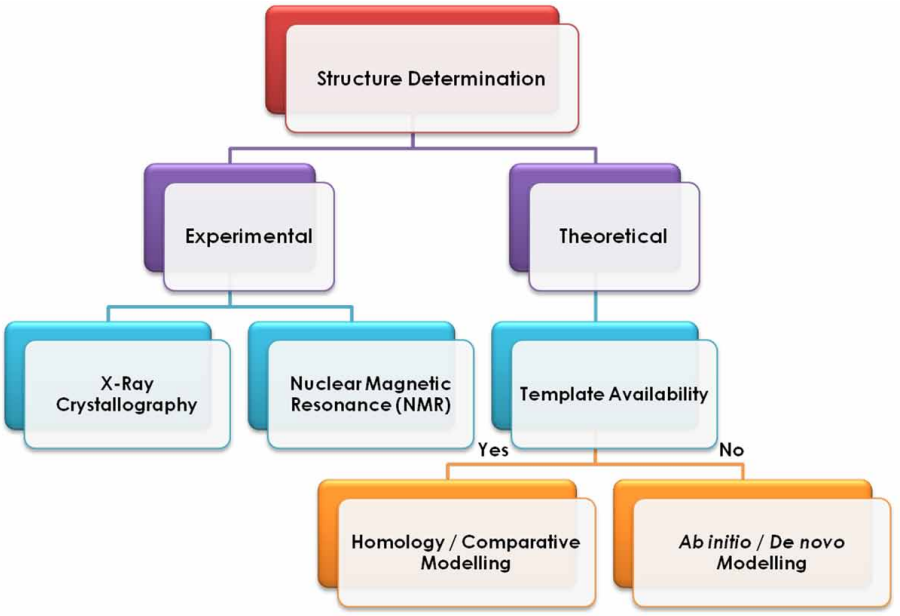
Several transporter membrane proteins are targeted so far and the drugs were discovered based on their structural information and the most important target among them are the ABC transporters (Leslie et al., 2005). There are justifications why the drugs are specifically to be targeted on membrane proteins and primary reason is that, several diseases are caused by mutations in the membrane proteins such as neurological disorders; schizophrenia and depression are due to mutations in the iron transport channels. Mutations in the ABC transporter protein system cause cystic fibrosis. The next important reason is more than 50% of known drugs binds to the membrane proteins on the surface of the membrane. If better drugs are to be discovered by aiming a disease, actual molecular structure of the drug molecule and its intermolecular interactions are required. Such structural information assists to develop better drug molecules with improved activity. Hence membrane proteins could be the major determinants of pharmacokinetic, safety and efficacy profiles of drugs (Giacomini et al., 2010).

Drugs will have their own specific way in the membrane proteins and according to their solubilities they distribute in the hydrophobic regions of the structure. Not only this, several questions also to be justified for a successful drug discovery such as selection of specific membrane transporter protein that should be clinically important in drug absorption and disposition. This will also clarify what kind of *in vitro* mechanisms are to be chosen. Specific attention has to be paid for the transporters that are confined to the epithelia of the intestine, liver and kidney, and in the endothelium of the blood–brain barrier.

MODELLING OF MEMBRANE PROTEIN STRUCTURES

Molecular modelling is not only a robust method for generating the theoretical models of proteins it is also an integral part of crystallography and Nuclear Magnetic Resonance (NMR) structure determination techniques. Experimental determination of membrane protein structures and their complexes is extremely a difficult task and more over the problem hinders with the size of the membrane protein also. The Membrane proteins represents approximately one third of the total encoded proteins of human and other genomes, but the currently available crystallographic structural information of membrane proteins is very limited (Frishman & Mewes, 1997; Wallin & Von Heijne, 1998). Many important puzzles in biology, chemistry and medicine remain unsolved because of limited understanding of the membrane structures, behaviour and their molecular interactions.

Usually the integral membrane proteins have two types of conformations such as (1) α−helices and (2) β−barrels. Till now it has been observed that the plasma membrane and reticulum membranes of eukaryotes contain α−helices whereas the β−barrel conformations are observed mainly in the proteins of outer membrane of gram-negative bacteria, mitochondria and in chloroplast membranes (Basyn et al., 2003). The α−helical conformations contain usually long hydrophobic helical structures and densely packed together. β−barrel conformations are very huge proteins possessing anti parallel β−sheets those folds into a barrel shape and closed by the first and last β−strands (Oberai et al., 2006; Elofsson & Heijne, 2007). In a protein with known amino acid sequence and unknown structure and function, the long run hydrophobic residues that represent spanning regions of membrane can be recognised easily in the



EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

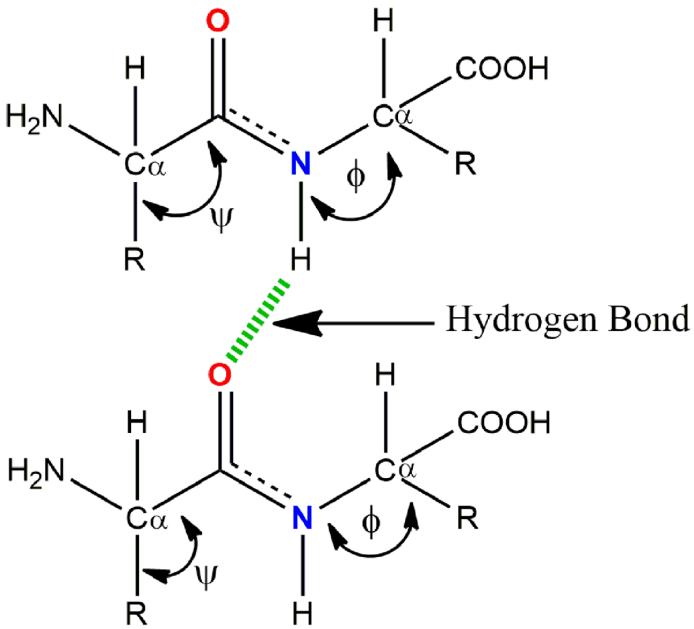
sequence than the less hydrophobic trans-membrane β-strands. *In silico* approaches works best for the prediction and identification of such membrane spanning α−helical bundles and β−sheet barrels. As it is difficult to determine the 3D-structure of an integral membrane protein experimentally, prediction of such secondary conformational elements from the sequence information helps best for the annotation of protein sequences to membrane protein families. Such information when combined with the recognition of structural motifs by bioinformatics approaches provides valuable structural information that will also helps to determine the function (Amico et al., 2006; Granseth et al., 2006). *In silico* methods offers robust methods and algorithms for the accurate construction of protein models.

The molecular structure of a membrane protein contains very essential information such as architecture of active sites on the surface of membrane, possible binding sites for ligands and antigens and evolutionary determinants. Such information from membrane protein structure is utilised for several proteomic approaches and designing of successful experiments. The electrostatic properties and the orientation of the membrane protein structure are essential to understand its interaction with its interacting partners which are all involved in the regulation of metabolic activities. Hence it is very essential to acquire a three dimensional structural information of a membrane protein.

Experimentally the membrane structures are determined and solved by either X-ray crystallography or by NMR method. Computationally, there are two main popular ways to construct the membrane models and even applicable universally for all the proteins. The first one is the homology or comparative modelling and the other is *Ab initio* or *de novo* modelling. Homology modelling is strictly based on the scaffold of the existing structure with homology, nothing but a template and the *de novo* modelling is based only on the sequence information where the propensities of each amino acid is taken into consideration that tends to form a specific kind of conformation (Figure 2). There will be other consideration such as prediction of secondary structure and membrane spanning regions before constructing the final three dimensional model.

Figure 2. Criteria and methods involved in the protein structure determination

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



Irrespective of the model chosen for the prediction of theoretical models for a specific protein, certain preliminary analysis is required to be done to acquire a reliable and accurate model without any obligations. Such criteria are discussed in detailed as follows.

Secondary Structure Prediction

Before proceeding for the construction of a three dimensional conformation of a protein, it is mandatory to determine their secondary conformations. These secondary conformations only further folds into a three dimensional conformations producing a functional protein. Hence the secondary conformational elements such as helices, sheets, turns and coils are the basements to build a perfect conformation of any protein. The multiple conformations of a protein are possible due to the rotation of CΨ and CΦ angles of peptide bond. Each amino acid with its specific R-group has its own role to form a specific kind of secondary conformation. The secondary structure is popularly said to be a local conformation of a polypeptide chain that is strictly formed and stabilised by hydrogen bonding. A hydrogen bond always forms in between the carbonyl oxygen of one peptide bond and amide hydrogen of another peptide bond by means of a hydrogen atom (Figure 3). These are the responsible factors for the stability of any secondary conformation of a protein.

A α-helical conformation forms when n^{th} peptide bond forms H-bond with $n+4^{th}$ peptide bond whereas a β-conformations forms when H-bond forms between a normal of 5–10 sequential amino acids in one bit of the chain with another 5–10 more remote down the chain. Loops are the locales of a protein chain that are between α helices and β sheets, of different lengths and three-dimensional arrangements, and on the surface of the structure. Hairpin loops that cause a complete turn in the polypeptide chain joining two anti parallel β strands may be as short as two amino acids long. A locality of auxiliary structure that is not a α-helix, a β-sheet, or a conspicuous turn is ordinarily eluded as a coil. All these types of

Figure 3. Formation of Hydrogen bond between two peptide bonds

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

conformational elements are taken into consideration while prediction of a full pledge secondary conformation from a given amino acid sequence. This will paves a reliable way for the next step to predict accurate three dimensional conformation of a protein.

Several secondary structure prediction methods were introduced in the early 1960 itself (Guzzo, 1935; Kotelchuck & Scheraga, 1969; Lewis et al., 1970; Prothero, 1966; Schiffer & Edmundson, 1967) relying on the recognition of likely α-helices and were constructed principally in light of helix-coil conversion models. More precised expectations that included β-sheets were presented in the 1970s and depended on measurable evaluations in view of likelihood parameters got from known comprehended structures. The transformative conservation of secondary structures can be abused numerous homologous sequences in a diverse sequence alignments, by computing the net optional structure inclination of an adjusted segment of amino acids. Working together with bigger databases of known protein structures and cutting edge machine learning routines, for example, neural networks and support vector machines, these strategies can accomplish up to 80% accuracy rate (Dor et al., 2006).

Algorithms in Secondary Structure Prediction

Chou-Fasman Method

The Chou–Fasman system is an experimental method for the prediction of secondary conformations in proteins, initially grew in the 1970s by Peter Y. Chou and Gerald D. Fasm (Chou & Fasman, 1974, 1978). The technique is in light of examinations of the relative frequencies of every amino acid in alpha helices, beta sheets and turns taking into account known crystal structures of proteins. From these frequencies an arrangement of likelihood parameters were inferred for the presence of every amino acid in every secondary structure, and these parameters are utilized to anticipate the likelihood that a given succession of amino acids would shape a helix, a beta strand, or a turn in a protein. The parameters discovered some solid propensities among individual amino acids to incline toward a specific kind of structural conformation over others.

GOR Method

The GOR method (Garnier-Osguthorpe-Robson) is an information theory-based method developed in the late 1970s (Garnier et al., 1996). This system is in light of likelihood parameters got from exact investigations of known protein tertiary structures from X-ray crystallography. Nonetheless, not like Chou-Fasman, the GOR technique considers not just the propensities of individual amino acids to frame specific secondary structures, additionally the contingent likelihood of the amino acids to shape a specific secondary structure given that its quick neighbours have effectively framed that structure. This technique dissects successions to anticipate alpha helix, beta sheet, turn, or arbitrary coils at every position in view of 17-amino-acid sequence windows. The unique explanation of this method is, it includes four scoring matrices with a size of 17×20, where the columns correspond to the log-odds score that reflects the likelihood of judging a certain amino acid at each position in the 17-residue sequence. The four matrices imitate the probabilities of the vital, ninth amino acid tends to be in a helical, sheet, turn, or coil conformation. This method was considered as finest requiring at least four neighbouring amino acids to attain alpha helices to organize the region as α-helical, and at least two adjoining residues for a β-sheet.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Machine Learning

Such methods popularly include Artificial Neural Networks (ANNs) and Support Vector Machines (SVMs). ANNs are a group of statistical learning models enlivened by biological neural networks and are utilized to estimate functions that can rely upon large quantity of inputs and are usually anonymous. They use the training set formed from experimental structures and investigate the similar sequence motifs connected with certain arrangements of secondary elements. SVMs have been demonstrated especially helpful for predicting the areas of turns, which are hard to identify using statistical methods. All machine learning strategies endeavour to predict the more fine-grained nearby properties of proteins, for example, backbone dihedral angles in unassigned areas (Kuang et al., 2004; Zimmermann et al., 2006).

Servers for Secondary Structure Prediction

A wide variety of servers are available for the prediction of secondary structures from a given protein sequence among which some are listed as in Table 1.

Transmembrane Prediction

The most important task in the membrane protein modelling is the identification of transmembrane regions. Several factors are to be considered for predicting membrane spanning regions. The free energies are summed over residues of 10-15 and the regions with high hydrophobicity are considered to be in the membrane. This idea works well with helical structures as all the residues present in the helix will have same kind of hydropathy scales. But this type of prediction is unable to work out to predict the membrane spans beta conformations. Utilising the evolutionary information from multiple sequence alignments and using machine learning approaches helps to predict transmembrane regions accurately. Several tools and servers exist based on these approaches that can predict the perfect topology of the membrane protein. The perfect orientation of membrane protein i.e. external regions, spanning regions and inside regions will be predicted based on the propensities, artificial neural networks (ANN), hidden markov models (HMM) and support vector machines (SVM).

Some of the online tools available for the prediction of transmembrane regions are given in Table 2.

Once the secondary structure and transmembrane spanning regions are predicted from a given sequence, the next step is to move towards the prediction of tertiary structure. It can be done in two methods i.e. homology modelling and de novo modelling.

Homology Modelling

Homology modelling otherwise called as comparative modelling is a most widely used popular method to construct the protein models based on the template similarity. This method is very important in case of membrane proteins as the experimental determination of their structures is prohibitively time-consuming and tough task (Wieman et al., 2004). Homology modelling found very important for membrane proteins as many of them such as ion channels are the primary drug targets for wide variety of diseases.

Unfortunately there are very less reports on the homology modelling of the membrane proteins which is due to several factors such as lacking of proper template, unambiguous prediction methods, poor resolutions, high rate of errors in model validation etc. Recently, there is an extensive increase in the number of structures in the PDB database that helps to analyse the hydrophilic surface areas and hydrophobic interiors based on the structural information but rather than the sequence information alone. Although the number of crystal structures is being increased in the PDB, membrane proteins are found to have poor resolution where 10% of available membrane structures have a resolution ranging from 3-4 Å. This situation made the homology modelling as an exceptionally significant task to construct their 3D models and also for the refinement of existing crystal structures with poor resolution (Sanchez et al., 2000). There are several steps for the prediction of membrane protein structures which are explained as follows.

Template Selection and Alignment

A template is the mandatory element to construct a homology model of a protein. The template should have high similarity to the target so that high quality model will be produced. Sequence coverage is also an important point under consideration during template selection. A template assuring a minimum of 98% coverage is responsible to produce the overall reliable quality of the model. A template with a similarity of 70% produces a model with an RMSD of 1-2 Å where as the low similarities of templates ranging around 25% will produce a model with an RMSD of 3-4 Å.

The quality of sequence alignment between the target and template sequence will decide the quality of the final model where the quality of the alignment is improved by BLOSUM and PAM matrices. But for the membrane protein alignment there is specific matrix for the improvements of alignments such as PHAT (Ng et al., 2000) that utilises the membrane protein specific substitutions and PRALINETM (Pirovano et al., 2008) is an example that utilises such matrix. JSUBST (Shi et al., 2001) is another membrane specific substitution matrix which is amalgamated with MP-T (Hill & Deane, 2013) tool that is a sequence-structure alignment tool. This tool also considers other environment factors such as

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

secondary structure, membrane spanning region and solvent accessibility regions such as intra cellular and extra cellular regions.

In many instances membrane proteins does not have any suitable templates for the entire sequence and in such cases discontinuous templates may be available. Discontinuous templates have similarity with the target protein at multiple locations rather being at a confined location and such templates may be from different sources. So such cases demand the use of multiple templates to construct the final model. Such methods are called as threading methods that utilises the alignment between target and multiple templates. Further sequence-structure alignment followed by scoring functions which are based on the factors such as secondary structure, residue pairing and mutatability produces a quality model.

Model Construction

Once the improved alignment has been generated, it can be used for the construction of homology model of the target using any homology modelling tools. Several tools are available for the homology modelling and some of them are given as follows.

- **RosettaMembrane:** This is the most reliable and oldest tool available for the membrane protein homology modelling. This tool is also able to model the open and closed conformations of the ion channels (Yarov et al., 2005).
- **MODELLER:** This is the most popular tool in the present days both in the modelling and experimental areas. This tool constructs the models by satisfying the spatial constraints derived from sequence alignment (Eswar et al., 2006).
- **MEDELLER:** This is a coordinate generation tool especially used for the membrane proteins. This tool works in conjunction with other tools like MEMOIR, HHPred and SWISS Model.

The overall outline of the homology modelling is represented in Figure 4.

De Novo Modelling

De novo modelling is an alternate to homology method where it is preferred when no suitable template is available for the construction of reliable model. De novo modelling works with the propensity of each amino acid in a protein sequence and build a specific kind of secondary structural conformation and produce the model. De novo methods able to predict the tertiary structure of a protein based on the sequence principles which are basis for protein folding energetics and statistical tendencies of conformational characteristics that experimental structures possess and never rely on template information. Amino acid sequence is the best and sole starting material for the de novo predictions.

De novo prediction algorithms usually predicts the structure initially by producing the multiple conformations of the protein and chose the best amongst based on the thermodynamic stability and energy levels. Most of the de novo prediction servers considers the following factors, (1) Accurate energy function that filters thermodynamically stable conformation and resembles to native structure (2) A potential search method for the quick identification of low energy conformation (3) Ability to select most near native conformation among multiple conformations.

The outline of de novo modelling method is represented in Figure 5.

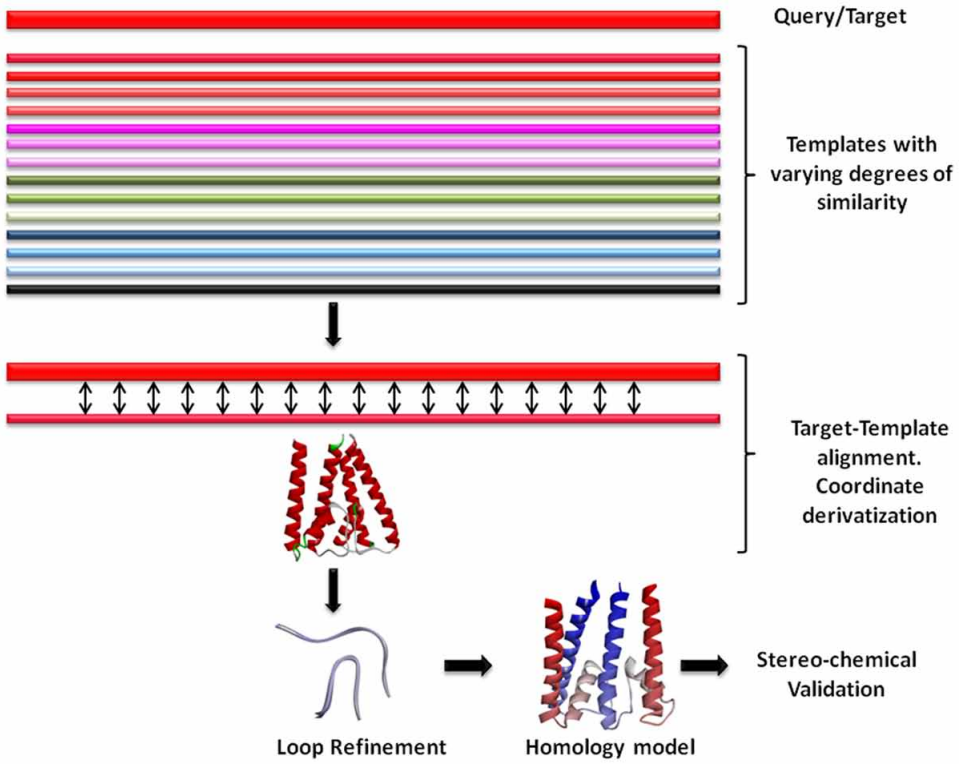
Figure 4. Outline of homology modelling of membrane proteins



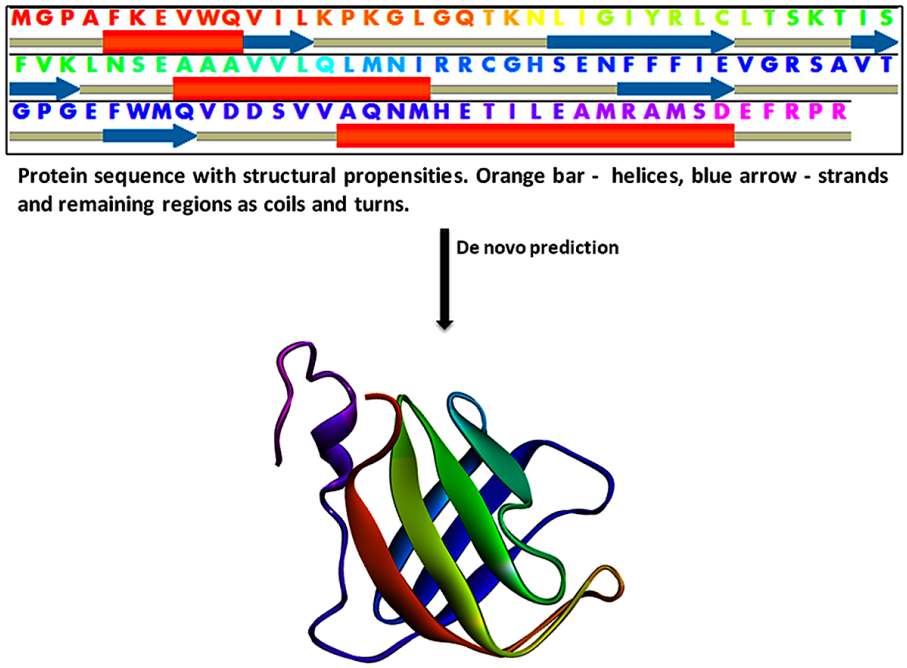


Figure 5. Outline of de novo modelling

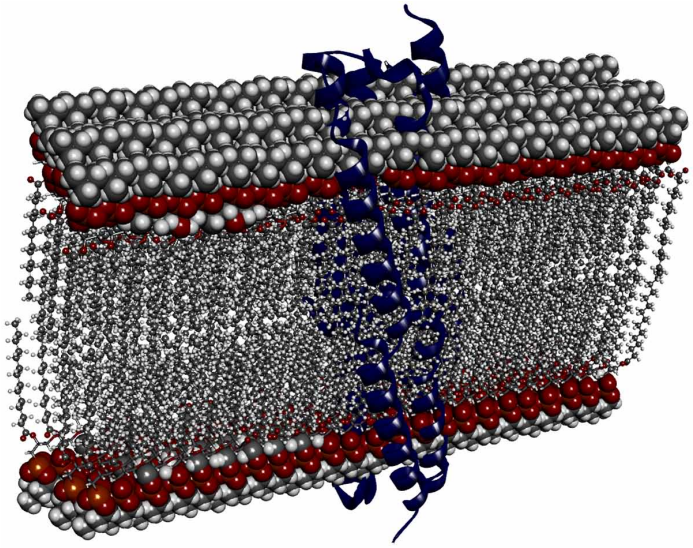
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

De novo prediction uses the strategies such as,

- **Ab Initio:** Initially the secondary structural propensities such as helices, sheets, coils and turns are elucidated from the primary sequence based on the physico chemical properties and neural net algorithms. Based on this information the tertiary folding will be determined.
- **Fold Prediction:** This method also initially predicts the secondary structure information and compare with the existing protein fold libraries such as CATH and SCOP databases.
- **Threading:** The fold recognition process is progressed to threading where the interaction of residue pairs is used based on the empirical energy functions and placed onto a putative backbone of the protein utilising the gaps and gap penalties.

The main disadvantage of de novo prediction methods is they require huge amount of efforts and computational time for the successful prediction of near native conformation of the protein. Few examples of de novo modelling servers are given in Table 3.

MOLECULAR DYNAMICS OF MEMBRANE PROTEIN MODELS



The majority and comprehensive information about the theoretical models of ion channels well provides by Molecular Dynamics (MD) simulations. The present available MD methodologies are capable to generate the trajectories that are very close to the realistic atomic models of typical biological membrane channel systems. MD simulations can be used to discover detailed atomic information about the molecular mechanisms behind the function of a specific membrane protein such as ion transport, selective entry and voltage gating of channel proteins. Although there is a vast improvement in the MD simulations of proteins of different sizes for the past two decades, still it remains as a challenge with the membrane protein simulations. The heavy size of the membrane proteins limiting the success rates of the simulations and several approaches are being put forward to solve the critical hindrance arising with membrane proteins. One such a solutions is limiting the size of protein to the short possible fragments and proceed for simulations. The complex membrane structure may be broken down into smaller fragments of specific importance such as function, domain, and structural elements so on. Such significant fragments are then added with membrane layers around and subjected to simulations to observe their behaviour in an isolated environment (Figure 6). Another important solution is the time scale of production phase, where the simulations can be carried out for a longer period rather than the traditional time

Figure 6. Alignment and orientation of a membrane protein into the lipid bilayer

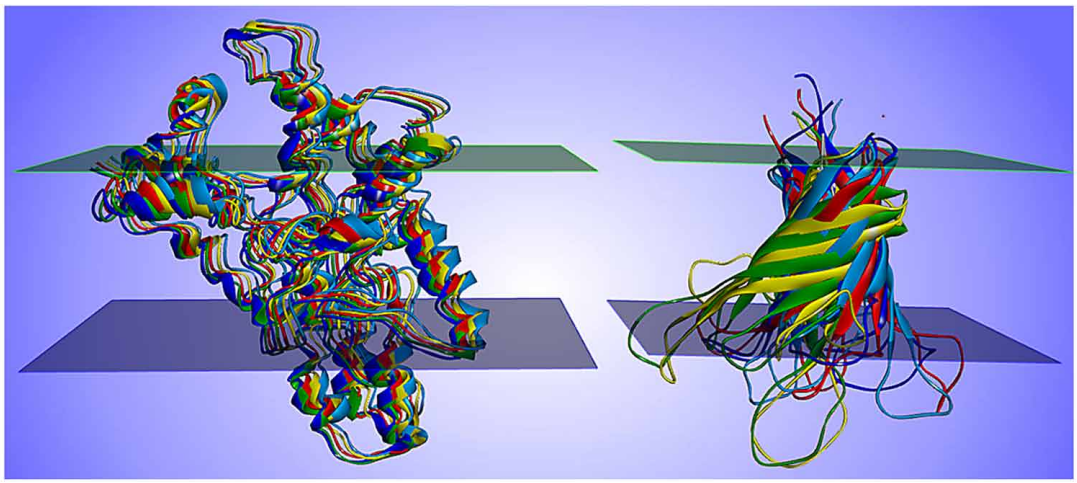
boundaries where a steady state is keep on monitored. The production phase may be terminated when a steady state is attained. It is applicable for the simulation of all proteins irrespective of their size, but the limitation could be the time factor needed for the computation. This situation will also demand the high end computing systems for the successful simulations.

Force Fields and Softwares

The folding of membrane proteins at the atomic levels in explicit membrane proteins proves challenges and basic problems with the specific force fields and simulation algorithms (Nymeyer et al., 2005; Ulmschneider & Ulmschneider, 2009). Employing new lipid force fields by the concern of the detailed atomic partitioning and folding of individual transmembrane regions into explicit lipid regions helps to achieve successful unbiased long time MD runs (Ulmschneider et al., 2011). Coarse-grained MARTINI force field is the most acceptable method developed specifically to model explicit lipid bilayers (Marrink et al., 2004). This force filed is used extensively to study the membrane bilayer parameters such as raft formation, membrane joining and membrane interactions. This force filed is more popular to study the large scale MD systems especially drug delivery strategies through lipid bilayers. To study the molecular mechanism of membrane folding, partitioning and it's inter molecular interactions requires detailed representation of hydrogen bonds at atomic level. This force filed will uncover the mechanisms behind ion transport, specificity, selectivity and gating properties of membranes. Several most common force fields are also available such as AMBER (Wang et al., 2004), OPLS (Jorgensen & Tirado, 1988) and CHARMM (Karplus, 1983) for the past few years. Highly accurate lipid parameters are added for these force fields in the recent years that made them to utilise for the simulation of membrane proteins with a variety of atomic models. But all these force fields are supplemented with MARTINI force field that has coarse-grained representations of proteins and lipids. Finally all the kinds of force fields are available with several kinds of software packages. The best example of such package is GROMACS (Van et

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

al., 2005), fastest and most popularly used package. Other best examples count with NAMD (Phillips et al., 2005) and Desmond (Shaw, 2005) which are also fastest but not used as popularly as GROMACS.



Several methods are in progress for the acceleration of MD simulations at faster rates in addition to the general approaches discussed above. One such popular method is replica exchange sampling or parallel tempering that creates indistinguishable replicas of an MD system which are simulated in parallel manner with an exponential ladder of temperature. The replicas are swapped at regular intervals using Monte Carlo approach and speed up the transitions towards near native state. Another related method to accelerate the MD process is using the elevated temperature ranges. This method is preferred during the unbiased partitioning of peptides into membranes. But the experimental confirmation of high thermo stability of the peptide is required. Equilibrium MD method is best suitable to accelerate the MD simulations of low energy conformations.

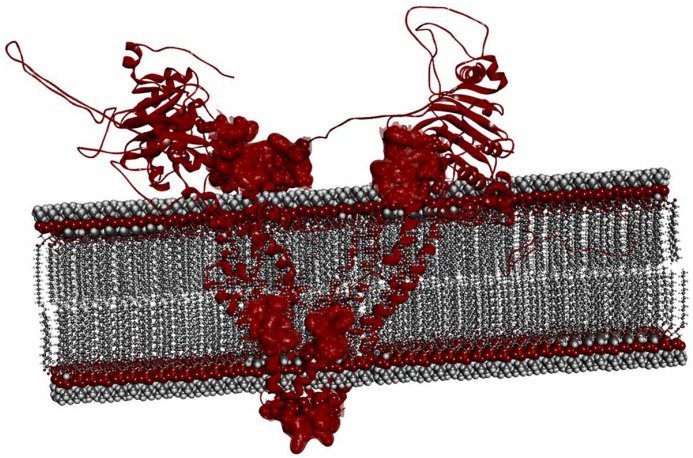
Conformational Analysis

Although the structure of a membrane protein is determined, it is not sufficient to predict its function. A single protein structure represents only a discrete conformational state and it never represent itself as a sole maker of its function, interaction with other molecules and its regulation by other elements in the bilayer. To understand the function of a membrane protein, different conformational states are needed which is hard to capture (Figure 7). The structure of a particular conformation can be characterized by altering the variable interactions and a specific snap shot of interest could be trapped. The function of membrane protein can be modulated by its properties such as energy levels and charge distribution. In addition the spring constant of the lipid bilayer also induce the changes in conformation and properties of a membrane protein. These specific considerations help to trace the required conformation of the protein that can be used for the interpretation of the function.

These computational studies of membrane protein modelling even though a challenging effort, a prospective and massive progress has been made in the field of computational modelling. So far the major efforts were put on the homology models whereas de novo modelling with a special concern with

Figure 7. Membrane proteins with multiple conformations represented in multiple colours

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



membrane proteins has yet to be progressed to a maximum extent. As of now we are able to model the membrane proteins in a coarse grained process further research is likely to focus on predicting the function of a membrane protein from multiple functional states of the protein. In addition the structures are needed to represent at high resolution both for protein and lipid bilayers.

PREDICTION OF BINDING SITES

The next challenging task with the membrane proteins is accurate prediction of binding sites that offers sites of interactions and molecular passages. Prediction and blocking of specific binding sites makes them efficient targets for several drugs especially the membrane proteins of potential pathogenic organisms. The ideal membrane protein models with explicit water molecules both inside and outside and with added phospholipid bilayer are the only perfect starting materials to find out such potential sites (Bordner, 2009). Like cytosolic proteins, it is not an easy task to predict the binding sites based on the cavities information obtained from the three dimensional models. Membrane proteins have a peculiar compartmentalized composition and orientation. The initial challenge is associated in solving the different regions of the membrane proteins, where such region/segment of the membrane protein has its own function. Then those regions with functional significance can be used to find out the binding sites. The actual challenges are concurrent with the accurate prediction of transmembrane, extra and intra cellular regions. Extra cellular regions are associated with protein-protein interactions especially involved in signal transduction and also offer specific sites as pores where the ions/molecule come and sits then enters the pore channels. Membrane regions are to be monitored to find out such pore regions where the channels are formed especially by beta barrel structures. Further the intracellular regions are to be concentrated where the pores opened into the cytosolic regions and also offers sites for the interactions with intracellular components that may be either proteins or small molecules. All these criteria are to be considered for the perfect prediction of binding sites (Figure 8).

Membrane proteins forms complexes with other molecules to perform their functions where the structural information about such interactions is helpful to generate experimentally acceptable hypoth-

Figure 8. Predicted binding sites in a membrane protein highlighted as surface clouds

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

eses which also further helps for structure based drug designing methods. The computational methods can address to predict the appropriate residues on the surface of membrane proteins which are involved in the interactions. Such predicted residues can also be used as constraints for the molecular docking processes such as protein-ligand or protein-proteins interactions. Presently available computational tools are able to predict the binding sites on the membrane proteins based on two approaches; (1) sequence based, and (2) structure based.

Sequence based approaches are applied only when no structural information is available and even no template structure is available. Structure based methods provide additional information such as solvent accessibility and residue proximity in the three dimensional orientation of the molecules. Structure based methods relies on the scoring functions, ANNs and SVMs that were trained on various properties for the efficient prediction of binding sites. But the problem lies with the membrane proteins especially with the intra membrane regions. The above said methods are well works with non-membranous proteins as they are trained on more experimental structures available. This situation now can demand the separate predictors that are trained on the specific class of membrane proteins. Random forest prediction methods came into existence that made for individual surface residues which then are averaged above a local surface region and a final prediction set is prepared.

MOLECULAR DOCKING OF MEMBRANE PROTEINS

The final great challenge is, finding the perfect intermolecular interactions with protein partners and small molecules. If the above steps are followed stringently, then this task will be facile and the result will be veracious (Deepshikha, 2002). There will be bit variations in the parameters to be chosen while setting a docking process for membrane protein. First, the site of interaction, nothing but the binding site and its location whether it is present in water or lipid environment. The interaction will be completely different as the hydrophillicity and hydrophobicity greatly alter the interaction mechanisms. Some sites will be spanning both membrane-intracellular and membrane-extracellular regions. Such situations are crucial to specify what kind of environment or force-fields. Membrane protein docking is more trivial as the length of transmembrane regions is not conserved and structural elements occasionally contain bulges and kinks that will challenge the perfect molecular interactions. Another challenge exists with numerous and diverse conformations with near similar energies and RMSD values (Nygaard et al., 2013). Choosing a correct one from thousands of likely conformations is of greatest challenge to proceed for docking. The next provoking challenge exists with multiple loops which are also involved in the generation of kinks in the structure and disturb the local conformations and interrupting the ensemble stabilization (Klco et al., 2005). These investigations and technical considerations may probably provide immense opportunities to understand the basic signalling that are useful to develop pharmacological tools and drugs that modulate function of membrane proteins which could be therapeutic effects. The molecular models of docking complexes provide vast opportunities for the fundamental understanding of signalling processes and help to develop pharmacological agents and drugs that modulate function of membrane proteins.

The docking methods such as DOCK, LibDock, CDOCKER and GOLD with their different scoring functions are used to predict small molecule interactions in the binding sites of membrane proteins both in intra and extra cellular regions. The binding affinity estimations relies on the scoring functions whereas the binding orientations on the docking methods. Regression-based scoring functions are used to estimate the binding affinities using the interaction terms derived from experimental complex struc-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

tural parameters. Regression methods give weights by fitting predicted and experimentally determined affinities to the training set complexes (Bohm & Stahl, 1999). The size and composition of the training set also a major concern to derive the weights. But the drawback is any new molecular scaffolds will be ignored that were absent in the training set complexes (Tame, 1999). Principle based approaches also calculate binding free energies based on the individual contribution of intermolecular interactions between the protein and ligands that are derived from physico-chemical theory and are not based on experimental data. The implicit solvent methods like Possion-Boltzmann and surface generalized born methods are used to calculate the salvation energies (Shoichet et al., 1999).

The flexibility of the integral membrane regions of the protein and their inter molecular interfaces influences the binding affinities and specificities of the ligands and their recognitions. The stabilities and flexibilities of the membrane structures during the molecular recognitions interfere with the binding energies and contact surface areas that could be linked with several functions such as specificity and permissiveness in recognition. All such points complicate the correct orientations of the protein-ligand complexes especially in the instance where the flexible binding sites in the membrane are unknown. Hierarchical approaches solve such problems to an extent by the consideration of the flexibilities of both the ligand and membrane proteins. Such approaches include multistage docking methods and hierarchical energy functions.

CONCLUSION

Membrane proteins have major problems especially construction of theoretical models, binding site prediction and molecular docking that are complicated by the flexible moments and multiple conformations of the huge membrane structures. Application of computational methods to solve the membrane protein structures and their conformational analyses were discussed in detail in a technical manner so as to give a clear glance to the readers. The methods were explained to construct the complete structure of huge membrane protein models in fragment based methods, combining and analysing them and choosing the possible reliable model. A range of molecular dynamics simulations were explained specific to membrane proteins to study the relevant moments and multiple conformations in the membrane regions. Further coarse grained methods are discussed to model, simulate, analyze and to predict probable binding sites. Such a specific analysis helps to predict the function of several membrane receptors in a less time.

Chapter 30
Molecular Docking Challenges and Limitations

Jahan B. Ghasemi

ABSTRACT

Today, the development of new drugs is a challenging task of science. Researchers already applied molecular docking in the drug design field to simulate ligand- receptor interactions. Docking is a term used for computational schemes that attempt to find the "best" matching between two molecules in a complex formed from constituent molecules. It has a wide range of uses and applications in drug discovery. However, some defects still exist; the accuracy and speed of docking calculation is a challenge to explore and these methods can be enhanced as a solution to docking problem. The molecular docking problem can be defined as follows: Given the atomic coordinates of two molecules, predict their "correct" bound association. The chapter discusses common challenges critical aspects of docking method such as ligand- and receptor- conformation, flexibility and cavity detection, etc. It emphasis to the challenges and inadequacies with the theories behind as well as the examples.

INTRODUCTION

Molecular recognition plays a key role in promoting basic biomolecular experiences such as drug-protein, enzyme-substrate and drug-nucleic acid interactions. Detailed understanding of the general principles that administrate the nature of the interactions (van der Waals, hydrogen bonding, electrostatic) between the ligands and their protein or nucleic acid targets may present a conceptual support for designing the desired potency and specificity of potential drug leads for a given therapeutic target. Practical application of this knowledge requires structural information for the target of interest and a route for evaluating

candidate ligands. To this end, a variety of computational docking methods are available(Mohan, Gibbs, Cummings, Jaeger, & DesJarlais, 2005)

Among the vast studies, there are several reports that represent molecular docking as worthwhile strategy to predict 3D structures of complexes. Molecular docking can overcome to experimental complications surrounding the structure determination of complexes, and can give valuable structural insights on biomolecular interactions. However, the process of binding a small molecule drug to its protein target is not simple; several factors affect on the interaction between two molecules, so these methods can be improved as a solution to docking problem. Despite great developments and achievements, the widespread application of docking methods, and the accurate and rapid prediction of protein–ligand interactions is still a challenging area to explore and some downsides still exist. The flexibility or mobility of both ligand and target, the effect of the protein environment on the charge dispersal over the ligand, and their interactions with the surrounding water molecules, complicate the quantitative description of the process.

This chapter reviews the literature in the last decades to account for the various abilities, limitations and challenges of the currently widespread applied algorithms which presently characterize this methodology. It introduces some efforts of drug developers for the improvement of algorithms to overcome the shortcomings and to enhance the computations for the incorporation of both ligand and receptor flexibility in the docking process, careful exploration of the ligand conformation within the binding site and improving complementarity between them, refinement and stability evaluation of the final complexes and thus accounting for induced fit. The discussion will further be limited to protein-small ligand complexes, omitting macromolecular complexes; however, much of what is presented here is also valid for that class of complexes.

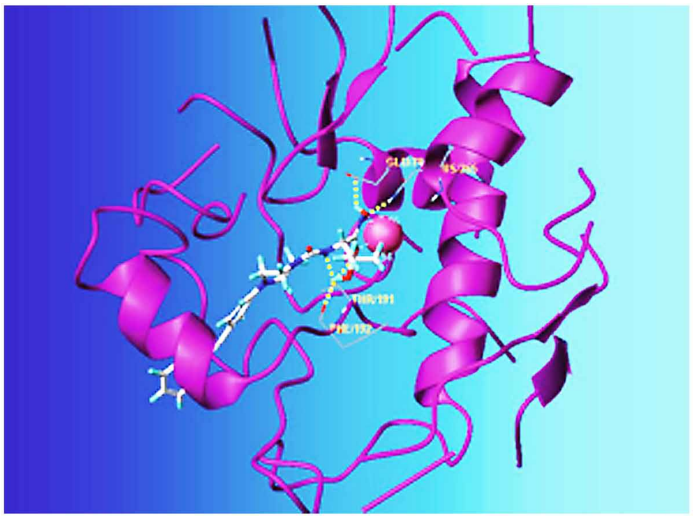
The chapter handles some critical problems of docking calculation such as the lack of speed, accuracy, protein flexibility and ligand sampling with somewhat aspects of fundamental basic concepts such as movements of side chains and the biased selection of ligands as a result of using ligand-bound protein structures during a docking process or mis-docking ligand. As mentioned before, something of the recent advances provide on the ligand sampling, protein flexibility, and scoring functions as important features in protein-ligand docking. Three types of ligand sampling algorithms will be discussed; shape matching, systematic search, and stochastic algorithms. Computational efficiency for each algorithm is represented according to their main advantages and disadvantages. Covalent docking is another issue of molecular docking which is to be considered in the last part. Authors hope that the recently published papers on covalent docking give insights on biomolecular interactions to the readers.

BACKGROUND

Mutual molecular recognition is the initial point for approximately all processes in biological systems. Today, molecular docking as a very demanding computational and algorithmic tool plays a fundamental and advanced role in structural molecular biology and drug design. These computational tools help us for understanding molecular interactions of two molecules such as protein–protein or protein–ligand that is a key for the understanding of chemical process in diseases and other life issue occurrence. Molecular docking has a wide range of potential uses and can be applied in the following fields of drug discovery:

- Structure–activity studies
- Lead optimization

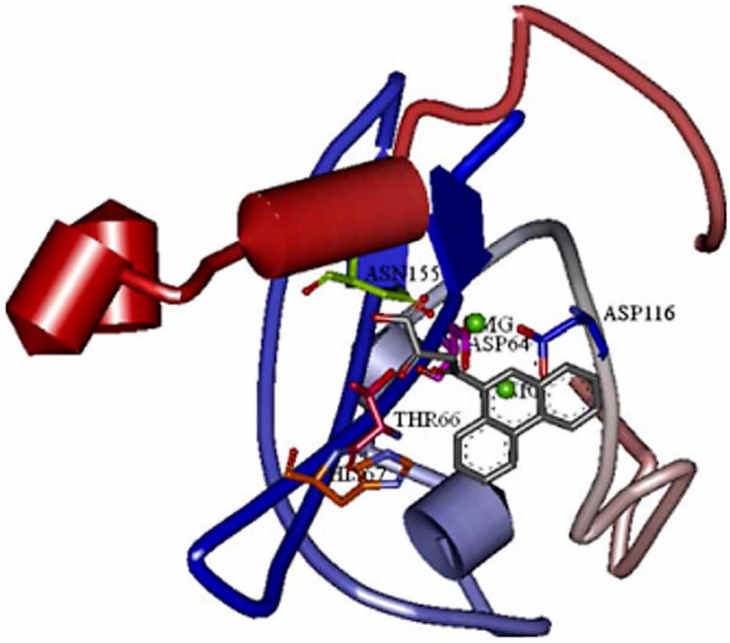
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



- Finding potential leads by virtual screening
- Providing binding hypotheses to ease predictions for mutagenesis studies
- Helping x-ray crystallography in the fitting of substrates (Figure 1 shows a x-ray crystallography structure as PDB) and inhibitors to electron density
- Chemical mechanism studies
- Combinatorial library design

Molecular docking techniques are designed to aid the development of therapeutic agents via predicting of positioning of a small molecule (ligand) when it is bound to a protein receptor or enzyme, and to find most stable conformation of a ligand and its target macromolecule or receptor. However, in a docking process study, both molecules are flexible and may alter each other's structure as they interact:

- Hundreds to thousands of degrees of freedom
- Total possible conformations are astronomical



Docking is an important *in silico* method widely used for recognizing drug led by 3D docking ligand to the three dimensional structure of a pre-choose target site continued with the optimization of binding configurations and assessment of binding possibility based on paired molecular interactions (Gozalbes *et al.,* 2008; Kitchen, Decornez, Furr, & Bajorath, 2004). Docking process is a combination of a search algorithm and a scoring function that attempt to find the "best" matching between two molecules: a ligand and a receptor. Now a relatively big and ever growing number of search algorithms and scoring functions are accessible. Reasonably, the best solution would be to associate the ideal searching algorithm with the ideal scoring function. Figure 2. Indicates an example of the best docking corresponding to the ideal scoring function. However, numerous studies have shown that the performance of docking is greatly depend on the specific features of both the binding site and the ligand to be explored, and that

Figure 2. The best docked conformation of one of the most active compounds, (compound 141) in the active site of IN
Ardakani and Ghasemi (2013)

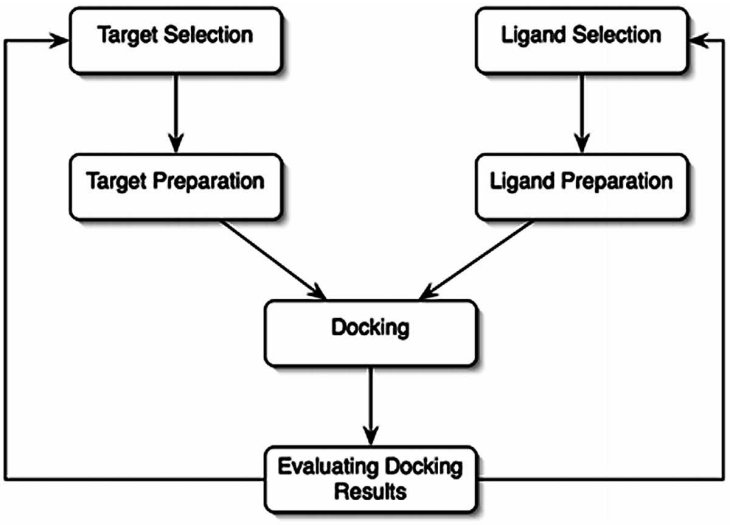
establishing which method would be more appropriate in a precise context is nearly difficult (Sousa, Fernandes, & Ramos, 2006). The molecular docking problem can be defined as follows: Given the atomic coordinates of two molecules, predict their "correct" bound association. In its most general form, no additional data are provided.

The present field mainly adapts to dock small molecules into macromolecule target especially protein molecule and its use is increasing year by year (Pei, Yin, Ma, & Lai, 2014; Sliwoski, Kothiwale, Meiler, & Lowe, 2014; Warren, Do, Kelley, Nicholls, & Warren, 2012; Zheng *et al.*, 2013). The goal to run a docking simulation of ligand–protein is to calculate the main binding mode(s) of a ligand with a protein of known 3D structures of its own components. Ligand molecule uses its action by binding to specific molecular parts of the cell such as modulating biochemical processes in an illness adapting manner. Considering the protein-protein docking and protein-small molecule docking, the following types of problems occurs:

- **Protein-protein docking**
  - Bound docking ("rigid redocking problem"):
  - Unbound docking: side chain flexibility
- **Protein-small molecule docking**
  - Rigid receptor, rigid ligand
  - Rigid receptor, flexible ligand
  - Flexible receptor, flexible ligand

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

The docking process is divided into two main stages: first, the correct situation of the ligand at the protein binding-site and, second, the estimation of the ligand affinity by a scoring function. Figure 3 shows more details of the key steps in docking that are used in all protocols commonly. To determine the structure of a biomolecular complex, this technique creates a broad set of conformations of the receptor complex, and then ranks them according to their stability (Morphy & Harris, 2012).



One key area for improvement in docking systems is in the methods for scoring putative protein-ligand interactions. Scoring is central to the docking problem. Development of protein structures for potential drug leads by molecular docking is critically dependent on methods for scoring putative protein-ligand interactions. An ideal function for scoring must exhibit predictive accuracy and high computational speed, and must be tolerant of variations in the relative protein-ligand molecular alignment and conformation.

In comparison to the rapid virtual screening (VS) methods similar to pharmacophore modeling, the performance of docking methods is a trade-off between computational demands and accuracy. The extent and specificity of binding depends on the complementarity between the ligand and its target in terms of shape, polarity, and chemical functionality (Reymond & Awale, 2012). Effective docking methods search high-dimensional spaces well and use a scoring function that properly ranks candidate dockings.

The success of small molecule or ligand roots from the following facts;

1. Matches of their size for most biologically relevant binding sites;
2. Sufficient existing of the structural and functional diversity in small molecules to reach strong and specific binding to most of these binding sites (see Figure 4.); and
3. The pharmacokinetics of ligand molecule can be adjusted while target binding to support efficacy and safety *in vivo* (Bon & Waldmann, 2010; van der Horst *et al.*, 2011).

Docking method is simple and has a variety of applications but some difficulties limit its ability. Over the last decade a wide effort has been directed toward developing efficient docking methods and for the identification of lead compounds. Considerable progress has been made in the computational prediction of ligand-target binding modes. A number of review articles in this emerging area of research have been recently published (Mohan et al., 2005). Some of the problems of docking calculation have been considered in the present text and a number of problem solutions considering some efforts have been introduced.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

COMMON DOCKING COMPLEXITY

For docking method, the equipment necessity and information of the structural aspects and molecular frameworks of active compounds is low (Alonso, Bliznyuk, & Gready, 2006; Chen, 2015), but its ability may have limited to the accounting of target flexibility (Hou *et al.,* 2013) and certain physicochemical features are vital for drug binding. These limitations arise from insufficient sampling of target conformational space, the use of gas-phase algorithms and parameters in scoring, poor modeling of solvation and entropic effects, and the use of simplified cut-off distances for non-bonded interactions. Careful calculation shows that accuracy is a major problem with docking studies, unless the docking is not approached with precision (Chen, 2015).

The complexity of computational docking increases in the following order:

1. Rigid body docking, where both the receptor and small molecule are treated as rigid.
2. Flexible ligand docking, where the receptor is held rigid, but the ligand is treated as flexible; and
3. Flexible docking, where both receptor and ligand flexibility is considered.

Thus, the most regularly used docking algorithms use the rigid receptor/flexible ligand model (Mohan et al., 2005)

Several factors influence the process of binding a small molecule to a target protein and make it quite complex; for example, the motion or flexibility of the small molecule drugs and receptor which affect the possible interactions solvent-receptor-ligand-solvent present depends on the molecular distribution of charges. There are common problems such as incorrect binding site of the target protein, the screening use of an improper small-molecule database, the selection of docking pose, and high dock score (binding affinity) but failure in molecular dynamics (MD) simulation, deficiency of clarity whether the compound is an inhibitor or agonist, or the docking results are unreliable with bioassays (Morphy & Harris, 2012). These problems in the elucidation of docking should be considered with caution and concern before performing docking (Chen, 2015).

The context covers joint critical aspects in all key steps with major emphasis to the general strengths and shortcomings. Enough theory behind these challenges is provided by avoiding many unnecessary equations, and details of calculation algorithms. Some literature within the last decades reviews to account the various capabilities, limitations and challenges of the currently widespread applied algorithms that presently characterize this methodology. Some efforts have been made by drug developers for improving algorithms by examples of its applications in drug design to overcome such shortcomings and computational enhancing for incorporation of both ligand and receptor flexibility in the docking process, extensive exploration of the ligand conformation within the binding site and improving complementarity between them (Figure 4 indicates the binding site of a case study and an active site in the same target), refinement and stability evaluation of the final complexes and thus accounting for induced fit. Discussion will further be limited to protein-small ligand complexes, omitting macromolecular complexes; however, much of what is presented here is also valid for that class of complexes. Future directions are included in the protein flexibility, ligand sampling, and scoring functions as important features in protein-ligand docking.

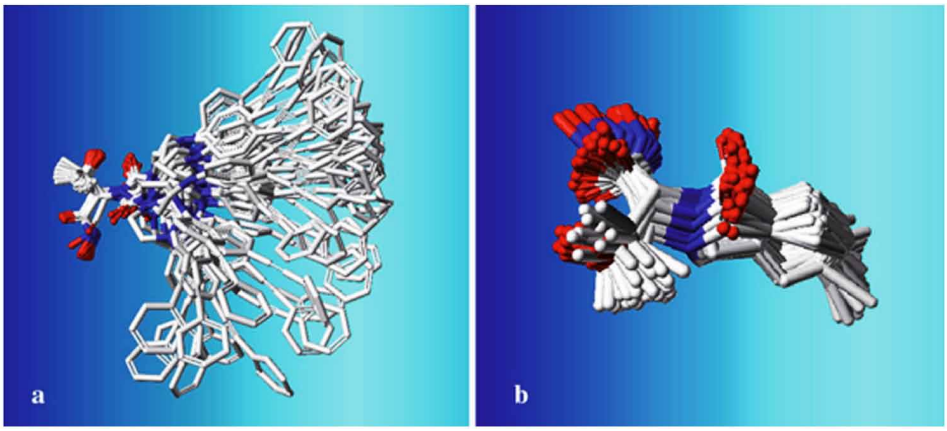
LIGAND CONFORMATION AND SAMPLING

Ligand - protein interaction complexes are the most important structures to get information about the mechanism of action of the chemicals compounds. A ligand molecule that can bind strongly to the target receptor should have energetically favorable interactions with the receptor with an appropriate relative geometry. In docking simulation, the problem of finding such geometry between ligand and target molecules is too difficult to be accomplished only by computational methods. To find a likely stable geometry and conformation, the ligand molecule is subjected to a series of interactive three-dimensional manipulations (rotation, translation, and bond rotation) inside the ligand binding site of the protein on the 3D-computer graphics display.



Ligand flexibility is one feature of docking simulation process. Small ligand-oriented docking schemes are either semiflexible or flexible. Small ligands are often highly flexible, with a broad range of populations, adapting their surface to optimally complement the receptor pocket. Therefore, one of the main features of drug docking schemes is enhanced ligand flexibility (Halperin, Ma, Wolfson, & Nussinov, 2002). Simulating ligand flexibility is also a computationally expensive process. Lomber and Shoichet reported that the number of possible ligand conformations increases in proportion to the power of the number of rotatable bonds (Lorber & Shoichet, 1998). They calculate that for an organic molecule with ten rotatable bonds, the number of possible conformations is 59049, if only three minima are considered per bond. However, allowing six minima per bond yields 3.48×10^9 conformations. To address the problem, one approach involves Monte Carlo simulation and simulated annealing to sample the ligand flexibility. In Goodsell et al., the binding site is rigid, whereas in Stoddard and Koshland some binding site flexibility is allowed (Halperin et al., 2002).

Rigid docking calculations are chosen when time is critical, i.e., when a large number of compounds are to be docked. Nevertheless, flexible docking methods are quite required for refinement and optimizing of poses found in an initial rigid docking process. With the development of computational resources and their efficiency, flexible docking approaches are commonly suitable. Three general algorithms are planned to give ligand flexibility: systematic methods; random or stochastic methods; and simulation methods (Sousa et al., 2006). Systematic search or systematic enumerations of conformations, and stochastic algorithms (such as genetic algorithms and Monte Carlo search method with Metropolis criterion (MCM)), shape matching and MD simulations (Figure 5 represents a typical MD calculation) are the most popular approaches for the improvement of efficiency. Systematic algorithms include ligand flexibility through a full search of a molecule's degrees of freedom. In this method, the current state of the system determines the next state. Starting from the same exact state and same set of parameters, systematic methods will yield exactly the same final state. Systematic methods can be categorized into (1) fragmentation algorithms and (2) exhaustive search algorithms (Sliwoski *et al.,* 2014).

A MD protocol was defined for docking small flexible ligands to flexible targets in water by Mangoni *et al.* (1999). They disjointed the center of mass motion of ligand from its inside and rotational motions (Mangoni, Roccatano, & Di Nola, 1999). Independent control of the different motions was conducted to permit flexible or rigid ligand and/or receptor. ROSETTALIGAND uses a knowledge-based scoring procedure with a Monte Carlo-based energy minimization scheme that reduces the number of conformations that must be sampled while providing a more rapid scoring system than offered through molecular mechanics force fields. ROSETTALIGAND through a Monte Carlo-based sampling of torsional angles includes ligand flexibility and side-chain during a high-resolution refinement stage and total torsion angles of ligand and protein are optimized (Sliwoski *et al*., 2014).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 5. Resulting from MD simulations to the most active compound, with common atom fit (a) and cluster alignment method (b)
Ghasemi et al. (2012)

Molecular flexibility in genetic algorithms (GA) was achieved through recombination of parental conformations with child conformations and the "fittest" or best scoring conformations was retained for another round of recombination. Genetic Optimization for Ligand Docking (GOLD) discovers full ligand flexibility with limited target flexibility by a GA (Jones, Willett, Glen, Leach, & Taylor, 1997).

Docking tools samples conformations of small molecules in protein binding sites; scoring functions are used to judge which of these conformations best matches the protein binding site. Scoring functions that predict the possibility of a compound being a ligand, mainly derived from three key methods based on their characteristics:

- Knowledge based scoring methods
- Force-field or physics based scoring methods
- Regression or empirical based methods

The main interest aspect of empirical scoring functions is the typically easy computation of the numerous terms. The key disadvantage of these methods is their dependency on the experimental data set used in the parameterization process (Leach, Shoichet, & Peishoff, 2006; Sousa et al., 2006).

Venkatachalam *et al*. have described a shape-based method, LigandFit, for accurately docking ligands into protein active sites. In their study a grid-based method for assessing protein–ligand interaction energies have been used for minimizing candidate poses in the context of the active site. They reported combination of LigandFit, with LigScore, as an internally scoring function, to the thymidine kinase receptor yields very good hit rates for a ligand pool seeded with known actives (Venkatachalam, Jiang, Oldfield, & Waldman, 2003).

Another problem of a ligand during a docking process is the biased selection of ligands as an outcome of using ligand-bound protein structures that was undoubtedly revealed in a series of cross-docking analyses. Displacement of particular portions of the protein backbone, movements of side chains, and mobility of metal atoms found within the active site produce most failure (see Figure 6 shows an active site in a case study). It was observed that the movements of side chains were usually linked to those of

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

the backbone Ca atoms and, as a result, it was essential to consider more than sidechain flexibility to avoid mis-docking of ligands.

Therefore, careful preparation of the structure of the receptor before the docking process is very important. While structures of ligand-bound protein may offer the highest enrichments, the final consequences might be biased towards certain types of ligands.

Erickson *et al.* have evaluated the effect of some key factors on docking accuracy with CDDOCKER, DOCK, FlexX, GOLD programs. In particular, they have studied the significance of ligand flexibility. Their studies showed that the accuracy of docking considerably decreased for ligands with 8 or more rotatable bonds: DOCK (14%); FlexX (28%); GOLD (19%); CDOCKER (71%). This indicates that the capacity to differentiate between correct or incorrect conformations may decrease for the most public docking programs for ligands with large numbers of probable low-energy conformations (Erickson, Jalaie, Robertson, Lewis, & Vieth, 2004).

RECEPTOR CONFORMATION AND FLEXIBILITY

The 3D structure of both ligand and protein are essential for the application of docking process. The 3D structure of a target obtained by NMR technique or X-ray crystallography (Clore & Gronenborn, 1991; Siegal, Van Duynhoven, & Baldus, 1999) is the best starting point for docking (Sliwoski *et al.*, 2014). Docking algorithms can search the enormous conformational space of small molecule in a reasonable cost and short time. While several ligand conformational structures may be relatively easy to predict,

Figure 6. Active site of the CC-chemokine receptor 5 (CCR5)
Ghasemi and Nouri (2013)

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

the lowest energy conformation obtained may not match that of the bound ligand. Compared to ligand, the structures of protein is a bigger challenge. While X-ray and NMR analysis are currently routine, in some cases intrinsic difficulties exist in the planning high-throughput process. The structure of many targeted proteins in drug design is not determined by above methods experimentally and, therefore, docking studies cannot be performed straightforward. In some cases, the structure of a closely related protein homolog is predicted through computational techniques.

Other significant drawbacks for docking process is the lack, or poor flexibility of the protein, which is not allowed to adjust its conformation during ligand binding (Sgrignani *et al*., 2009). This problem often ignored in great virtual screening (VS) calculations because of the high computational cost, but it can be managed by more focusing of docking process, and the consistency of the predicted poses can be improved (Lexa & Carlson, 2012).

Variations of existing docking program mostly treat the receptor as (more or less) rigid which is unlike of the biological facts and the ligand as flexible (Leach et al., 2006). Induced-fit docking and ensemble generated from MD simulation snapshots have been used for inducing receptor flexibility. Induced-fit algorithms agree small overlap between the ligand and receptor along with side chain movements, subsequent in elasticity. Another way to incorporate receptor flexibility in docking algorithms, known as ensemble-based screening is applied multiple fix receptor conformations (Sliwoski *et al.*, 2014). Other methods such as umbrella sampling, metadynamics, accelerated MD, etc. are used as sampling method (Sinko, Lindert, & McCammon, 2013).

ENTROPY IN BIOMOLECULAR INTERACTIONS

Binding affinity is a function of the free energy of binding which is composed of entropy and enthalpy terms dependent on the properties of an ensemble of structures. In a computational manner to scoring drug affinity, entropy of fixation can be expressed in terms of the number of ways in which a rotatable bond can be incorporated, $\Delta S = RTlnW$. If we assume that there are 3 orientations per rotatable bond then $\Delta G = RTln\ (3^N) = \sim N$ kcals/mole. Quantitation of these effects requires temperature dependent measurements of the free energy of complex formation.

The processes involving ligand binding are extremely complicated, both ligand and protein are flexible molecules, and the energy inventory between the bound and unbound states must be considered in aqueous solution. The most common handling of receptor flexibility in structure-based drug design is to ignore it and to design ligands to bind to more rigid regions of the receptor (Morton & Matthews, 1995). This has the advantage that the entropic costs of immobilising a receptor on binding a ligand are minimized.

There is an entropic cost when two molecules associate in any biomolecular interaction process. The entropic cost is a result of degrees of freedom of motion that lost when two molecules are strictly constrained within a complex. If the binding process involves capturing a flexible molecule, whose internal rotations about single bonds must also be restricted, the consequence is a further adverse entropic penalty that results in a reduction in binding constant ***K***, according to the classical relationships

$\Delta G = \Delta H - T\Delta S$ and $\Delta G = -RTlnK$.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

If we are to begin to predict binding constants for bimolecular associations in a manner that might develop useful rules for understanding the forces that drive molecular recognition,' then we need to be able to semiquantitate the adverse cost in free energy of generating conformational order from associations of flexible molecules(Searle & Williams, 1992).

Approximate methods can be used to estimate the loss of configurational entropy of the ligand by counting the number of torsional angles that have become restricted upon binding to the protein, and if desired, this entropy loss can be subtracted from the total energy change(van den Berg et al., 1995) (Burgen, Roberts, & Feeney, 1975).

The estimation of the entropic cost is difficult for several reasons.

- The entropies of molecules in solution are subject to uncertainties.
- The amount of residual motion present in a complex formed by association in solution is also uncertain.
- This amount of residual motion in a complex may vary as a function of the nature and extent of the intermolecular forces (enthalpy term) involved in binding.

Moreover, the issue is complicated by the fact that the accounting of the balance of entropy changes may be done in different ways. For example, it may be considered that the degrees of vibrational freedom associated with residual motion in the complex are translational and rotational entropy of the separate components which are not lost upon association. Otherwise, this vibrational freedom can be regarded as a benefit of the association, appearing after the interacting components have lost all of their translational and rotational entropy (Searle & Williams, 1992).

STRUCTURAL WATER MOLECULES

The handling of structural water molecules is a particular problem in molecular docking. Recently, structural water molecules in ligand protein recognition have intensely been studied and its importance is a well-known topic. However, handling the difficulty of structural water molecule in docking designs is still problematic and different guidelines have been suggested for managing water molecules during docking (Sgrignani, Novati, Colombo, & Grazioso, 2015). Now, some methodologies are applied to tackle this problem including: penalizing the existence of water molecules, awarding rational situation of structural water molecules in an active location or cavity and no amendment for water. Single water molecules in the interface may be particularly important in small ligand docking, mediating hydrogen bonds. The water solvent is described by a soft sphere Langevin dipole model, with discrete dipoles that interact with the electric field of the protein but subject to random thermal fluctuations that reduce the effective electric field at the dipole itself. van der Waals and field-dependent hydrophobic terms are also included(Halperin et al., 2002).

A number of currently available programs suffer the lack of satisfying to account for structural water molecules which can be either displaced in ligand binding or mediate protein-ligand interactions. Some of research aims is data generation to enable the worldwide work of evolving scoring functions in docking programs to account for contributing of structural water molecules. This is done by validating the performance of docking using a simple model system (such as cytochrome C peroxidase (CCP) W191G) containing four well-arranged structural water molecules which are known to either interact with a li-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

gand or to be moved upon ligand binding. The goal of working on molecular dynamics simulations of Sotriffer's group is estimation the enthalpic and entropic influences of the structural water molecules in CCP W191G to ligand binding affinity (Z. Li & Lazaridis, 2003; Olano & Rick, 2004). In a similar study on molecule docking in the framework of structural water molecules, the performance was certified by the following methods:

- Comparison of the binding modes with the docked ligands and the crystal structures,
- Comparing docking scores with the ligands in the different situations,
- Improving of the ligands from a database of decoys
- predicting new ligands from the decoy database (Wahlström, 2009).

The GOLD docking program lets water molecules to be "changed on and off" with a penalty for enabled waters thus preferring water movement by working with the first approach *(*Verdonk *et al*., 2005). Sgrignani *et al* in study of boronic acid have reported, GOLD 5.2 provides a correct computational process for management water molecules in binding sites, permitting to alteration water placing during docking calculations (Sgrignani *et al.*, 2015). The FlexX program puts the second tactic by awarding interactions of the ligand with the water molecule and penalizing for unoccupied interaction sites at the water molecule (Kramer, Rarey, & Lengauer, 1999). In an extension to DOCK 3.5, interactions of structural water molecules with a ligand were scored in similar mode as interactions with protein atoms (Huang & Shoichet, 2008). For the entropically disapproving fixation of water molecules in the active site, no penalties were added.

Recent surveys pay attention more carefully to account selected *water molecules* in docking calculations (Roberts & Mancera, 2008; Weill, Therrien, Campagna-Slater, & Moitessier, 2014). These reports show the undiscriminating inclusion of all the water molecules placed in or around the binding site can lead to a noticeable decrease of the predictive performances of the docking simulation process (Kumar & Zhang, 2013). Sgrignani *et al*. have evaluated the significance of the protein flexibility and catalytic site hydration during docking simulations in order to tune up a robust covalent docking practice for boronic acids. They set out to identify the solvent molecules more often present in the Amp/ boronic acid crystal structures, for identifying the minimum number of water molecules to provide accurate results. Their results show a reasonable cooperation between computational speed and structural accuracy (Sgrignani *et al*., 2015).

This difficulty of predicting and scoring the above parameters, binding modes unambiguously generates false negative and positive scoring compounds as it has been made obvious previously. One example was Warren *et al.* who docked 1303 known ligands into 7 receptors using 10 different docking programs and compared the docking poses to the structurally determined binding modes. The result for the different algorithms performance ranged from 0% to 90% satisfactorily predicted docking modes (Wong *et al*., 2006).

CAVITY DETECTION

A variety of algorithms have been proposed with the aim to identify cavity detection. The vast majority of cavity detection algorithms have been developed to treat static structures like crystal structures of proteins available in the protein data bank (PDB). However, this represents a serious limitation to ac-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

count for the intrinsic plasticity of the binding pocket. Protein dynamics act on a multitude of aspects in protein function. For instance, side chain flipping or domain motions can obstruct or free internal cavities or channels that allow migration of ligands and reshape the binding sites (Bidon-Chanal et al., 2006; Carrillo & Orozco, 2008; Spyrakis et al., 2011). In turn, these findings raise challenging questions about the impact of protein flexibility on the topological features of cavities and their binding properties.

Few works have tried to account for the dynamical behavior of proteins in the identification of binding cavities and tunnels. The interplay between protein dynamics and ligand migration pathways can be characterized by tools that rely on prior molecular dynamics (MDs) simulations and further post-processing of the trajectory. VOIDOO (Kleywegt & Jones, 1994) allows internal cavity and volume calculations, but it is rather time consuming and its use is not straightforward. CAVER (Beneš et al., 2010) is a PyMOL plugin that allows internal channel detection on MD trajectories. CAVER was improved to a software called MOLE using computational geometry principles instead of grid-based calculations (Petřek, Košinová, Koča, & Otyepka, 2007). Wolfson and coworkers have proposed a method called MolAxis for detection of channels from the interior of the protein to the bulk solvent (Yaffe, Fishelovitch, Wolfson, Halperin, & Nussinov, 2008). These methods are designed to detect channels on static structures or conformational ensembles of the protein. MDpocket is another generic pocket detection program. The aim of MDpocket is to identify and characterize binding sites and channels that might be transiently formed in the protein from the analysis of conformational ensembles generated by MDs or other sources. The core of this program is the recently published open-source platform Fpocket (Le Guilloux, Schmidtke, & Tuffery, 2009), which is a very fast geometry-based cavity detection algorithm.

Although many softwares and algorithms to discern different types of cavity are introduced and guidelines for assessing the accuracy and improving the comparability of cavity calculations are given, we need an accurate protocol to find the best cavity.

COVALENT DOCKING

Many methods of target-based drug design have been established for prediction of the protein/ligand complex structure and, they are used to this aim, (Warren *et al.*, 2006; Warren *et al.*, 2012; Weill *et al.,* 2014; Wong *et al.,* 2006). In the docking field, a number of methods mainly focus on the studying of docking between the two molecules through non-covalent interactions (the electrostatics interaction, van der Waals interaction and hydrogen bonding) or non-covalent complexes, while covalent docking is a crucial aspect in the docking field. Only a few methods are accomplished to predict the 3D structure of complexes in which the ligand is covalently bound. However, except non-covalently drugs, there exist other classes of drugs, i.e. the covalent drugs that bind non-covalently to the active site. Covalent ligands are not given significant attention in the traditional drug discovery process due its off-target reactivity besides of toxicity profile. However two FDA-approved covalent inhibitors targeting HCV, namely telaprevir and boceprevir highlighted the focus on covalent inhibitors. *GOLD* and *Autodock* software support feature of covalent docking, but they have major limitations. However, this problem has been addressed in *CovDock* and *CovalentDock* by automatic preparation of ligand files.

In the frame of these considerations, Sgrignani *et al.* have assessed the importance of catalytic site hydration and the protein flexibility during docking calculations for boronic acids with GOLD program. GOLD permits water molecules to be rotated round their three principal axes (to optimize hydrogen bonding) during docking. Moreover, GOLD can switch automatically whether a water molecule should

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

be bound or displaced by the ligand during docking. To certify the accurate geometry of the bound ligand, GOLD 5.2 applies the angle-bending potential from the Tripos Force Field, merged in the fitness function during covalent docking process (Sgrignani et al., 2015).

SOLUTIONS AND RECOMMENDATIONS

Some of drug developers focused their attention on the enhancement of computational protocols. These improvements include several methods. A number of target flexibility approximation methods have been used to tackle the risks connected with some searching methods to take a proper ranking of the final complexes in order to improve docking performance. For performance increasing, the molecular dynamics-enhanced docking approach has been used to try to account for the target flexibility (Morphy & Harris, 2012). The most common of approximate methods include:

- Combining docking and MD simulation
- Soft docking
- Side chains flexibility
- Rotamer-based flexible docking (conformation of binding-site residues are tested by rotamer libraries as backbone-dependent or backbone-independent)
- Molecular relaxation
- Joined protein grid docking (several structures and conformations are combined into an energy-weighted or geometry-weighted average depiction)
- Protein ensemble docking
- United description of receptor docking (multiple structures and conformations are overlaid and an average structure is made from conserved features)
- Conformational sampling of receptor side-chain
- Conformational sampling of combined ligand, and
- Receptor backbone energy minimization

More details on the some popular methods of the above list have been presented in the next sections.

Currently, *in silico* structure-based methods have lower throughput and poor consideration of solvation and conformational flexibility. Then, ligand-based virtual screening is considered as more robust hit generation for multi-target drugs in future development of improving of the speed and fidelity of docking-based methods. Conformational flexibility in both ligand and protein can adopt different conformations in binding the same ligand (Wong *et al.*, 2006) and the same ligand can bind to different targets in very different conformations (Smid *et al.,* 2005).

The development of search algorithms for better and efficiently sampling from conformational space of the protein–ligand and inclusion of solvation and rotational entropy contributions in the scoring function are attempts to improve the level of success of docking (Sousa *et al.,* 2006).

There are three key properties in an ideal scoring function:

1. Accuracy in predicting binding affinities
2. Speed
3. Tolerance to inaccurate ligand pose.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

The first two are obvious, but the end requires some discussion. A geometric search engine attempting to generate suitable poses for a ligand given a protein binding site will create the 'correct' pose within some tolerance with some probability within some amount of time. As the tolerance increases, so does the probability of generating a good enough pose quickly. So, the degree to which a scoring function is able to compute an accurate binding affinity given an inaccurate pose will have a significant impact on its utility in such a system.

The deficiencies in the scoring function are the main limiting factor. Scoring functions in docking program routinely make some assumptions and simplifications to let a more computationally efficient assessment of ligand affinity, but logically at the cost of accuracy. (Sousa *et al.,* 2006). Unfortunately, current scoring functions achieve predicting binding free energies poorly. Improved scoring functions would increase the capability to distinguish binders from non-binders. However, the enhancement of scoring functions has been stuck by the lack of a hard formalism for obtaining binding free energies from molecular docking.

COMBINED DOCKING AND MD SIMULATION

In recent years in order to improve docking performance, and have a reliable model of the complex ligand-receptor docking methods have been joined with MD simulations. Docking is applied to search for conformations of the ligands, and in the long run contains the screening of giant libraries of drug-like compounds in a short period of time. The problem is that the conformation of the receptor is not permitted to change in the binding process. Here, MD is a tool that can augment some flexibility to the receptor, ligand allow some modification upon the binding experience. Different procedures have been established for the MD insertion before or after the docking process. Multiple conformations of the receptor can be produced during the receptor structure preparation and then subjected to docking as an ensemble (Alonso *et al.*, 2006). MD simulations can help us to refine the resulting docking complexes. The dynamics can augment some flexibility to the ligand and receptor, refine their assembly and improve the intermolecular interactions between two molecules. Furthermore, the stability of the complex structure during a simulation path shows that the complex is true and it was appropriately docked. The interaction of the solvent with the complex is another significant feature of MD running after docking that the solvent molecules influence on the stability of the ligand's docked pose. MD simulations can be used to improve a docking procedure for the most of docking algorithms do not consider the contribution of the mobility of the receptor or the interactions with the molecules in the explicit solvent (Carlson, Masukawa, & McCammon, 1999).

SOFT DOCKING

Soft docking is a simpler procedure for dealing with protein flexibility in an indirect way. Despite handling the receptor as a rigid object, the repulsive expressions of the Lennard-Jones potential can be diminished by making a *soft* interaction. Thus, this method involve allowing the small molecular drug to partially penetrate the binding site surface of the protein in order to account for localized changes that could occur in a more flexible environment (Morphy & Harris, 2012).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Soft docking describes the molecular surface and volume as a "cube representation". This cube representation mentioned implicit conformational variations by way of size/shape complementarity, close packing and, most importantly, liberal steric overlap. Soft docking method containing of two steps, geometric docking and interaction scoring, is able to accommodate conformational charges associated with the molecular complexing process, and to identify the correct complex model or a small number of complex models, which can be further screened visually or based on other experimental results to recognize the correct complex model(Jiang & Kim, 1991). The soft docking concept has evolved primarily toward use in protein-protein docking (Fernández-Recio, Totrov, & Abagyan, 2002; C. H. Li, Ma, Chen, & Wang, 2003; C. H. Li, Ma, Zu Chen, & Wang, 2003; Palma, Krippahl, Wampler, & Moura, 2000; Schneidman-Duhovny et al., 2003) and protein-receptor modeling combined with experimental NMR data (X. Morelli, Czjzek, et al., 2000; X. Morelli, Dolla, et al., 2000; X. J. Morelli, Palma, Guerlesquin, & Rigby, 2001).

SIDE CHAIN FLEXIBILITY

The mobility of some residues mainly those within an enzyme active site can be managed in a different and more comprehensive tactic either during the docking process or after the ligand has been approximately placed. The receptor is generally held rigid in studies in which docking is required to be fast. However, some methods permit explicit treatment of side-chain (and a few selected backbone) torsions, e.g. by Monte Carlo (MC) (Abagyan, Totrov, & Kuznetsov, 1994) or Conformational search (CS)(Leach, 1994) procedures, and more computationally demanding molecular dynamics approaches allow binding site back-bone and side chain mobility to be simulated.

In study of receptor-ligand interactions, commonly two methods to treat side-chain flexibility during docking have been examined:

1. Systematic CS of discrete side-chain rotamers. The number of possible states is defined and therefore partition functions and free energies can be computed.
2. Stochastic MC exploration of a continuous probability distribution of side-chain rotamers.

A set of rotamer libraries can be used to discover the conformational space of selected side chains. Side-chain flexibility increases the computational cost but it lets localized protein movement and improved fit of the ligand in outcomes (Källblad & Dean, 2003).

COMBINED PROTEIN GRID

Some alternative structures of the protein receptor can be combined into a single representation of the ensemble to account for bigger conformational changes that may be critical for the binding process. The averaging can be done over atom coordinates, to generate a final average structure, or over the grid representation of all receptor conformations to produce an average docking grid.

In a similar approach, Wei *et al*. (Wei, Weaver, Ferrari, Matthews, & Shoichet, 2004) used a modified version of the program DOCK to incorporate receptor flexibility during the docking process. In this case, the interactions between a given configuration of the ligand and different flexible parts of the receptor

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

were calculated independently. Then, those flexible regions that present the best interaction energies with the ligand were recombined into a final representation of the protein receptor.

The inclusion of protein flexibility during the docking procedure using a united description of the protein with rigid conserved regions and alternative flexible parts can improve the screening process and produce new ''hits'' in a shorter time than simple sequential docking against each protein structure. For obtaining an adequate ranking of the final complexes, the internal energy of the receptor must be taken into account, as high-energy conformations of the protein may lead to unrealistic low-energy positioning of a ligand.

Briefly, docking methods that have combined multiple protein structures, whether from NMR, X-ray complexes, or MD simulations, into a single grid representation of the target molecule have provided better results than grids from single structures. The choice of combination procedure, however, has an even greater impact on the final outcome, with weighted-average protocols providing better results than simple average combination of structures.

FREE ENERGY CALCULATIONS

For a docking process to be successful, it is necessary that both the right conformation of the ligand–receptor complex is predicted, and that the ranking of final structures will be correct. The procedure needs to be able to differentiate among similar conformations of the same system, as well as to predict the relative stability of different complexes.

As most contain empirically fitted parameters, their performance on any particular problem will depend on the set of structures used for the calibration. So far, no scoring function has proven to be reliable for every docking case tested. The main constraint on their improvement rests with the need for speed; when ranking hundreds, if not thousands, of complexes a compromise in accuracy must be made. Knowledge-based functions used in the ranking of molecular interactions may not be general and accurate enough, because of the limited number of interactions that can be inferred from crystal structures and the inadequate description of repulsive forces.

Molecular dynamics simulations present an attractive alternative for structural refinement of the final docked complexes. They incorporate flexibility of both ligand and receptor, improving interactions and enhancing complementarity between them, and thus accounting for induced fit.

Recently developed approaches called MM/PBSA and MM/GBSA improves ligand ranking and, marginally, binding affinity prediction (Yuriev, Agostino, & Ramsland, 2011; Yuriev & Ramsland, 2013). The correlation between MM/GBSA energies and experimentally determined binding affinities was found to degrade with greater variability in the affinity data and/or increased structural faults in the complex structures, either experimental or computational. These findings demonstrate that improving pose prediction methods could improve the computation of binding affinities using implicit solvation methods.

Some of drug developers have focused their attention on the enhancement of computational protocols. These improvements include: incorporation of protein flexibility in the docking process, extensive exploration of the ligand conformation within the binding site, refinement and stability evaluation of the final complexes, and estimation of the binding free energies. The refinement of docked complexes deals with the applications of MD for the optimization and validation of the final complexes.

SUMMARIZES

This chapter handles some of crucial aspects such as the lack of accuracy, speed, ligand sampling, protein flexibility and basic concepts such as movements of side chains, displacement of particular portions of the protein backbone, and mobility of metal atoms within the active site and the biased selection of ligands as a result of using ligand-bound protein structures during a docking process or mis-docking ligand. Meanwhile, it describes approximate methods such as soft docking and side chains flexibility and protein ensemble docking to tackle the risks associated with some searching methods to obtain an adequate ranking of the final complexes. The solvent effect and the direct contribution of water molecules in protein–ligand interactions, the restricted resolutions of crystallographic receptors, and obviously, protein flexibility, both in terms of intrinsic structural flexibility and in terms of conformational alterations upon ligand binding, are some of the most crucial of docking calculations (Sousa *et al.,* 2006).

Here, briefly three types of ligand sampling algorithms are discussed; shape matching, systematic search, and stochastic algorithms. Computational efficiency for each algorithm represents according to their main advantages and disadvantages.

CONCLUDING REMARKS

Molecular docking is a computational method for predicting the location of ligands in the binding sites of their receptor(s). Ruling principle of molecular docking is essential in drug discovery process. Despite considerable advances and success the widespread application of docking methods, accurate and rapid prediction of protein–ligand interactions is still a challenge area to explore and still holds several hidden weaknesses. The most docking algorithms do not explanation for receptor flexibility or the effect of explicit water molecules, MD simulations can be used to complement and improve a docking protocol. In order to improving docking performance most common of approximate methods including combining docking and MD simulation, soft docking, side chains flexibility, rotamer-based flexible docking, molecular relaxation, joined protein grid docking, protein ensemble docking, conformational sampling of receptor side-chain and conformational sampling of combined ligand are applied.

Chapter 31
Different Types of Molecular Docking Based on Variations of Interacting Molecules:
Variations of Molecular Docking

Amit Das
University of Kalyani, India

Simanti Bhattacharya
University of Kalyani, India

ABSTRACT

Molecular docking plays an important role in drug discovery research by facilitating target identification, target validation, virtual screening for lead identification and lead optimization. Depending upon the nature of the disease of interest, targets can be either protein or DNA while drugs are mostly organic small molecules. Different types of molecular docking techniques like protein-protein or protein-DNA or protein-small molecule or DNA-small molecule are employed for achieving the above mentioned objectives. This chapter provides a clear idea of the position of molecular docking in drug discovery with detailed discussion on different types of molecular docking based on the varieties of interacting partners. Subsequently the authors provide a detailed list of tools that can be used for docking in drug discovery and discus some examples of molecular docking in drug discovery before concluding with a remark on future areas of improvement in molecular docking related to drug discovery.

1. INTRODUCTION

Present day drug discovery faces several major issues like rising cost, high development time and high failure rate at different stages of development. On average it takes 10-12 years and around one billion US dollar to market a drug but less than 5% of the compounds which are selected to undergo the drug-discovery pipeline, only end up being marketable. This high failure rate is associated with every stages of drug development starting from initial screening to final patient trial. Since the marketed drugs are

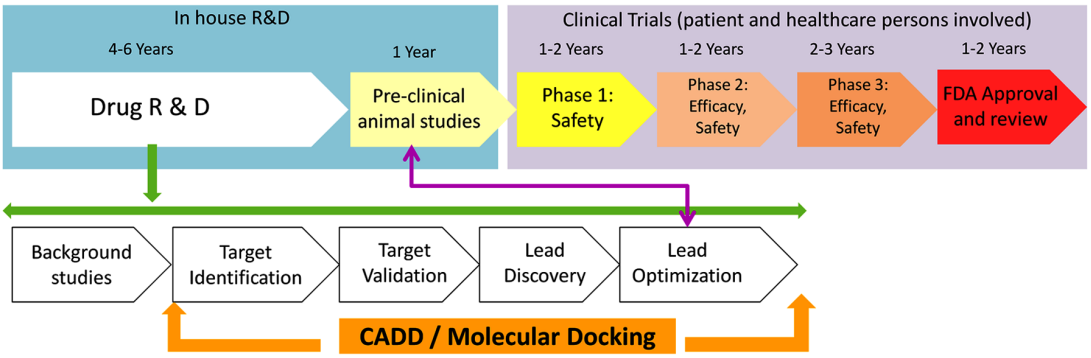
only available for revenue generation which has to cover the development cost of all the trials, including the ones which failed at different developmental stages. Thus it is easily understandable that optimizing strategies that save both time and money are of significant interest to the drug-discovery world. It should also be kept in mind that subsequent stages of drug development are also associated with exponential increase of cost. To counteract these issues, computer aided drug development (CADD) has played significant role to reduce cost and time for the last two decades and has established itself as an essential part of modern day drug discovery.

Combined with the above mentioned issues, the ever rising compound library has imposed another challenge in terms of selection of proper compounds which can be used for initial screening. While a few thousand compounds can be screened using standard high throughput screening (HTS) methods, the challenge remains to find these few thousands from the immensely large compound library which houses several tens of thousands of compounds, sometimes in the ranges of hundreds of thousands. CADD plays an important role not only in this aspect but also in two other ways – a) by computationally generating secondary modifications of compounds which saves both time and money in comparison to synthesizing them in real world, b) by analyzing the quantitative structure-activity relationship (QSAR) of the compounds of interest. All the three above mentioned ways, in which CADD plays an important role in drug discovery, require the association of the compound with the target of interest which can be either DNA or protein and the technique which facilitates this association in a computational way is known as 'Molecular Docking'. However the benefit of molecular docking extends beyond this small molecule–DNA/protein interaction as it facilitates the docking of DNA with proteins as well as of proteins with proteins.

The benefit of molecular docking is exhibited at several stages of drug-discovery. Even before the beginning of drug-discovery pipeline, molecular docking facilitates the proper understanding of several potential target molecules by facilitating DNA-protein and protein-protein interactions. Later this technique facilitates virtual screening which enables screening of compound libraries to find the potentially promising ones as well as helps in understanding of the best suitable secondary modifications. Thus it can be clearly envisioned that different types of molecular docking depends on the types of interacting molecules. Keeping in mind the scope of this chapter, further discussion on molecular docking with respect to drug discovery will be limited to different types of molecular docking.

As we have previously discussed, small molecules or ligands, DNA, proteins and short peptides are four different individual components with which molecular docking can be performed. Based on the combinations of participating components, drug discovery can be of several types. In case of protein-ligand docking, molecular docking is performed with a small molecule ligand and a protein receptor. Interaction of 'dorzolamide', used for treatment of glaucoma, with carbonic anhydrase is an example of protein-ligand docking. It should be highlighted at this point that most of the known or developed drugs fall in to this category. Platinum containing cancer drugs interact with DNA and thereby results in cell death. Studies of interactions of such drugs with DNA are facilitated through DNA-ligand type molecular docking. Azacitidine and decitabine containing drugs which are used for treatment of myelodysplastic syndrome and acute myeloid leukemia act through several mechanisms that ultimately inhibit DNA-methyltransferases. Understanding the mechanism of actions of such drugs require proper knowledge of interaction of DNA, it's bases and base analogues with DNA-methyltransferases.DNA-protein docking analyses such interactions. The tyrosine protein kinase BCR-Abl when mutated can become constitutively active and thereby causes uncontrolled target phosphorylation which ultimately causes abnormal cell growth. Imatinib effectively blocks this constitutive BCR-Abl phosphorylation activity by binding to

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



the enzyme which also blocks the binding of target proteins. Effective understanding of imatinib actions require proper understanding of BCR-Abl and its target proteins interactions, both in the form of wild type and mutant enzyme. Protein-protein docking facilitates such studies while the interactions of imatinib with BCR-Abl kinase as well as with the enzyme-target protein complexes can be analyzed through protein-ligand and protein complex-ligand types of docking respectively. This chapter provides a detailed discussion on these several types of molecular docking based on the variations of interacting molecules.

The chapter begins with very brief discussion on basic molecular docking with an introduction to ligand, receptor and inhibitor concept. Then detailed discussions are followed on different types of molecular docking that are mentioned above. Subsequently different tools that can be used to perform molecular docking are listed to aid readers in order to make them free from the tedious work of finding out the right tool to perform their job. Thereafter this chapter discusses on case studies i.e. different known drugs which have been reported to be significantly benefitted from molecular docking. Towards the end an emerging aspect of highly potential alternative therapeutic approach, termed as 'peptidomimetics' is introduced. Finally the chapter concludes with highlighting the present day challenges which are required to overcome in order to make molecular docking and CADD more effective in drug discovery.

2. BACKGROUND

The aim of rational drug discovery is to find a small molecule which when made available within the body, reacts with its target molecule of interest to achieve some desired modification of the target molecule and thereby exert a positive effect toward disease cure. Historically drug discovery was a trial and error type of work. Although several lifesaving drugs were discovered in this way, modern day drug discovery is a much more systematic effort (Figure 1). As shown in Figure 1, present day drug discovery is broadly grouped in to two parts – 1. in-house drug research and development (R&D) and 2. clinical trials. Both of these two parts constitute of several sub parts (Figure 1). Success at the previous sub part only ensures progress towards the next sub part. It is true that several drugs have been develop by this systematic developmental pipeline but hundreds of disease are yet to find a cure even when underlying

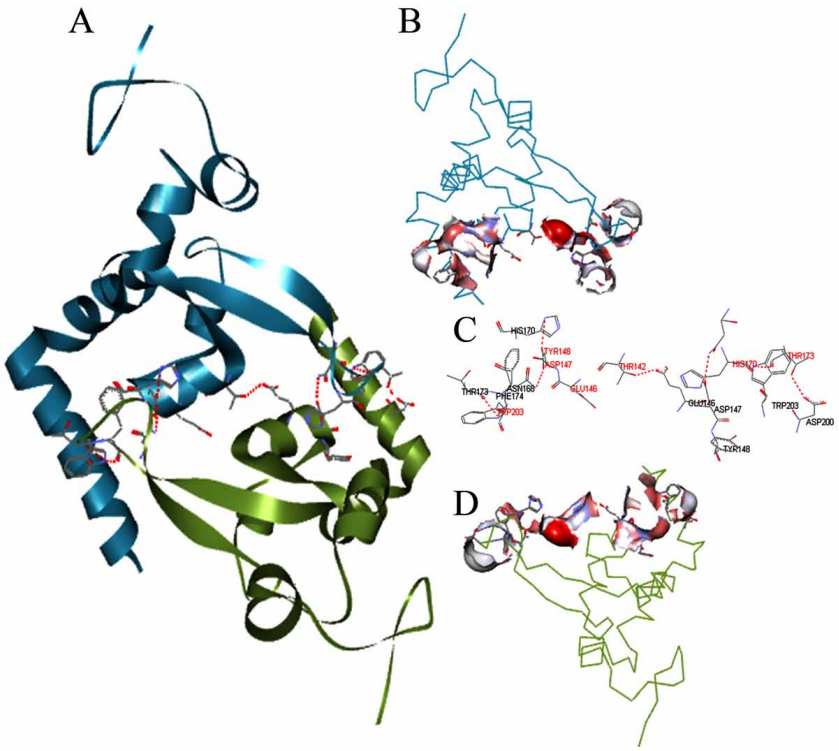
Figure 1. Involvement of CADD and molecular docking in the drug discovery pipeline; drug discovery primarily constitutes of two parts – in-house R&D and clinical trials. Virtual screening and QSAR works for lead identification and optimization part of in-house R&D takes the advantage of molecular docking for better management of time and cost of drug discovery.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

molecular reasons are known (Bhattacharya, Das, Dasgupta, & Bagchi, 2014). Thus there is an ever growing need for development of new drugs for un-treatable disease as well as development of more efficient drugs for those diseases with some level of existing treatment. To address these urgent requirements, potential drug molecules are required to be identified which can be sent for clinical trials. In house R&D is responsible for generation of these potential drug molecules. As detailed in Figure 1, the process of generation of these molecules starts with background data analysis for target identification and validation, followed by screening of compound library to find lead molecules and subsequent lead optimization which runs in conjugation with pre-clinical animal model studies.

As discussed in previous sections, drug design is a very time and resource intensive process. Thus there was always a need to apply as much automation as possible. Initially HTS proved to be a significant step forward by allowing automatization of the screening process. However preparing the resources required for HTS along with assay development is another challenge. Hence computers were brought in to this drug design and optimization arena to make the whole scenario faster, cheaper and more streamlined. Figure 1 highlights the role of CADD in this aspect. Molecular docking is an integral part of CADD and has found its application at almost all levels of in house drug R&D (Kapetanovic, 2008; Meng, Zhang, Mezei, & Cui, 2011; Shoichet, McGovern, Wei, & Irwin, 2002). Molecular docking has made it possible to find out suitable target, screen initial compound set to find a handful of lead molecules along with enabling QSAR analysis of optimized lead molecules. However different types of docking are required at different level of drug R&D. The following section provides a detailed discussion on different types of molecular docking, their underlying principles, advantages and fundamental limitations.

3. DIFFERENT TYPES OF DOCKING



Molecular docking requires two interacting partners. In biological, especially drug discovery context, these two partners can either be proteins or DNA or small organic molecules. Based on the type of two interacting molecules, molecular docking can be of 4 different types which are discussed in details in the following sections.

3.1 Protein-Protein Docking

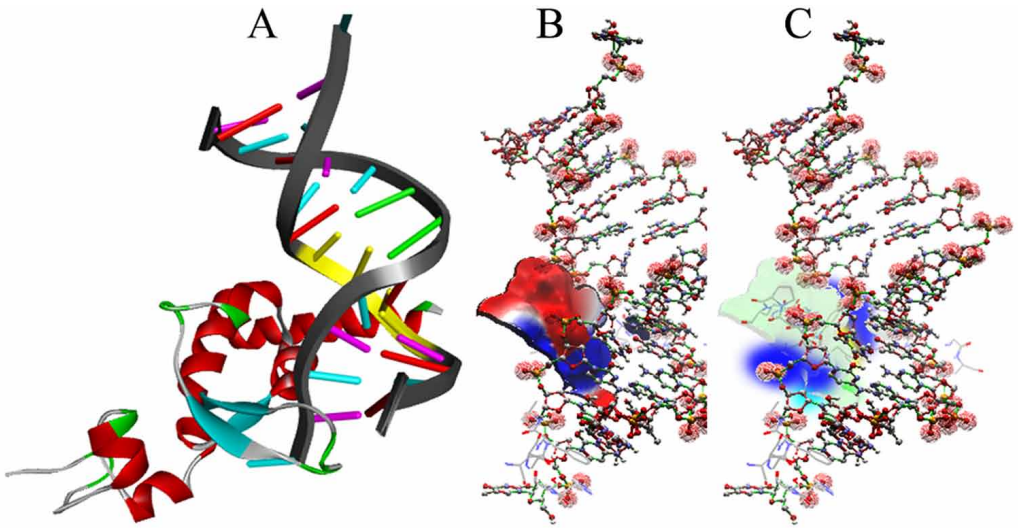
As the name implies, protein-protein docking is the type of molecular docking in which both the interacting partners are proteins in nature (Figure 2). Proteins in this context are a three dimensional stable conformation of an amino acid chain. Essentially protein-protein docking algorithms do not specifically discriminate between peptides, truncated proteins, protein domain structures and full proteins (Bhattacharya, Das, Ghosh, Dasgupta, & Bagchi, 2014; Das, Bhattacharya, Bagchi, & Dasgupta, 2013) which allows uniformity of tools and algorithms. The main challenge associated with protein-protein docking is the inherent flexibility of proteins and its constituting bonds. However protein-protein docking being the major point of interest across different types of docking, several tools have been designed to take care of these issues. However the speed and output of these tools are essentially a tradeoff between the computing resources and time against the degree of flexibility allowed. Thus it is fairly easy to understand that rigid body protein-protein docking is significantly faster and less resource intensive than flexible docking while the later ensures better quality of output with a time penalty.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 2. Schematic illustration of protein-protein docking; two protein molecules (one in blue, another in green) were docked with each other (A). The binding surface of blue color protein is shown in figure 2B while 2D shows the binding surface of green color protein. Intermolecular hydrogen bonds are shown in red dotted lines (A and C). Elucidation of contact surface and its properties along with residues of significance often come handy in drug discovery research.

In the drug discovery context protein-protein interaction plays major role in target identification and validation i.e. at the very beginning of drug discovery pipeline (Figure 1). Before the screening of compounds for a potential lead molecule, it is essential to identify a target molecule which in most cases a protein like enzyme, receptor or membrane associated pump or similar other proteins of significant functional interest. Protein-protein docking helps in understanding the various interactions of protein molecules with their interacting partners (Figure 2B-2D). With the increase in protein structure data, protein-protein docking is becoming more and more important in unraveling significant details of bimolecular interactions which are very essential for proper target identification. Not only target identification, protein-protein docking also helps in identification of potential drug binding pocket and elucidation of several characteristics of binding surfaces and interacting residues (S. Grosdidier & Fernández-Recio, 2012; Sable & Jois, 2015).

Several tools that can be used for protein-protein docking with different degree of flexibility are discussed in a later section.



EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

3.2 Protein-DNA Docking

DNA carries the genetic information of a cell whereas proteins are the molecules of execution. DNA-protein interactions hence are an important hub to regulate the mechanisms of replication, transcription (or gene expression) and recombination. Proteins with helix-turn-helix motif, zinc binding sites, leucine zipper form a large cluster of proteins that can bind DNA. Several transcription factors bind to DNA at promoter regions to regulate the expression of certain genes. Mutation in the promoter region or in the DNA binding region of the transcription factor can result in the improper interaction between these two partners, resulting in improper regulation of the concerned genes. A number of diseases have been associated with mutation in either of the two or in both cases (Heidenreich, Rachakonda, Hemminki, & Kumar, 2014; Songdej & Rao, 2015). However in many cases the underlying molecular mechanism either unknown or poorly understood. Protein – DNA docking can play a significant role in unraveling these unknown issues. With the progress in researches that showed the importance of protein DNA interaction in living cell environment, the research on DNA-protein docking has gained new attention (Gao & Skolnick, 2009; Takeda, Corona, & Guo, 2013; van Dijk & Bonvin, 2008).

As the name implies, in case of protein-DNA docking, there is no receptor-ligand complex since both the interacting partners are bio-macromolecules (Figure 3). However depending upon the nature of algorithm or the requirements of the docking program, sometimes it may be necessary to declare either of the molecules as a receptor and the other as a ligand but theoretically this should not make much difference in to the output. The main challenge associated with protein-DNA docking is the size of the interacting partners and their associated molecular and structural flexibility. DNA has its inherent

Figure 3. Protein-DNA docking: (A) schematic illustration of docking between a protein and a DNA molecule. The region of significance of the DNA molecule is highlighted in yellow. Figure 3B highlights the binding surface of the protein while Figure 3c also shows the energy map of those residues. Identification of DNA interacting residues and their surface properties of a protein are of vital interest from drug discovery point of view while the binding region of the DNA (yellow in Figure 3A) provides the consensus sequence required for proper protein binding.

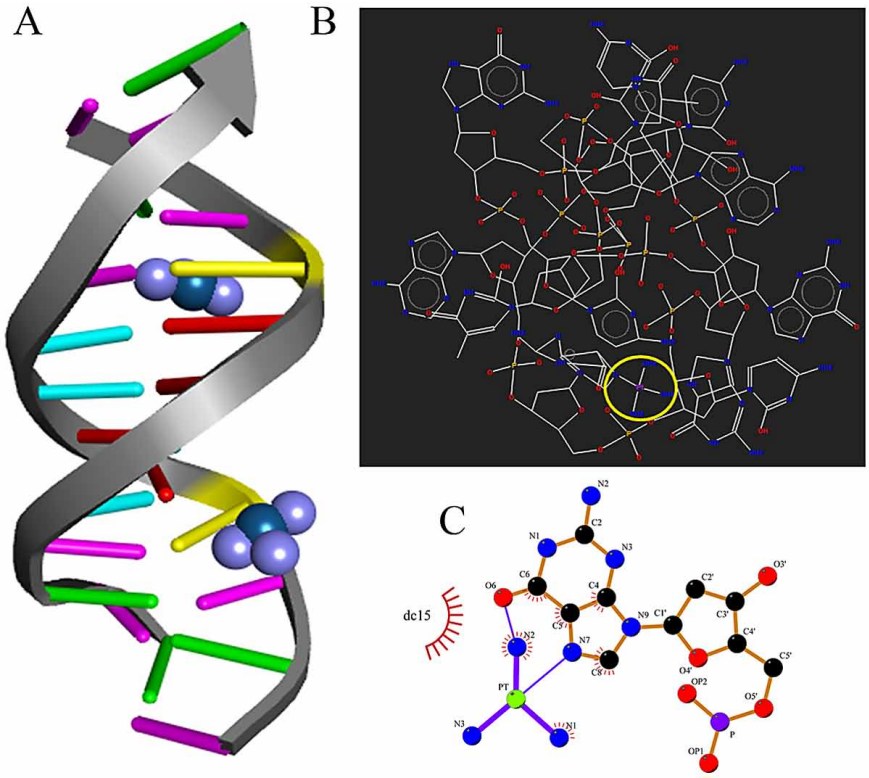
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

flexibility and also there remains a lack of proper information for the particular interacting residues on DNA structures. These have made the situation unfavorable to generate effective docking methods for proper docking of DNA with protein. Computationally it is a huge task to take into account all the rotational and vibrational flexibility of each and every atom and bond during the search for the best docking pose. While some docking algorithms take the advantage of associated information to counteract this issue (Takeda et al., 2013), few other programs only allow partial flexibility (Banitt & Wolfson, 2011). However some docking tools take the advantage of advanced computing architecture to allow greater flexibility and more parameters like explicit addition of water (van Dijk, Visscher, Kastritis, & Bonvin, 2013; Wu, Hong, Takeda, & Guo, 2012).

The structural basis of protein DNA recognition process has been deciphered with X-Ray crystallography, NMR and many other biochemical and biophysical experiments. With the increasing availability of structural data on protein-DNA interaction, it can be expected that molecular docking will play greater role in discovering the underlying mechanisms of disease causing mutations of transcription factors, DNA promoters and other DNA binding proteins. Such knowledge will help to develop new drugs for several diseases.

3.3 DNA-Small Molecule Docking

Molecular interaction of ligand to its targeted macromolecules plays pivotal role in designing sensible therapeutic agents. Being the genetic material, DNA has always been the subject of interest and have been targeted with small molecules or drugs to inhibit replication, transcription, in other words, the central dogma to kill cancerous cells or tumor cells, auto-immuned cells as well as fungal, viral and pathogenic microbial growths (Rohs, Bloch, Sklenar, & Shakked, 2005). DNA is negative in charge distribution and hence it attracts molecules with positive charges (Figure 4). Based on structural scaffolds and orientation flexibility, small molecules bind to either major or minor groove of DNA molecule and therefore interfere with replication and transcriptional machineries which in turn mostly activates the cellular apoptotic pathway (Pandya, Islam, Kumar, Jayaram, & Kumar, 2010). The biological activity of these molecules depend on slow rate of dissociation from DNA complexes which affects intra and intermolecular hydrogen bonds, planar interaction between DNA bases and small molecules and several other van der Waal interactions.



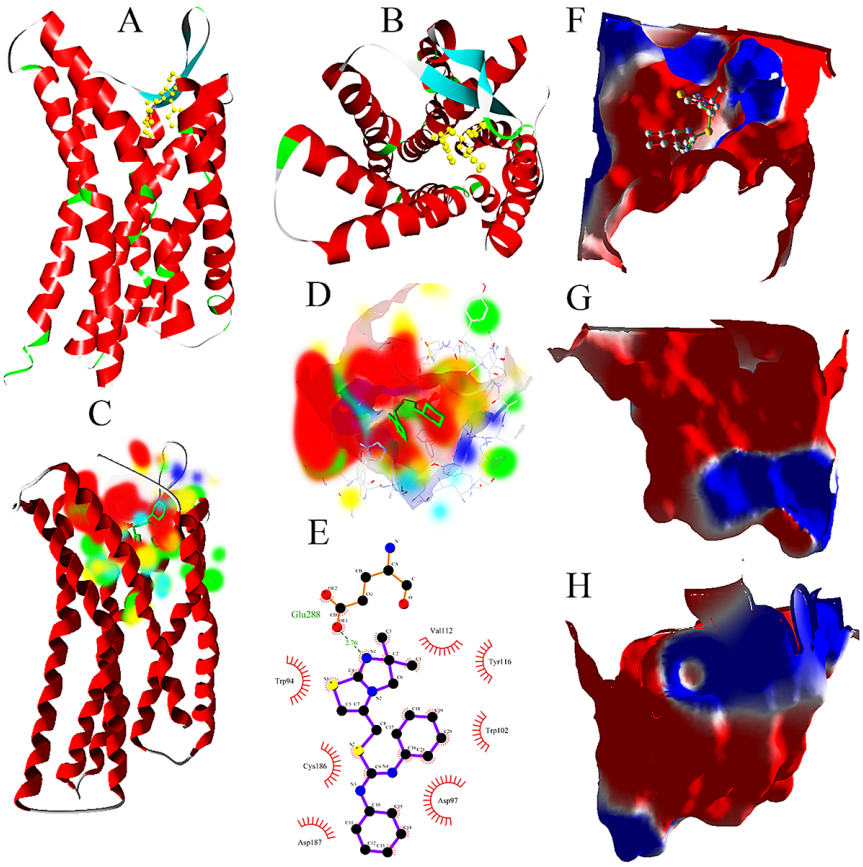
Molecular docking between DNA and small molecule takes in to account the above mentioned fundamental aspects of DNA-small molecule interaction during drug development and optimization. Selection of cation carrier molecules, their orientations (cis-trans), poses, DNA binding groove, binding affinity etc can be analyzed from DNA-small molecule docking (Figure 4B-4C). Similar to Protein-DNA docking, availability of proper tools is also a challenge with DNA-small molecule docking.

3.4 Protein-Small Molecular Docking

Proteome world in a cell depends on the central dogma: sequence, structure and function. The last trail of this pattern requires the knowledge whether a structurally fit protein can interact successfully with its partner proteins. If the former question gets its answer then determining the active sites and residues responsible for interaction play central role to build up the stage to study protein interaction world. To cure diseases, medical chemistry needs drugs or small molecules to be delivered successfully to the ailed system. Their bio-activity, stability and reduced toxicity form the key parameters for proper development

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 4. DNA-small molecule interaction: (A) schematic diagram of two platinum containing small molecules after being docked to a DNA molecule. The small molecules are shown in blue spheres while the interacting guanine residues of the DNA are highlighted in yellow. (B-C) Two different representations of the Ligand map of one the small molecules with DNA. Understanding the interaction map of small molecules with DNA is of prime importance for the development of drugs that target DNA.



of a lead compound. But at the same time, the mode of interaction of these small molecules with their respective cellular receptor or target protein form the golden stone to pave the path in curing diseases. Not only working as therapeutics, protein small molecule interactions are key factors in enzymatic reactions and signaling cascades.

Protein-small molecule docking takes the center stage of modern day drug discovery as most of drugs available at market are organic small molecule in nature and bind to protein targets like enzymes, cell receptors, membrane pumps etc (Figure 5). This form of docking is associated with virtual screening, lead discovery, QSAR studies and lead optimization. Thus several tools are available to dock proteins with small molecules as well as to analyze different parameters of their interactions (such tools are mentioned in a later section).

In general, protein-small molecule docking is classified into two categories: bound docking where a complex is reproduced based on the template known complex and unbound/ de-novo docking where scoring functions and probability estimation generate the idea to dock the residue to target protein (Taylor, Jewsbury, & Essex, 2002). All small molecules docking program have three principal components: understanding the molecular architecture, generating search algorithms and assigning scoring functions for energy evaluation. While variety of search algorithms have been developed to study protein small

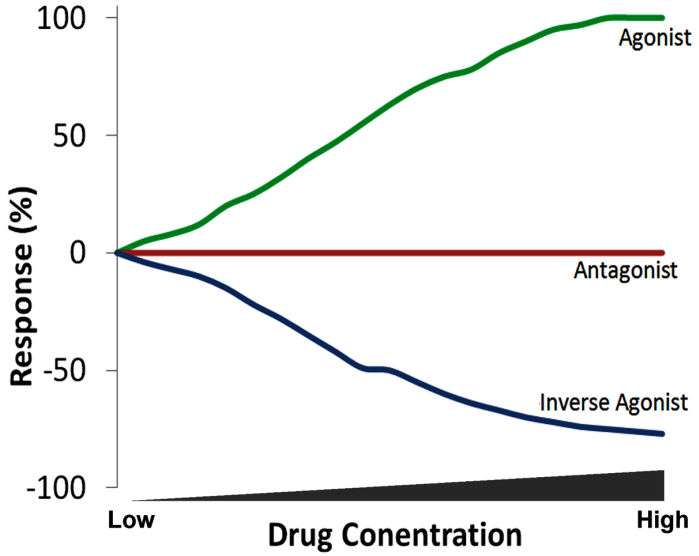
Figure 5. Example of protein-small molecule docking: (A) an organic small molecule is docked to a multi pass trans-membrane protein (A) side view, (B) top view. The small molecule is shown in yellow ball and stick while the protein is colored according to its secondary structure. C-D. Energy plot of this interaction (C-side view, D-top view). E. Interaction map between this small molecule and the interacting residues of the protein. F-H. Ligand interaction surface of the protein (F) top view, (G-H) two different side views. Deciphering the ligand interacting residues of a protein and characteristics of these important residues have pivotal role in optimization of drug molecules. Also the characteristics of this binding pocket determine the nature of the interacting ligand.

molecule docking, less attention has been given to the relative side chain flexibility of the proteins involved in these interactions (Meiler & Baker, 2006). Side chain conformational changes frequently occur upon small molecule (ligand/drug) binding. But recent studies have come up with plausible consideration to simulate the real world interactions which has brought the protein-small molecule research at its ease. Moreover, ligand flexibility has also been taken into account with the application of Monte Carlo sampling of torsion angles in small molecules. Search algorithms have dealt with the scoring functions majorly, but de-solvation and entropy functions remain the two major problems to solve. Finally an effective benchmark system for the evaluation of the robustness in scoring functions also needs be taken care of (Huang & Zou, 2010).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



Beyond the computational and algorithmic view of protein-small molecule docking, there lies another physiological view of understanding protein-small molecule docking. Based on the nature and outcome of an interaction between a protein and a small molecule, small molecule ligands can be broadly classified in to two groups – agonists and antagonists.

Agonists are nature identical small molecules that upon binding to its receptor, activates it while inverse agonists exert opposite effect (Figure 6). For example a drug meant for vasodilation would be acting as an agonist if upon administration it dilates blood vessels while an inverse agonist will cause vasoconstriction. Both agonists and inverse agonists bind to the same receptor binding site and its effects can be either full or partial.

Antagonists are small molecules that attenuate the effect of an agonist (Figure 6). They can be either competitive or non-competitive in nature and in each case can be reversible or irreversible in nature. Competitive antagonists bind to the same agonist binding site of a receptor while non-competitive ones bind to some other allosteric site of the receptor. Reversible antagonists bind non-covalently and can be out-competed in a concentration dependent manner while non-reversible antagonists form covalent bonds and often exert permanent effects on the receptor. For example Naloxone acts as an opiate antagonist by binding to the same receptor binding site of opiate agonists.

Information available on drug agonists and antagonists have been widely used by researchers for different purposes (Kim, Gao, Jeong, & Jacobson, 2006; Kortagere et al., 2010; Lu et al., 2010; Ng et al., 2014). Not only basic research usage, drug agonist and antagonist information are of equally high importance in the drug discovery scenario. During screening of molecules as well as during lead development and optimization, agonist and antagonist information (pose, rotamers, binding affinity, nature of interaction etc.) are taken in to consideration to select and optimize a potential drug molecule base on its intended purpose.

Figure 6. Relationship between physiological effects of agonists, antagonists and inverse agonists in a concentration dependent manner; while agonists help in activation of its receptor, inverse agonists exert opposite effects. Antagonists attenuates the effect of any agonist.

4. TOOLS FOR DIFFERENT TYPES OF MOLECULAR DOCKING

To facilitate molecular docking, several tools have been developed by researchers and companies over the years. Table 1 provides a detailed list of such tools which have proven to be reliable and have been popular across wide range of researchers which include basic science scientists as well as researchers or experts specifically involved in drug discovery projects. It should be noted that not all tools facilitate all the previously mentioned types of molecular docking. Table 1 also highlights the type of docking that can be performed by each tool. Most of these tools are online where the users can either provide their custom receptor and ligands (mostly in the.pdb format) or can select the receptors or ligands from standard known databases like the protein data bank (PDB, available at www.rcsb.org). Online tools or servers enable the users to make the most of the facility without any added cost (both hardware and software wise) along with enabling multiple users to be able to submit their jobs which can be run simultaneously. However several online servers are only accessible to academic users and thereby require an academic affiliation (in most cases an academic email id is sufficient). Standalone programs either free or paid are required to be installed or compiled on local computers, often a very high end desktop computer or a standard workstation. These programs provide the users the freedom to modify it as per their requirements as well as ensure data security.

Table 1. List of docking servers and softwares

Sl. No.	Server / Software Name	Type of Docking Performed	Online Server / Standalone Program (O/S)	Free/Paid (F/P)	Remark	Reference
1	AutoDock / AutoDockVina + AutoDock Tools	Protein-Ligand	S	F	Flexible docking	(Morris et al., 2009; Trott & Olson, 2010)
2	FlipDock	Protein-ligand	O	F	Flexible docking	(Zhao & Sanner, 2007)
3	HADDOCK	Protein-protein, protein-DNA	O & S	F	Data / information driven flexible docking	(de Vries et al., 2007; Dominguez, Boelens, & Bonvin, 2003; van Dijk, van Dijk, Hsu, Boelens, & Bonvin, 2006)
4	ClusPro	Protein-protein	O	F	Best outputs are filtered from several poses generated by the program.	(Comeau, Gatchell, Vajda, & Camacho, 2004a, 2004b)
5	PyDock	Protein-protein	O	F	Rigid body docking, require academic email	(Cheng, Blundell, & Fernandez-Recio, 2007; Gabb, Jackson, & Sternberg, 1997; Jiménez-García, Pons, & Fernández-Recio, 2013)
6	Patchdock	Protein-protein, protein-ligand	O	F	Rigid body docking, outputs can be further refined by Firedock	(Andrusier, Nussinov, & Wolfson, 2007; Duhovny, Nussinov, & Wolfson, 2002; Mashiach, Schneidman-Duhovny, Andrusier, Nussinov, & Wolfson, 2008; Paquet & Viktor, 2013)

As we have already described, molecular docking, in drug discovery context, is significantly involved in virtual screening of compounds. Several docking programs have been developed with this added screening facility. Among the softwares or Standalone programs mentioned in Table 1, some of them feature this added facility. Such programs are mentioned as 'virtual screening' enabled in the remarks section of Table 1. There are some other programs like MSDOCK (Sauton, Lagorce, Villoutreix, & Miteva, 2008), EUDOC (Pang, Perola, Xu, & Prendergast, 2001) etc. which have been specifically designed to aid drug discovery by facilitating virtual screening and drug interaction site identification.

A list of useful resources related to docking and virtual screening is available at the Click2Drug repository which can be accessed via http://www.click2drug.org/bibliography/docking/webservices.html and http://www.click2drug.org/bibliography/screening/webservices.html.

5. INDUCED FIT DOCKING: OPTIMAL BALANCE BETWWEN FLEXIBILITY AND RESOURCE COST

In principle, to obtain the best possible ligand receptor pose (in the form of complex or docked structure), an explicit solvent MD simulations with the presence of ligand and receptor structures would prove to be best solution. However it is quite evident from the previous discussions that significant time and resource cost would implemented to obtain such level of precision. Additionally different force field parameters, optimization of simulation environment add further level of complexity. To reduce such complex setup without much sacrifice in the quality of docking outcome, induced fit docking has been established as an optimal solution (Xu & Lill, 2013).

The biological principle behind induced fit docking is that in real life, protein, unlike computer structures (for example pdb structures), are flexible molecules and their active site residues often incorporate certain degrees of rotational freedom to accommodate the ligand in most effective conformation. Even there are certain receptors which only attain ultimate stable confirmation when bound to ligand. So impact of presence of ligand on receptor structure and conformation (especially of active site) is beyond doubt.

Induced fit docking takes in to account the above mentioned ligand impacts to figure out best ligand and receptor active site poses to facilitate the following benefits:

1. Generation of active ligand conformation that cannot be simply docked in to a rigid body receptor.
2. Rescue of poorly scoring true ligands (false negatives) during virtual screening experiments.

An induced fit docking algorithm primarily undertakes following steps:

1. Preparation of receptor molecule,
2. Identification of flexible residues, including potential ones,
3. Rotamer sampling of those flexible residues,
4. Interaction analysis and sampling,
5. Docking and complex/pose refinement,
6. Scoring of complexes,
7. Selection of best outputs

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

There have been numerous studies taking advantage of induced fit docking (Nabuurs, Wagener, & de Vlieg, 2007; Zhong, Tran, & Stang, 2009) and now a day it has become a pretty common feature of many softwares (example: Schrodinger Glide) or servers (example: Fleksy) that facilitate virtual screening to incorporate these protocols for generation of better outputs.

6. DOCKING AND DRUG DISCOVERY

Since molecular docking is an integral part of present day drug discovery procedure, almost all the drugs that come to market or clinical trial are designed by CADD to a significant extent. Docking being an essential part of CADD, contributes to a great extent in the development of such drugs. Notably development of several anti-HIV drugs has been associated with CADD and molecular docking (Esquieu et al., 2003; Liao & Nicklaus, 2010). A number of drugs like Dorzolamide, Captopril, Oseltamivir, Aliskiren, Saquinavir, Zanamivir, Rupintrivir, Boceprevir, Nolatrexed etc have been designed through CADD and progressed to the level of clinical trials or marketed after regulatory approval (Talele, Khedkar, & Rigby, 2010; Zhang et al., 2013). These molecules are very well representatives of protein-small molecule docking.

With the advent of multi-drug resistant (MDR) varieties of *Mycobacterium tuberculosis* and other MDR type causative agents for visceral leishmaniasis and several other pathogenic diseases; development of new drugs are becoming essential for the survival of a significant portion of human population. Not only these few diseases, several cancers often develop MDR properties after a few doses of standard treatment. The ever changing influenza viruses are also causing greater number of causalities with each passing year. The two main benefits of molecular docking and CADD are its abilities to save time and money and these two apparently seems to be the best weapon in hand to deliver new drugs to address the above mentioned challenges within a foreseeable future.

7. FUTURE RESEARCH DIRECTIONS

Drug discovery, especially in today's context, is becoming even more dependent on computational techniques that ensure best utilization of time and money. But it should be acknowledged that neither computers can alone deliver a magic bullet nor computers, however advanced it may be, can take in to account all parameters at a time. All the biological interactions of a cell cannot be simulated by any computer in a reasonable time frame. Thus the entire process of a drugs entry to a human body till it is metabolized and subsequently excreted can only be mathematically modeled, not simulated (with the consideration of all degrees of freedom). Thus the future areas of development which bear the potential of efficient use of molecular docking in drug development can be broadly classified in to two parts – 1. technological advancement and 2. methodological changes.

Technologically there are two areas of development. First efficient use of present day computer architecture, especially the general purpose graphics processing unit (GPGPU) promises a significant level of advancement in the speed of molecular dynamics (MD) simulations. It is beyond any point of argument that flexible docking with MD simulations ensures best output. However additional time requirements and hardware associated costs have often been limiting factors in flexible docking and MD simulations. To counter these issues, rigid body docking was the choice of many. However with the advent of advanced computing facilities like GPGPU, MD simulation jobs have become significantly

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

faster. These present day multi-core (often in the range of several thousands) GPGPUs can significantly accelerate MD simulations by offloading a huge portion of load from the computer/workstation CPU (with essentially run in serial mode and only contain a few cores, often at a maximum number of 20 in high end standalone workstations). Present day MD simulation programs like GROMACS or NAMD (Phillips et al., 2005) are intrinsically equipped to harness the power of a computer architecture created by pairing of GPGPU with CPUs. These GPGPU-CPU combinations (both as single node and cluster) not only significantly lowers the simulation time but also enables users to take in to account greater number of molecular parameters without much time penalty and added cost. GPU based algorithms of molecular docking should be developed to generate better quality of outputs compared to rigid body docking. The added benefit of all atom flexible docking with MD simulations which can easily be performed at a GPGPU-CPU combined system, is that it can be employed to docking studies with all kinds interacting molecules i.e. DNA, protein and small molecules or ligands. If technological advancements (mainly in the form of efficient algorithms) can be directed to harness the power of upcoming computing architectures, molecular docking would be able to provide greater in-sights in to the interaction patterns of biological macromolecules and/or their interacting small molecules in much greater details and that too within a reduced time frame.

Methodologically docking in drug discovery has been traditionally associated with virtual screening, lead discovery and optimization steps. While the contribution of molecular docking in saving valuable time and billions of dollars cannot be ignored in any way, it should also be acknowledged that the much hyped benefit of CADD, QSAR or docking has failed to a significant extent to keep up to their expectations. However it is very important to understand the reason behind such gap of expectations and achievements of molecular docking in drug discovery. One fundamental point in this aspect is what to dock with which i.e. what molecule to dock to which molecule. Much like the exponential increase in protein or DNA structural data, compound libraries have also been increasing exponentially over the years. Despite such remarkable achievements, not many drugs with significant potentials have made it to the market in recent years. Thus it can be clearly understood that there lies some issues with the best utilization of this increased structural and chemical data. Several factors like administrative, financial, intellectual property etc. can be linked to the causes of such issues. It is very essential to overcome such factors in order to make best use of present day and upcoming computational facilities and docking algorithms to achieve increased success with molecular docking in drug discovery. Greater collaboration between industry and academia as well as sharing of molecule libraries are potentially the avenues of achieving higher success with molecular docking based lead discovery and optimization aspects. Further distributed computing architecture can be employed globally to increase the rate of docking with higher degree of flexibility.

Finally it should be noted that the greatest benefit of molecular docking has been in the area of virtual screening which has significantly reduced the time, effort and expenditure of assay development, result interpretation and infrastructural requirement of standard high throughput screening. However it should be noted that to make more reliable outputs with maximum specificity, both virtual screening and HTS should be employed to a reasonable level while virtual screening should be allowed to use as many parameters as possible (Ferreira et al., 2010; Gschwend, Good, & Kuntz; Okimoto et al., 2009)

Beyond such apparently traditional solutions of making molecular docking more efficient in drug discovery, another approach which promises much greater potential is the use of peptidomimetics. It makes great use of protein-protein docking during its design, optimization and efficacy analysis part.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

7.1 Peptidomimetics and Drug Discovery (Role of QSAR and Molecular Docking)

A part of present day drug discovery aims at developing modified peptides with increased stability and better pharmacokinetic trends. In short this technique is known as peptidomimetics and can be defined as synthetic molecules that are developed by modifying the natural peptides or proteins. Peptidomimetics are applied in targeted chemotherapy, in mitochondria apoptosis, as antimicrobial and antiviral agents as well as in cosmetics production (Walensky et al., 2004). Peptidomimetics can be synonymous with Molecular mimicry to a certain extent (Vagner, Qu, & Hruby, 2008). Recently, bioactive peptides are used as powerful tools for initial investigation in disease biology. However, these natural peptides are associated with certain problems: 1. physiological stability, 2. lack of oral bio-availability, 3. poor DMPK properties and 4. prone to peptidase digestion and susceptibility to proteolysis (Vagner et al., 2008). Peptidomimetics is employed to broadly circumvent these problems associated with natural peptides. The pharmacophores (hotspots which are necessary for the molecular recognition of a ligand by a biological macromolecule) of peptidomimetics retain the ability to interact with the target proteins and help to mediate the natural biological activities.

Various peptide bond modifications are designed and synthesized to obtain natural peptide analogues with improved pharmacological properties. These added advantages in these compounds come from significant differences in their structures. Such modifications contribute to protect the peptidomimetics from protease cleavage and significantly improve their metabolic stability. Structure activity relationship (SAR) is the founding step in designing a peptidomimetic compounds. It defines minimal active region and key residues required for identical biological effects. The binding relationships of target molecule and the peptide analogues are evaluated and this evaluation is done majorly through amino acid scan, truncations and N- and C- terminal modifications. This is followed by stable bioactive conformation generation. The stepwise structural modifications require computational approaches, whereas the confirmation for bioactive set generation largely depends on experimental evaluation. In all these steps of peptidomimetic design and optimization, molecular docking plays crucial role as it technically eliminates the experimental part of synthesizing each and every modifications and performing their binding assays. By enabling virtual screening and in-silico analysis, molecular docking allows fast and efficient screening of peptidomimetic compounds (Hruby, al-Obeidi, & Kazmierski, 1990; Kharb, Meenakshi, Sharma, & Yar, 2011; Singh, Dolphin, Razkin, & Dumy, 2006).

8. CONCLUSION

CADD has been well established as an approach to accelerate in house R&D related to drug discovery. Among several aspects of CADD, target identification and validation as well as lead identification and optimization are the most important parts for couple of reasons. First maximum numbers of failures occur at these steps of drug discovery. Secondly these steps being the early steps of drug discovery pipeline, failure at these steps incur less time and economical penalty. Computerization and automatization of these steps to a significant extent using molecular docking techniques have further reduced the above mentioned penalties in case of failures. Depending upon the type of disease of interest, protein-protein or protein-DNA or protein-ligand or DNA-ligand types of docking programs can be employed for proper identification of the potential drug target. Thereafter in-silico mapping techniques can be employed to

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

figure out potential drug binding pockets which in turn save lot of experimental time and other resources. Subsequently computer based virtual screening, which essentially employs protein-ligand / DNA-ligand docking algorithms, can be used to screen tens of thousands of molecules to pick up only a few lead molecules. Such lead molecules can be used, in conjunction with limited experimental studies, for efficacy analysis using QSAR. Based on the outputs of QSAR and other efficacy analyses, in-silico secondary modifications of lead molecules can be generated which can further be subjected to molecular docking with its receptor of interest. Jointly these molecular modeling and docking techniques enable faster generation of all possible secondary modifications as well as analyses of potential impact on efficacy due to the introduced changes. All these steps, if were performed in traditional ways, would have posted several challenges like – synthesis and purification of all the modified lead molecules and their subsequent storage and structural validation using NMR or similar techniques, experimental analyses of their efficacy and manual comparison of efficiency of all the incorporated modifications. Thus it is fairly easy to understand the benefit of different types of molecular docking techniques on different segments of the R&D part of drug discovery. Especially the ability to virtually interact all possible types of bio-macromolecules with each other and other organic ligands has made molecular docking and indispensable part of present day drug discovery. However time has come to explore more efficient docking algorithms for better accuracy of output prediction as well as identification of newer avenues of implementations of various docking techniques to further accelerate drug discovery.

KEY TERMS AND DEFINITIONS

Computer Aided Drug Design: Computer aided drug design or CADD means the use of computer programs or softwares or online resources for the purpose of identification and optimization of potential drug molecules. The functionality of CADD also extends to identification of potential drug targets.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Docking: The process of finding a thermodynamically and physiologically relevant pose of interaction between two biological macromolecules or between a small molecule and a biological macromolecule. Surface complementarities and energetic parameters are often taken in to account to find out such poses.

HTS: HTS stands for High Throughput Screening, a process which can be automated to a very large extent to facilitate the screening of molecules of interest without much human intervention. In present day, often robotic liquid handling systems facilitate HTS.

Ligand: In molecular docking, ligand is referred to a organic small molecule that can bind to another large biological macromolecule like a DNA or a protein and upon binding, often causes structural and functional alterations of the concerned macromolecule.

Online Server: An online facility that hosts certain website or program and makes it available to global users. In the context of this chapter, several online docking servers enable the users to dock their molecules of interest by making the docking algorithm available in the form of a website.

QSAR: QSAR stands for Quantitative Structure Activity Relationships. QSAR is the process of quantitative identification of relationship between a chemical structure and its functional activity, primarily pharmacological. QSAR is often used in drug discovery for the efficacy analysis of the molecule of interest.

Receptor: A biological macromolecule (mostly a protein) to which a ligand or small molecule binds.

Small Molecule: In drug discovery or docking context, small molecules are synonymous with ligand.

Standalone Program: A computer program that is required to be installed or compiled in a local computer or workstation to make it usable. In docking terms, several docking programs are available as source codes or binaries which the users can download from the web and thereafter can either compile or install on their local systems. Depending upon the program type it can be either GUI (graphic user interface) based or command line based.

This work was previously published in Methods and Algorithms for Molecular Docking-Based Drug Design and Discovery edited by Siavoush Dastmalchi, Maryam Hamzeh-Mivehroud, and Babak Sokouti, pages 148-172, copyright year 2016 by Medical Information Science Reference (an imprint of IGI Global).

ABSTRACT

This chapter, composed of two parts, firstly provides molecular docking overview and secondly two molecular docking case studies are described. In overview, basic information about molecular docking are presented such as description of search algorithms and scoring functions applied in various docking programs. Brief description of methods utilized in some of the most popular docking programs also applied in our experimental work is provided. AutoDock, CDOCKER, GOLD, FlexX and FRED were used for docking studies of the DC-SIGN protein, while GOLD was further used for docking studies of cathepsin K protein. Methods and results of our studies with their contribution to science and medicine are presented. Content of the chapter is therefore appropriate for public of Medicinal and Organic Chemistry as an overview of docking studies, and also for Computational Chemists at the beginning of their work as the introduction to application of molecular docking programs.

INTRODUCTION

Those who devote their time to molecular science are well aware of the amount of molecular data available that has rapidly increased in the past few decades due to breakthrough in structural biology. Since 1975 development of high-throughput protein purification, crystallography, and nuclear magnetic resonance spectroscopy techniques predominantly contributed to structural details of macromolecules and complexes with ligands. In 2014, after less than four decades, the number of structures exceeded the 100.000 with 10.000 structures per year being deposited in Protein Data Bank (PDB). PDB is the single worldwide repository of information about the 3D structures of large biological molecules, including proteins and nucleic acids (Berman et al., 2000; Berman, Kleywegt, Nakamura, & Markley, 2014).

These advances are responsible for computational methods to become indispensable in all aspects of drug discovery including the structure-based drug design and computer-based analysis of molecular interactions. Interactions between biomolecules are fundamental to biological processes; using these interactions, living organisms maintain complex regulatory and metabolic mechanisms responsible for the life course. Experimental research work is fundamental for a better understanding of biological processes; however, computer simulations and analysis are of mayor importance to extract information from large amount of multivariate experimental data. Application of these scientific methods provides exploration of molecules that can be utilized as bioactive substances able to modify and control molecular interactions. For bioactive substances, molecular recognition of the constituents is imperative. Binding mode, binding affinity, and kinetics play the crucial role in molecular recognition as they characterize intermolecular interaction.

Due to the limitations of experimental methods for determining the structure of molecular complexes, as they are expensive, time consuming and not always feasible, computational methods are preferable for predicting putative binding modes and binding affinities. Nowadays, the main advantages of rational drug discovery approaches, such as virtual screening, are low costs and effectiveness when compared to high-throughput screening. Molecular docking is one of the virtual screening methods used since 1980's. It is based on modeling of interactions between two molecules, a small molecule (ligand) and its receptor/protein (target). The predicted interactions allow us to characterize the binding mode and binding affinity of the ligand-target complex.

Currently there are more than 50 molecular docking programs available, which all have similar implementations. This chapter provides explanation and comparison of computational approaches, specifically different algorithms enclosed in software for molecular docking, considering several of the most commonly used program tools (AutoDock, FRED, CDOCKER, FlexX and GOLD). Authors also present the use of these algorithms in the comparative study for docking of small ligands to specific protein, lectin Dendritic Cell-Specific Intercellular adhesion molecule-3-Grabbing Non-integrin (DC-SIGN) and covalent docking of cathepsin K.

BACKGROUND

Molecular docking, in the case of small molecules also known as ligand docking, can be defined as computational method for prediction of the structure of ligand-receptor complexes. Ligand docking process involves two basic steps: prediction of ligand conformation and orientation (the pose) by search algorithms and assessment of binding affinity by scoring functions.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

By search algorithms as mentioned above different ligand conformations and orientations are searched and therefore different modes (poses) are generated. Over time different search algorithms, all being defined by set of rules and parameters applied to predict conformations, were developed and became available for users. Algorithms differ regarding to constituent molecules flexibility consideration, therefore several approaches can be utilized that are classified as: methods for "rigid-body" docking and methods for "flexible docking". Depending on how much conformational space is covered, speed and effectiveness are two critical elements in search algorithms. Rigid-body docking methods use either a single conformation or multiple conformations implemented by user to consider ligand flexibility. Search algorithms here consider only geometrical complementarities between molecules and that is limiting factor concerning specificity and accuracy of prediction. Methods for flexible docking consider various conformations of ligand or receptor (or both molecules at the same time) generated by program itself, what makes prediction more effective at higher computational time cost. So far, molecular docking software generally uses one or more methods for binding mode prediction: matching algorithms, incremental construction, Monte Carlo simulations, genetic algorithms, etc.

Assessment of the different orientations and conformations of a ligand is the second step in molecular docking, where scoring functions delineate the correct poses from incorrect poses or binders from inactive compounds. It is necessary to mention that scoring function involve estimation adopting various assumptions and simplifications, rather than calculating accurate binding affinity between constituent molecules. Scoring functions can be applied for ligand binding mode identification, binding affinity prediction, and consequently virtual database screening. There are numerous available scoring functions that can be classified into three main categories: force-field based, empirical and knowledge-based. Force-field based scoring functions calculate the sum of intermolecular interaction and atomic forces for assessment of binding energy, whereas empirical scoring functions estimate binding energy of a complex by summing up the weighted energy terms. Knowledge-based scoring functions employ statistical analysis of molecular complexes crystal structures. Moreover there has been additional strategy introduced; consensus scoring combines several different scores from multiple scoring functions to assess a docking conformation/orientation.

There are lots of reviews about molecular docking and since the beginning of the new millennium practically every year new publications are available that report recent advances and challenges in the field, compare programs available and outline growing number of applications of molecular docking in drug discovery (Table 1).

SEARCH ALGORITHMS

Search algorithms for molecular docking originate from computer analysis studies of intermolecular interactions. Calculations of protein-protein interactions led to the development of first algorithms for computing molecular interactions starting from the structure of two components. These algorithms utilize approximate shapes of two molecules represented as rigid bodies. As these algorithms essentially consider the geometrical complementarities between molecules, they are termed shape matching algorithms. Although this approach does not take into account the conformational space of molecules it is still convenient for the applications in drug design and discovery, such as for initial stages of virtual screening studies and as a part of strategies of other more sophisticated docking algorithms.

Development of sophisticated docking algorithms practically coincided with the increasing power of computers, allowing the integration of more parameters into search algorithms. Considering more degrees of freedom a new methodology emerged. Flexible docking accounts for conformational space of molecules that is responsible for molecular dynamics essential for all biological systems. Since the molecular complex is composed of two molecules, it would be optimal to consider both of them as flexible. Even though, due to the computational limitations, predominate algorithms considering only flexibility of the ligand, there are several examples of specialized algorithms and computational strategies that account for partial flexibility of the receptor.

Computational tools for molecular docking use different methods to deal with ligand or receptor flexibility. There are three categories of algorithms that consider ligand flexibility: systematic, random or stochastic and deterministic (Figure 1) and some of these are appropriate and applied also for exploring receptor flexibility. Difference between docking software depends on the nature of algorithm implementation. This subchapter describes basic search algorithm approaches that progressed from the time of first intermolecular interaction studies.

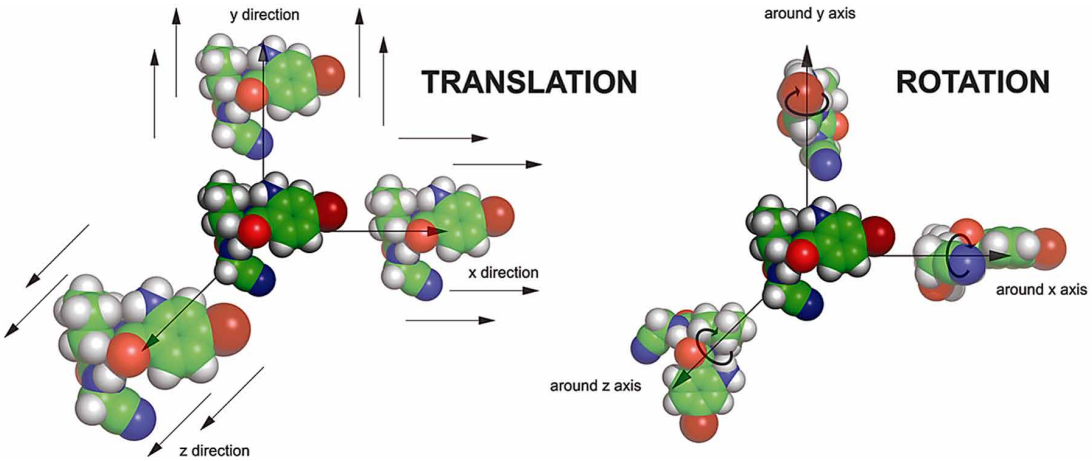

Figure 1. Search algorithms that consider receptor and ligand as rigid/flexible bodies

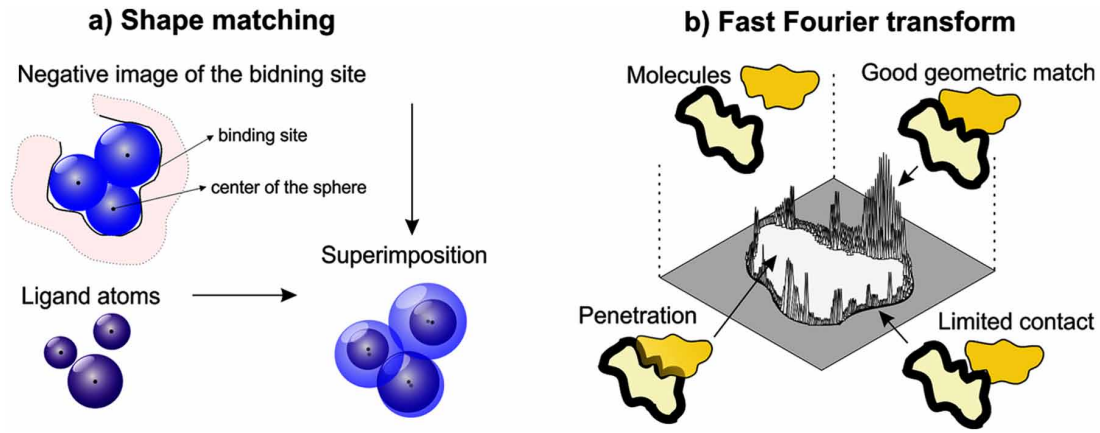
Search Algorithms that Consider Ligand and Receptor as Rigid Bodies

All primer algorithms calculating intermolecular interactions of molecular complexes considered molecules as rigid bodies. Rigid body, according to physics, is an idealization of a solid body whose deformation is neglected and its position determined by the position of its center of mass and by its altitude, taking into account 6 basic parameters referred as degrees of freedom. There are 3 rotational and 3 translational degrees of freedom that represent possible movements of rigid body in three-dimensional space (3D) (Figure 2). These algorithms consider geometry match between molecules and are based on Shape Matching (SM) and Fast Fourier Transform (FFT).

Figure 2. Demonstration of rigid body movement in 3D space considering 6 degrees of freedom (three translational and three rotational); molecule – ID 3 represents rigid body in 3D space
Borišek et al., 2015.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Shape Matching



First calculations and structural analysis of protein-protein interactions (Levinthal, Wodak, Kahn, & Dadivanian, 1975; Selemme, 1976; Wodak & Janin, 1978) led to development of shape matching algorithms applied to search for shape complementarities between two molecules. Kuntz et al. (1982) first presented a method to explore geometrically feasible alignments of ligands and receptors of known structure, where negative images of the receptor were generated. Negative images are represented by spheres that fill the binding sites and algorithm attempts to superimpose the center of these spheres onto ligand atoms (Figure 3a). Several programs such as DOCK (Ewing, Makino, Skillman, & Kuntz, 2001; Allen et al., 2015) and MSDOCK (Sauton, Lagorce, Villoutreix, & Miteva 2008), utilize this approach as part of their search strategies of flexible docking algorithms.

Fast Fourier Transform

Ten years later, new geometric recognition approach was developed by Katchalski-Katzir et al. (1992). Algorithm involves atomic coordinates for the digital representation of molecule by 3D discrete functions that distinguish between surface and the interior of the molecule. Algorithm also calculates correlation function that assesses the degree of molecular surface overlap and penetration considering 6 degrees of freedom using Fourier transformation (Figure 3b). This approach, in comparison with shape matching algorithms, more rapidly evaluates possible associations between molecules. FTDOCK (Gabb, Jackson, & Sternberg, 1997) and ZDOCK (Chen & Weng, 2002, 2003) are examples of docking programs that apply Fourier transformation.

Algorithms that consider ligand and receptor as rigid bodies were initially developed for intermolecular interaction analysis. Latter these methods were optimized for searching binding sites and appropriate ligand pose prediction in ligand-receptor complex where 3D structures of constituent molecules were known. These algorithms, however, are not successful if there is conformational change upon binding of the ligand. Currently, practically all molecular docking software utilizes different approaches for

Figure 3. Schematic representation of shape matching algorithm and fast Fouirer transform

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

considering conformational space of ligand (and in some cases receptor) molecule. Therefore, it can be suggested that nowadays there are no limitations concerning rigid body consideration in molecular docking since several approaches to cope with molecular flexibility are available (details discussed below).

Search Algorithms that Consider Ligand and Receptor as Flexible Bodies

Flexible bodies with consideration of rotational, translational and conformational degrees of freedom are somehow more realistic imitation of biological molecules. Therefore, molecular docking with flexible ligand and flexible receptor is rather accurate approximation of *in vivo* complexes formation, especially when conformational changes upon formation are present. At first flexible-ligand docking algorithms emerged, which considered partial or full flexibility of just ligand and afterwards, due to importance of 'induced fit' paradigm, some specialized algorithms were developed considering also partial flexibility of the receptor/protein. Depending on which molecule of the complex (ligand or receptor) is considered as flexible, the molecular docking is categorized in flexible-ligand docking and flexible-receptor/protein docking methods. Former consider only ligand (partial or full) flexibility, meanwhile latter consider ligand and partial receptor/protein flexibility.

This section of chapter provides description of search algorithms available that consider ligand and/or receptor as flexible bodies and their advantages and limitations. There are three categories of flexible-ligand docking methods (Brooijmans & Kuntz, 2003; Bras, Cerqueira, Sousa, Fernandes, & Ramos, 2014): systematic, random or stochastic, and deterministic.

Systematic Methods

Example of systematic search algorithm is incremental construction or "anchor and grow procedure" approach, (DesJarlais, Sheridan, Dixon, Kuntz, & Venkataraghavan, 1986; Leach & Kuntz, 1992) where ligand is split into several fragments that are separately docked in the receptor site and covalently linked to reassemble the ligand. This method is one of the most applied and employed by several docking programs such as DOCK (Ewing et al. 2001; Allen et al., 2015), FLOG (Miller, Kearsley, Underwood, & Sheridan, 1994), LUDI (Böhm, 1992), etc. FlexX (Rarey, Kramer, Lengauer, & Klebe, 1996; Rarey, Wefing, & Lengauer, 1996) uses this strategy, where chemical interactions are basis for placing the fragments. Therefore the generation of a large set of geometrically feasible solutions is avoided. For placing the base fragment into active site of the protein, FlexX uses pose clustering, where algorithm merges initial placements into clusters. Another systematic search algorithm is database search approach, where libraries of multiple conformations of each ligand structure are constructed. FLOG is the program that constructs Flexibases (Kearsley, Underwood, Sheridan, & Miller, 1994) for ligand flexibility consideration. OMEGA (Hawkins & Nicholls, 2012) is program that generates multi-conformer structure databases used by docking program FRED (McGann, 2011).

Random or Stochastic Methods

There are several types of docking programs that apply random approach: Monte Carlo, simulated annealing, evolutionary algorithms, particle swarm optimization, etc.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Monte Carlo (Caflisch, Niederer, & Anliker, 1992; Hart & Read, 1992) is method that searches for global energy minimum of the conformers. It generates random changes in the ligand conformation, thermodynamically explores different states and selects energetically favorable states to create more reliable protein-ligand complexes. Monte Carlo is standard minimization method and tends to be trapped in local minimum, therefore simulated annealing has been applied to avoid this issue. Simulated annealing (Kirkpatrick, Gelatt, & Vecchi, 1983; Goodsell & Olson, 1990; Yue, 1990) is a technique, where changes in temperature are involved during the run for every conformation and therefore more detailed conformational state (flexibility) at different thermodynamic states is considered. MCDOCK (Liu & Wang, 1999) is a program that utilizes Monte Carlo method for global minimum searching, while AutoDock (Morris et al., 2009) uses simulated annealing approach for more accurate conformations exploration.

Evolutionary algorithms (Morris, Olson, & Goodshell, 2000; Thomsen, 2003), same as Monte Carlo methods, generate and optimize low-energy conformations and orientations of the ligand and thus search for global energy minimum. They have the ability to simultaneously explore the search space with a population of candidate solutions represented by artificial "genes" and form new solutions by combining existing ones. Evolutionary algorithms encompasses a range of algorithms that are based on the principles of biological evolution and the most popular variant of these algorithms are genetic algorithms (GA) (Jones, Willet, & Gleen, 1995; Jones, Willet, Glen, Leach, & Taylor, 1997; Oshiro, Kuntz, & Dixon, 1995) implemented in docking program GOLD (Verdonk, Cole, Hartshorn, Murray, & Taylor, 2003).

Genetic algorithms mimic the process of evolution by manipulating a collection of data-structures called chromosomes. Chromosomes represent randomly generated population that are different ligand poses, where each ligand pose is characterized by a set of state variables that describe translation, orientation and conformation of the ligand in relation to the protein. Each state variable corresponds to a gene, ligand's state corresponds to the genotype and atomic coordinates of ligand correspond to the phenotype. Each of the chromosomes is evaluated with appropriate fitness score, where fitness represents the total interaction energy of the ligand and the protein. Genetic operators like mutations and crossovers, are applied to the population for offspring generation or, in the case of molecular docking, pose space sampling. Selection of the offspring of the current generation occurs based on the fitness of the individual, where the best chromosomes are saved, chromosomes with good scores are selected for propagation into new generation, whereas chromosomes with poor scores perish. The survival of the best chromosomes enables evolution of optimal solutions that represents the correct binding mode. AutoDock uses a hybrid of a genetic algorithm search method together with local search method, named Lamarckian genetic algorithm (LGA) (Morris et al., 1998), which has enhanced performance relative to genetic algorithm alone. This is due to the concept of local search during optimization, which can help to escape local minimum. Although this method is superior to standard genetic algorithm there are still several million evaluation steps needed for the prediction of a reliable protein-ligand pose.

Another stochastic method is particle swarm optimization (Eberhart & Kennedy, 1995), a bio-inspired evolutionary approach to model swarm intelligence. It simulates the social behavior among individuals (particles), with a population (swarm) moving through a multidimensional search space. Each particle of the swarm represents a possible solution described by its location in the search space. As particle between each other share their knowledge about their own best position, the swarm moves towards the best overall solution. In the case of molecular docking swarm represents population of the ligands and particles represent an individual pose, which are determined by translation, orientation and conformation. Each ligand pose moves through the search space and if one of them recognizes a region with low energy the rest of the particles will follow quickly and the best solution is memorized. This

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

method is implemented in AutoDock program (PSO@AutoDock) (Namasivayam & Günther, 2007) as it outperforms default LGA and standard GA in terms of speed, robustness and accuracy of the predicted protein-ligand complex.

Deterministic Methods

Third category that considers ligand as flexible body includes deterministic methods, such as molecular simulations. Simulations provide fine detail that concerns the motions of individual particles as a function of time. Molecular simulations for example numerically solve Newton's equation of motion and therefor allow observation of structural fluctuations with respect to time. Therefore simulations can quantify the properties of a system at a precision and on a time scale that is otherwise inaccessible. Molecular dynamics, energy minimization and also Monte Carlo (Caflisch et al., 1992; Hart & Read, 1992) are methodologies that can be used to investigate and study the dynamics of the system with known atom coordinates (Adock & McCammon, 2006). AMBER (Case et al., 2005; Salomon-Ferrer, Case, & Walker, 2013) and CHARM (Brooks et al., 1983) are example of programs using molecular simulations for different poses generation. Molecular simulations computations are very demanding and require long computation time, which is the reason this method is not popular for virtual screening of large compound libraries. With more powerful computers, there are more and more docking programs that incorporate this method, for example CDOCKER (Wu, Robertson, Brooks, & Vieth, 2003).

SCORING FUNCTIONS

After the first step in molecular docking, where different ligands and ligand poses are determined or generated by various search algorithms, the assessment with scoring function follows, where correct poses from incorrect poses are delineated. The main goal of scoring function is the calculation of the energy that estimates the binding affinity between the protein and the ligand, which can be expressed by the binding free energy (ΔG_{bind}):

$$\Delta G_{bind} = G_{complex} - G_{protein} - G_{ligand} = \Delta H - T\Delta S \tag{1}$$

where ΔG_{ligand} is the free energy of the ligand, $\Delta G_{protein}$ is the free energy of the protein and $\Delta G_{complex}$ is the free energy of the complex formed by the constituent molecules. Binding free energy, also known as Gibbs free energy can be measured by determining the equilibrium binding constant K_{eq}. ΔG_{bind} is related to the K_{eq} by the following equation:

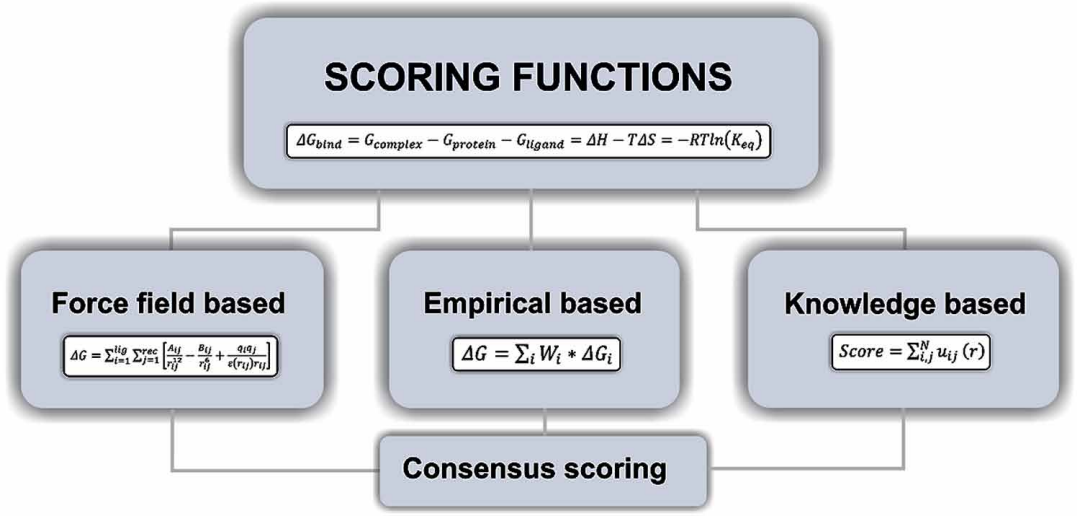
$$\Delta G_{bind} = -RT \ln\left(K_{eq}\right) \tag{2}$$

where R is the perfect gas constant and T is the temperature.

There are numerous methods that are capable to computationally predict the binding free energy of a molecular complex. They significantly differ in accuracy and speed. Scoring function has to follow several criteria for being appropriate for molecular docking applications. Despite being sufficiently fast,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

it must be capable to estimate interaction between molecules that is proportional to the binding free energy, correctly rank the poses, discriminate binders from nonbinders or active compound from inactive compounds, all in comparison with experimentally determined 3D structures of complexes. Free energy perturbation (Zwanzig, 1954) and thermodynamic integration (Straatsma & McCammon, 1991) are methods, which enable very accurate calculation of binding free energies with very high calculation time consumption and that is the reason these are not applied for molecular docking. Other less accurate and therefore less time consuming methods rely on several assumptions and simplifications for binding free energy estimation. These scoring functions are generally classified into four main categories: force-field based (first principle based approach), empirical, knowledge-based and consensus scoring (Gohlke & Klebe, 2001; Brooijmans & Kuntz, 2003; Huang et al., 2010, Meng et al., 2011; Bras et al, 2014) (Figure 4). Below, brief description of every category is provided.



Force Field Based Scoring Functions

Force field based scoring functions basically take into account the non-bonded terms of the molecular mechanics force field, which means they estimate the interaction energy between the protein and the ligand. Non-bonded terms in this case represent electrostatic and van der Waals interactions, where electrostatic term is estimated by a Columbic formulation and van der Waals term by a Lennard-Jones potential function (Mehler & Solmajer, 1991; Meng, Shoichet, & Kuntz, 1992):

$$\Delta G = \sum_{i=1}^{lig} \sum_{j=1}^{rec} \left[\frac{A_{ij}}{r_{ij}^{12}} - \frac{B_{ij}}{r_{ij}^{6}} + \frac{q_i q_j}{\mu\left(r_{ij}\right) r_{ij}} \right] \tag{3}$$

where r_{ij} is the distance between protein atom i and ligand atom j, A_{ij} and B_{ij} are Lenard-Jones parameters, q_i and q_j are atomic charges and ε is distance dependent dielectric constant in the Coulombic term.

Figure 4. Scoring functions applied for assessment in molecular docking

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

DOCK (Ewing et al., 2001; Allen et al., 2015) and AutoDock (Huey, Morris, Olson, & Goodsell, 2007) are based on force field scoring functions.

Besides non-bonded forces there are forces present in protein-ligand binding, such as ionic bonds and hydrogen bonds and also conformational changes after ligand binding, which have to be considered for free energy estimation. Empirical force field scoring function used in AutoDock 4.0 for example (Huey et al., 2007) applies thermodynamic model of the binding process which includes intramolecular terms for the free energy estimation and also a full desolvation model, that includes terms for all atom types (favorable energetics of desolvating carbon atoms and unfavorable energetics of desolvating polar and charged atoms). This semiempirical approach estimates the energetics of the complex formations using pair-wise terms to evaluate interaction between molecules and an empirical method to estimate the contribution of surrounding water. In this aspect semiempirical approach differs from traditional molecular mechanics force field, which uses explicit water molecules for evaluation of solvation contributions and does not include entropic terms that are important for the interaction energy assessment. In some cases implicit solvation models are used for the estimation of desolvation energies of the ligand and the receptor. Poison-Boltzman-surface (Grant, Pickup, & Nicholls, 2001) and generalized Born-surface area (Still, Tempczyk, Hawley, & Hendrickson, 1990; Hawkins, Cramer, & Truhlar, 1995) are examples of models that treat water as continuum dielectric medium.

Empirical Based Scoring Functions

Approximation of binding free energy with empirical based scoring functions is composed of a sum of various energetic terms (Huang et al., 2010; Bras et al., 2014):

$$\Delta G = \sum_i W_i * \Delta G_i \tag{4}$$

where ΔG_i represents different energy terms such as van der Waals energy, electrostatics, desolvation, hydrogen bond, entropy, etc. The coefficients W_i that correspond to specific energy term are derived from regression analysis of known (protein-ligand) complex structures binding affinities.

Böhm (1994) developed first empirical scoring function, implemented in docking program LUDI, which takes into account hydrogen bonds, ionic interactions, lipophilic protein-ligand contact surface and the number of rotatable bonds in the ligand. Afterwards various docking programs implemented similar scoring functions. ChemScore (Eldridge, Murray, Auton, Paolini, & Mee, 1997) for example is parametrized form 82 complexes and is implemented in program GOLD (Cole, Nissink, & Taylor, 2005; Liebeschuetz, Cole, & Korb, 2012) and is also one of the functions available in FRED (McGann, 2011). In comparison with Böhm's scoring function ionic interactions term is absent in ChemScore, whereas metal-ligand binding contributions are taken into account. FlexX (Rarey et al., 1996) docking program also uses similar scoring function with additional aromatic group interactions term consideration. Various docking programs, despite applying similar energy terms typical for empirical scoring functions, implement different computations of specific term.

Empirical scoring functions are generally simpler than force filed based functions, therefor binding score calculations of former are faster. As these functions are dependent on experimental data set used for parameterization it is not necessary that the binding affinity will be predicted correctly for structurally

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

different ligands from those exploited in the training set. With the increasing number of protein-ligand complexes with known 3D structures, functions can be trained with higher number of known binding affinities, which leads into development of scoring functions appropriate for various ligands.

Knowledge Based Scoring Functions

Knowledge based scoring functions are statistical methods, where the parameters of the potential functions are extracted from the structural information of experimentally determined atomic structures. This approach implicitly incorporates physical interactions (electrostatic, van der Walls, cation-π interactions), where high frequency of occurrence/non-occurrence of specific atom-atom interactions is assumed to represent favorable/unfavorable contact (Brooijmans & Kuntz, 2003; Li & Liang, 2006; Huang et al., 2010; Bras et al., 2014). Potential function is the weighted linear sum of pairwise contacts, presented in following formula:

$$Score = \sum_{i,j}^{N} u_{ij}\left(r\right) \tag{5}$$

where i and j represent protein and ligand atom type, r is the distance between atom pair, N is the number of all possible atom pairs in the system and u_{ij} corresponds to the pairwise potentials between atom types, obtained from the occurrence frequency of atom pairs in a database using inverse Boltzman relation:

$$u\left(r\right) = -k_B T\, ln\left(\frac{\acute{A}_{ij}\left(r\right)}{\acute{A}_{ref}\left(r\right)}\right) \tag{6}$$

where k_B is the Boltzmann constant, T is the absolute temperature of the system, $\rho_{ij}(r)$ is the normalized probability of protein-ligand atom pair to be in contact at distance r, and $\rho_{ref}(r)$ is the reference probability - the state where atomic interactions between protein and ligand are zero.

First ideas of statistical potentials originate from the field of protein folding and structure prediction (Huang & Zou, 2006). Tanaka and Scheraga (1976) were first that discussed about the statistical mechanical basis for obtaining the parameters for interactions between amino acids in proteins for prediction of the 3D structure. Since then, knowledge based approaches have been extensively used to develop the scoring functions for protein-ligand interactions and nowadays such scoring functions are implemented in various docking programs, e.g. DrugScore^{CSD} (Velec, Gohlke, & Klebe, 2005), AutoDock Vina (Trott & Olson, 2009) and also GOLD, where knowledge based Astex Statistical Potential (Mooij & Verdonk, 2005) is used as one of the scoring functions for docking. Another interesting method for scoring protein-ligand interaction is knowledge based quantitative structure-activity relationship (QSAR) (Ballester & Mitchell, 2010), where distance-dependent atom pair occurrences are utilized as descriptors for QSAR. Here is machine learning used instead of reverse Boltzman relationship and advantages of this methods are application of a very large training set of binding affinities besides structural data (traditional knowledge based methods use only structural data).

Knowledge based scoring functions, in comparison with force field based and empirical based, offer good balance between accuracy and speed, since the computation is relatively simple and the potentials

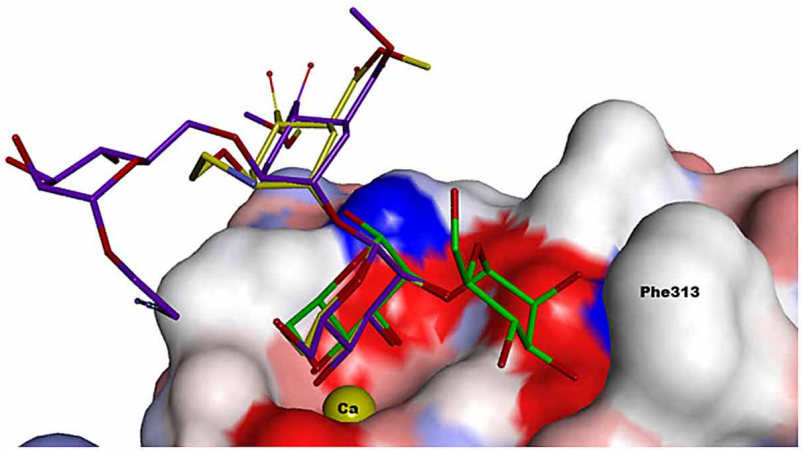
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

are extracted from the known structures of protein-ligand complexes. These functions are also able to implicitly capture the binding effects that are difficult to model explicitly (e.g. sulfur-aromatic and cation-π interactions). The disadvantage of these functions is the accuracy of the reference state, where different methods were developed with attention to solve this problem, for example the adjustments of the pair potentials with iterative method (Huang & Zou, 2006).

Consensus Scoring

Consensus scoring combines results from various scoring functions to improve the performance of scoring in molecular docking. Charifson et al. (1999) first presented the results, where consensus scoring provided reduction in the number of false positives identified by individual scoring functions, leading to a significant enhancement in hit rates. Since then, several studies were published where consensus scoring that indicate improved quality of the results, was applied for evaluating ligand-protein interactions for molecular docking and ligand based virtual screening (Stahl & Rarey, 2001; Clark, Strizhev, Leonard, Blake, & Matthew, 2002; Baber, Shirley, Gao, & Feher, 2005). Improvements depend on the applications, the consensus method and the conditions of the computational tests. However, it should be mentioned that blind combination of arbitrarily chosen scoring functions will not necessarily lead to better results (Feher, 2006). For this purpose Oda et al. (2006) compared the performance of consensus scoring strategies, where multiple scoring functions were used simultaneously and demonstrated that choosing the most appropriate type of consensus score is essential for model selection in computational docking.

CASE STUDY: COMPARATIVE EVALUATION OF SEVERAL DOCKING TOOLS FOR DOCKING SMALL MOLECULE LIGANDS TO DC-SIGN



DC-SIGN: How to Dock Non-Drug-Like Saccharide Ligands into a Non-Druggable Target?

DC-SIGN or Dendritic Cell-Specific Intercellular adhesion molecule-3-Grabbing Non-integrin is a C-type lectin located specifically on dendritic cells (DCs). Several pathogens like HIV-1 enter DCs using DC-SIGN as an entry receptor, but escape the normal lytic pathway thus avoiding the host immune system (Anderluh, Jug, Švajger, & Obermajer, 2012). Potential anti-infectives that would inhibit DC-SIGN-pathogen interaction as the very first step in pathogen infection would act via completely new mechanism of action as compared to the current mode of anti-infectives' action. Therefore, the main scope of the research was the design of new DC-SIGN carbohydrate recognition domain (CRD) antagonists that could act as novel anti-infectives (Anderluh et al., 2012; Obermajer et al., 2011; Tomašič et al., 2014). Authors have envisaged docking studies as a great help in the design of new DC-SIGN antagonists to virtually preselect potential antagonists to be synthesized and characterized thus avoiding a vast effort in synthetic and biochemical laboratory (Jug, Anderluh, & Tomašič, 2015; Obermajer et al., 2011; Tomašič et al., 2014). Unfortunately, DC-SIGN proved to be a hard target for docking studies for several reasons and therefore authors decided to seek a docking tool that would address the below listed issues to a highest possible extent (Jug et al., 2015).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

- As a lectin, DC-SIGN specifically binds glycosylated proteins, oligosaccharides and monosaccharides. The main determinant of its binding site is the hexacoordinated Ca^{2+} ion that forms two complex bonds with water molecules in the unbound state (Figure 5). Similar interactions are formed with the hydroxyl groups of the bound monosaccharide at positions 3 and 4 alone (i.e. D-mannose or L-fucose) or as a part of glycoconjugate with aglycone part attached to increase binding affinity. Accordingly, a key question was whether the docking algorithm can predict the coordination bonds between the core mannose and DC-SIGN and whether the scoring functions are able to evaluate the coordination bonds accurately.
- Desolvation is expected to be of paramount importance in docking studies of highly solvated ligands like (oligo)saccharides (Kroemer, 2007). DC-SIGN binds oligosaccharides and non-drug-like glycoconjugates that undergo massive desolvation of saccharide moieties upon binding, so different docking algorithms were tested to correctly evaluate their binding, even if desolvation effects are not considered explicitly or ignored.
- Docking of small molecules to a flat/shallow binding site is likely to result in a number of different (either correct or wrong) docked poses (Gowthaman, Deeds, & Karanicolas, 2013). Accordingly, the values of assigned binding energy could be of similarly diverse values because scoring functions are not able to accurately estimate all of the possible interactions and desolvation of the target protein and ligand poses. DC-SIGN CRD binding site is rather flat and shallow, and hence non-druggable, so there is a high probability of docking protocol failing to correctly predict the binding pose of a ligand.

Figure 5. Binding site of DC-SIGN with bound ligand(s) from several crystal structures of DC-SIGN CRD; Ca^{2+} ion and flexible side chain of Phe313 are explicitly named. The protein is presented as a surface colored according to the electrostatic potential and the Ca^{2+} ion is presented as a yellow sphere. Ligands shown on this figure were taken from the above stated crystal structures and are presented as sticks in following color: ligand from 2IT6 (dimannoside Manα1-2Man) is presented in green, ligand from 2XR5 (pseudo-dimannoside mimic) is presented in yellow, and ligand from 2XR6 (pseudo-trimannoside mimic) is presented in violet (Jug et al., 2015)

Selected Docking Programs and Crystal Structures

Five docking tools that differ in the search algorithms and scoring functions have been validated in the study: FlexX (Rarey et al., 1996; Rarey et al., 1996) as available in LeadIT 2.1.2 (BioSolveIT GmbH), CDOCKER (Wu et al., 2003) as available in Accelrys Discovery Studio 3.0 (Accelrys Inc.), FRED 2.2.5 (McGann, 2011) (OpenEye Scientific Software, Inc.), AutoDock 4.2 (Morris et al., 2009) and GOLD 5.2 (Verdonk et al., 2003) (The Cambridge Crystallographic Data Centre). GOLD and AutoDock use a genetic algorithm (Kitchen et al., 2004), FRED uses a docking algorithm based on Gaussian function (McGann, 2011), CDOCKER uses a molecular dynamics simulated annealing-based docking algorithm (CHARMm) (Wu et al., 2003) and FlexX uses an incremental construction algorithm (Rarey et al., 1996). Re-scoring was performed with HYDE (Schröder et al., 2013) (BioSolveIT).

Re-docking of ligands from selected crystal structures has been performed to allow high ligand diversity. The 3D structures of all ligands used for docking validation were extracted from selected crystal structures of D-mannose containing ligands in complex with DC-SIGN CRD (Figure 5) (PDB codes: 2IT6, 2XR5 and 2XR6). Description of specific ligand preparation and docking protocols is beyond the scope of this chapter and may be found in the original publication (Jug et al., 2015).

RMSD (root-mean-square deviation) was selected as the key parameter for evaluation of docking success (Jain, 2008). Ligand poses from the above mentioned crystal structures were used as a reference for calculation of RMSD values. The upper RMSD limit which still fulfils criteria of acceptance was set to 2.00 Å. A visual comparison of crystal structure ligand pose and the docked poses was done after every successfully completed docking run. Afterwards, RMSD values for the top ten ranked poses were calculated and compared.

Results

The aim was to set up the docking protocols within all numbered programs in such a way that the top pose of docking will also have an RMSD less than 2.00 Å or, in the best possible situation, that the top pose will also have the lowest RMSD value. The calculated RMSD values for the top ranked ligand pose for all three crystal structures and all stated docking programs are listed in Table 2.

FRED gave the lowest RMSD values for the top ranked poses of all three ligands that were re-docked within the RMSD cut-off value of 2.00 Å (Figure 6). Furthermore, FRED performed the best among

chosen docking tools when considering overall RMSD values - taking into account RMSD values of the top ten ranked poses for all three ligands. Promising results were also achieved using CDOCKER, which did not perform well only for the most complex ligand (2XR6). FlexX, which was used in previous study (Obermajer et al., 2011) showed exceptional performance with the first ligand (2IT6), but intriguingly failed later with the other two ligands. However, when FlexX docking poses were re-scored by HYDE, significant improvements of RMSD values were observed in these cases. GOLD and AutoDock performed exceptionally well in docking studies of targets with constrained binding pockets, but failed to perform satisfactorily even at re-docking of the least complex disaccharide ligand (2IT6). Authors presume that the major reason for different performance of the selected tools is the difference between their search algorithms. Majority of them were designed for non-carbohydrate ligands and druggable binding sites, where a small difference in the ligand conformation might result in a substantial difference in the score due to the steric clash and/or repulsive electrostatic interactions, but when faced with the large, flat and shallow binding sites, these algorithms presumably tend to overestimate the influence of small changes in the ligand conformation. For example, AutoDock and GOLD use a genetic algorithm (stochastic) that requires a large number of ligand conformations to explore all the conformational space available for the ligand. In this manner, a vast number of conformations combined with poorly defined (large, flat and shallow) binding site results in a combinatorial explosion that inevitably leads to a higher number of wrongly predicted docking poses. The results also suggest that the incremental construction algorithm used by FlexX should not be considered as the first choice for docking studies involving DC-SIGN and possibly to other non-druggable binding sites. On the other hand, FRED uses a systematic docking algorithm based on Gaussian function and a multi-conformer structure database pre-generated by OMEGA (Hawkins & Nicholls, 2012) that is limited to a much smaller number of ligand conformations. As a consequence, FRED's scoring function is faced with an easier task to distinguish between rather different conformations, so fewer errors are made. Furthermore, observed differences in docking tool performance might be a consequence of inadequate estimation of desolvation penalties and/or complex bonds. One rather simple and expected general rule could be extracted from the results; re-docking of all the ligands with all five docking programs showed that the RMSD increases with greater complexity of the ligand. However, relative differences between all 3 ligands do not correlate among docking tools as these are smaller when using FRED and CDOCKER compared to other docking tools, so again it is presumed that their search algorithms perform better when faced with non-druggable targets and/or large ligands.

The second aim of the study was to check how well the selected docking programs are able to reproduce the pose of the core mannose in comparison with its pose in the crystal structure. The core mannose pose is presumed to be even more important than the overall position of the ligand, as is strongly related to establishment of the coordination bond with Ca^{2+} and the hydrogen bonds with the amino acid residues in the active site. The RMSD values for core mannose for all of the three crystal structures are presented in the Table 3.

Most programs successfully predicted core mannose pose (when considering RMSD for the mannose only), but not when RMSD values for the whole ligands were considered. Once again FRED performed well (Figure 6), with an average RMSD for the core mannose of 0.79 Å. CDOCKER outperformed FRED with an average RMSD for the core mannose of 0.62 Å, which might imply that CDOCKER calculates complex interactions better than FRED. Taking into account the positioning of core mannose only, the fair performance of FlexX should be noted. Authors presume that FlexX possibility of defining Ca^{2+} ion as a "pharmacophore" allows better estimation of complex bonding and thus correct prediction of the core mannose pose. GOLD also showed promising results for the pose prediction, while AutoDock was

not satisfactory. HYDE re-scoring improved the RMSD in the case of the least complex ligand (2IT6), while in other two cases RMSD surprisingly slightly increased. The graphic presentations of the docking results can be obtained in the original publication (Jug et al., 2015).

To conclude, results in this study show that even widely used docking programs have certain limitations when faced with a rather shallow and flat (i.e. non-druggable) binding site, as is the case of DC-SIGN. FRED and CDOCKER were found to be appropriate for docking studies on DC-SIGN, as evaluated by the calculated RMSD values for each of the re-docked ligands and for the core mannose only, while other programs showed more or less weaknesses. Among these two, FRED was found as the best tool for docking ligands to DC-SIGN and therefore authors suggest it as a suitable docking program for docking studies on DC-SIGN and similar targets with non-druggable binding sites.

CASE STUDY: COVALENT DOCKING OF CATHEPSIN K

Covalent Docking

There are several drugs on the market that act by covalent inhibition (e.g. acetylsalicylic acid, amoxicillin, omeprazole, rivastigmine). Their mechanism of action is connected to their electrophilic "warheads", which target nucleophilic protein residues such as serine and cysteine, and they can form reversible or irreversible covalent linkage (London et al., 2014; Weerapana et al., 2010).

The main aim of designing covalent inhibitors is to increase selectivity and potency, particularity by targeting non-conservative protein residues and shallow binding pockets. However, covalent inhibitors could also possess promiscuous behavior causing off target effects and can be toxic due to prolonged duration off biological effects in case of irreversible binding mode. Therefore, specific noncovalent interactions are crucial for warhead orientation relative to protein nucleophile, stabilizing ligand-target complex and increasing selectivity in order to achieve desired selectivity and potency. Thus the main goal of covalent docking is to identify scaffolds that optimally orientate electrophilic warhead, and as in the case of noncovalent docking, to minimize the number of compounds that have to be prepared and biochemically/biologically evaluated (Kumalo, Bhakat, & Soliman, 2015; London et al., 2014).

In covalent docking studies, the reaction between ligand and receptor has to be taken into account. That could be achieved by "link atom" approach, which utilizes predefined link atom for both, the ligand and the target. It mimics the covalent binding event by forcing ligand link atom to occupy the same steric volume as the target link atoms (GOLD docking software) (Verdonk et al., 2003). On the other hand, "grid based method" and "modification of the flexible side chain" methods are utilized in covalent docking approach of Autodock software (Morris et al., 2009). Another covalent docking approach is based on treating covalent bond as a noncovalent interaction with the sum of additional energy contribution from the covalent bond formation - program CovalentDock (Ouyang et al., 2013).

It has to be mentioned that covalent docking has also its disadvantages; similar to noncovalent docking, poor scoring functions, limited protein flexibility, speed and accuracy are the main issues. Besides that, lack off automation and ligand preparation steps are time consuming (Kumalo et al., 2015).

There are several software packages and webservers suitable for covalent docking:

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

- **Software:** GOLD (Verdonk et al., 2003), CovalentDock (Ouyang et al., 2013), Autodock (Cosconati et al., 2010), Glide (Friesner et al., 2006), CovDock (Zhu et al., 2014), CovDock-VS (Warshaviak, Golan, Borrelli, Zhu, & Kalid, 2014), etc.
- **Webservers:** CovalentDock Cloud (Ouyang, Zhou, Ge, Li, & Kwoh, 2013), Dockovalent (Irwin et al., 2009), etc.

Covalent Docking of Potential Cathepsin K Inhibitors by GOLD Docking Software

The covalent molecular docking studies were performed on 254-membered benzamide-containing aminonitriles dataset by GOLD Suite v5.1 docking package (Verdonk et al., 2003). Crystal structure of cathepsin K (Cat K) was derived from PDB with entry code 4DMX (Dossetter et al., 2012). Binding site was defined around experimental coordinates of the 0LB301 (Dossetter et al., 2012) bound ligand in radius of 6Å. In order to perform covalent docking, dummy sulfur linking atom was attached to each studied ligand. Subsequently, ligands were renumbered in a way that previously added sulfur's atom number was set to 1. Cat K sulfur atom on Cys25 was then matched with dummy sulfur atom of ligand. Preparing ligands in this way was necessary for GOLD to recognize and set the correct covalent bond between predefined ligands and proteins linking atoms (Schröder et al., 2013).

Re-docking procedure was performed by docking reference ligand 0LB301 into the binding site with early termination allowed if the top three solutions were within 1.5 Å of the root-mean-squared-deviation value in order to define optimal parameter and scoring function (Kirchmair, Markt, Distinto, Wolber, & Langer, 2008). Finally, each ligand was docked into the binding site by the selected scoring function and applying the following parameters of the GOLD genetic algorithm: population size = 100, selection pressure = 1.1, no. of operations = 100,000, no. of islands = 5, Niche Size = 2, migrate = 10, mutate = 95, crossover = 95 (Jones et al., 1997).

Results

Co-crystallized Cat K inhibitor 0LB301 was used to access visual fitness and orientation of docked compounds. Re-docking ligand validation gave satisfactory results as GOLD managed to reproduce accurate binding poses of experimentally bounded ligand 0LB301 with good accuracy. Scoring function ChemScore (CSF) yielded the lowest RMSD value (0.19 Å) for re-docking procedure and was chosen for the assessment of the binding affinities.

Post docking analyses were divided into two parts. In the first part, docking dataset was visually examined as visual fitness and orientation were compared to experimental pose of the 0LB301 ligand. If visual fitness and orientation of a studied compound were correct, the second level post docking analyses were performed by measuring interatomic distances between docked compound features and key amino acid residues of 4DMX.Visual inspection yielded 113/254 compounds from docking dataset with orientation and fitness in concordance with experimentally bound ligand.

In the second part of post-docking analyses the key distances between ligands features and binding site of protein residues 4DMX were measured. According to previously published data (Palmer et al., 2005), three H-bond interactions between ligand and protein were used: (R- N**H**-CH_3 - CN)-(Asn161-C**O**) [$d_{4DMX\text{-}1}$ = 3.28 Å], (R-C**O**-NH-CH_3-CN)-(Gly66-N**H**) [$d_{4DMX\text{-}2}$ = 3.22 Å], (R-Ph-CO-N**H**-R`)-(Gly66-C**O**) [$d_{4DMX\text{-}3}$ = 2.9 Å]. Because of dynamic nature of biological systems, the tolerance of ±1Å for each

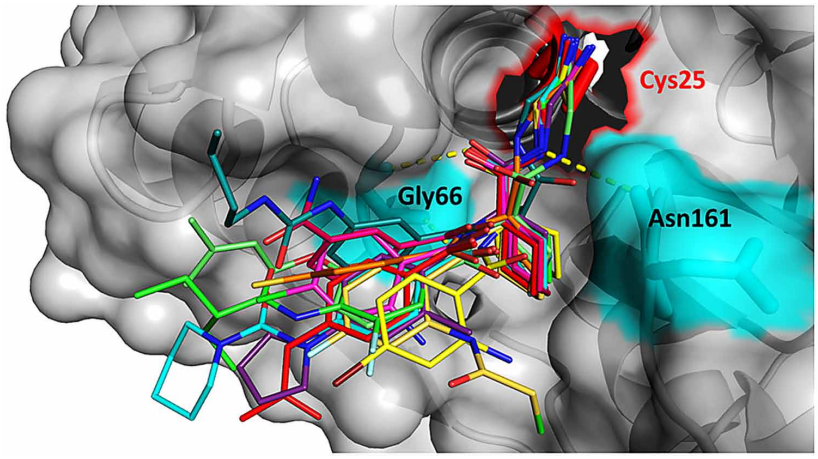
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

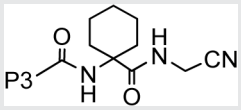
interaction distance is used: (R- N**H**-CH_3 - CN)-(Asn161-C**O**) [d_{4DMX-1} = 2.28 - 4.28 Å], (R-C**O**-NH-CH_3-CN)-(Gly66-N**H**) [d_{4DMX-2} = 2.22 – 4.22 Å], (R-Ph-CO-N**H**-R`)-(Gly66-C**O**) [d_{4DMX-3} = 1.9 - 3.9 Å]. Interatomic distance measurement yielded 12/254 correct compounds (Figure 7).

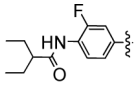
Additionally, QSAR model for prediction of biological activities were applied (Borišek, Drgan, Minovski, & Novič, 2014) which resulted in 4/254 finally valid compounds (Table 4).

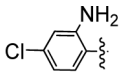
Resulted compounds from the docking study were thereafter synthesized and proved to be reversible and selective inhibitors of Cat K in a nanomolar range (Borišek et al., 2015).

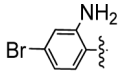
Figure 7. Close view of the 12 GOLD-calculated covalently bound combinatorial Cat K ligands; the key attachment point for covalent bond formation is Cys25 and the amino acid residues Gly66 and Asn161 (depicted in cyan) are important for the stabilization of the ligand through H-bonding.











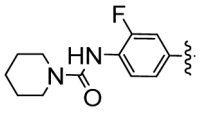


Table 4. Resulted 4/254 compounds after combining molecular docking and QSAR modeling results

ID	P3	CSF	d_{4DMX-1}	d_{4DMX-2}	d_{4DMX-3}	K_i (nM)

Authors decided to employ GOLD docking software for covalent docking since the familiarness with this program and positive experience relating to noncovalent docking in GOLD. There is also easy to follow step by step description of covalent docking procedure in GOLD tutorial. It has to be stressed that ligand preparation for covalent docking was not automatized and was more time consuming compared to noncovalent docking. Additional studies are planned to compare several docking programs and webservers for covalent docking in order to find most suitable one for particular ligand-target system.

CONCLUSION

This chapter provides overview of computational approaches for molecular docking, considering several of the most commonly used program tools (AutoDock, FRED, CDOCKER, FlexX and GOLD). The application of these algorithms authors present in the comparative study for docking of small ligands to specific protein, lectin Dendritic Cell-Specific Intercellular adhesion molecule-3-Grabbing Non-integrin (DC-SIGN) and covalent docking of cathepsin K with GOLD. As explained in the chapter, five docking tools have been validated in the case study based on the in-house availability, but above all because of the intrinsic difference among them. They differ in the search algorithms and scoring functions, and those with most different algorithms and scoring function were selected. Of course, the selection of various other docking software would be more appropriate (like ADAM, DARWIN, DOCK, eHiTS, FLIPDock, Glide, YUCCA, etc.), but it is practically impossible to evaluate all of them. It was presumed that the mentioned intrinsic differences would most probably result in significant differences in performance of various software, which indeed turned out to be true.

ABSTRACT

The computational strategies permeate all aspects of drug discovery such as virtual screening techniques. Virtual screening can be classified into ligand based and structure based methods. The ligand based method such as Quantitative Structure Activity Relationship (QSAR) is used when a set of active ligand compounds is recognized and slight or no structural information is available for the receptors. In structure based drug design, the most widespread method is molecular docking. It is widely accepted that drug activity is obtained through the molecular binding of one ligand to receptor. In their binding conformations, the molecules exhibit geometric and chemical complementarity, both of which are essential for successful drug activity. The molecular docking approach can be used to model the interaction between a small drug molecule and a protein, which allow us to characterize the performance of small molecules in the binding site of target proteins as well as to clarify fundamental biochemical processes.

INTRODUCTION

The Molecular modeling expression is used to describe the use of computers to build compounds and carry out a variety of calculations on these compounds in order to predict their chemical characteristics and behavior. The computational strategies also permeate all aspects of drug discovery such as virtual screening techniques in comparison to the process of trial and error that was used in the search for novel drugs.

The most important challenges that medicinal chemists face today is the design of new drugs with improved potency and less side-effects for treating human diseases such as AIDS and others. Medicinal chemists begin the process by taking a lead structure and then finding analogs exhibiting the preferred biological activities. Next, they use their experience and chemical insight to eventually choose a candidate analog for further development. This process was not only difficult but also expensive and time consuming. The conventional methods of drug discovery are now being supplemented by shorter approaches made possible by the accepting of the molecular processes involved in the original disease. In this view, the preliminary point in drug design is the molecular target, which is a receptor or enzyme in the body as an option of the existence of the known lead structure.

The effective design of chemical structures with the desirable therapeutic properties is directed towards Computer Aided-Drug Design (CADD) a well-established area of Computer Aided-Molecular Design (CAMD). The main applications of CAMD are the clarification of the basic requirements for a compound to obtain a determined activity, the simulation of the binding between a ligand and the receptor, the discovery of new active compounds and the prediction of activities for non-synthesized analogues. Two major modeling strategies right now are used in the designing of new drugs. In the first strategy, the design is based on the comparative analysis of the structural features of known active and inactive molecules that are interpreted in terms of their complementarily with a supposed receptor site model. This strategy is called *ligand based design* and one of its approaches is quantitative structure activity relationships (QSAR). This discipline was promoted by Hansch and his group (Fujita, 1990). In the second strategy, the three-dimensional features of a known receptor site are directly considered and this strategy is called *structure based design* method. In structure based drug design, the most widespread method is molecular docking (Mahajan A., Gill N.S & Arora R., 2014; Xuan-Yu Meng, Hong-Xing Zhang, Mihaly Mezei & Meng Cui, 2011) The molecular docking approach which will be discussed in details in the coming section can be used to model the interaction between a small drug molecule and a protein, which allow us to characterize the performance of small molecules in the binding site of target proteins as well as to clarify fundamental biochemical processes.

This chapter deals with the two strategies that are used in designing new drugs. At first, focus will be on the ligand based design or QSAR approach. The QSAR section starts with history and the earliest efforts made in this field, types of descriptors and statistical analysis methods. Moreover, validation of QSAR models, the internal as well as the external validations. Second, the focus will be on the structure based design or molecular docking approach. The different types of docking methods will be discussed including the different software used. At the end, applications or case studies done by the authors and others will be discussed also. For example, Exploration of human serum albumin binding sites by docking and molecular dynamics, Docking study related to non-peptide HIV-1 protease inhibitors, Homology modeling, molecular dynamics and docking simulations of rat A2A receptor, Exploring the ligand recognition properties of the human vasopressin V1a receptor using QSAR and molecular modeling studies and others. These studies will introduce the reader to the field of molecular docking and its use in structure based drug design. Finally, more attention must be dedicated to the combination of the two approaches in designing new drugs.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

BACKGROUND

The approach of designing new drugs can be classified into ligand based and structure based methods. The ligand based method such as quantitative structure activity relationship (QSAR) is used when a set of active ligand compounds is recognized and slight or no structural information is available for the receptors. In structure based drug design, the most widespread method is molecular docking. The molecular docking approach can be used to model the interaction between a small drug molecule and a protein, which allow us to characterize the performance of small molecules in the binding site of target proteins as well as to clarify fundamental biochemical processes.

LIGAND BASED DESIGN METHOD

Quantitative Structure Activity Relationships (QSAR)

QSAR is a way of finding and modeling a simple mathematical equation between molecular descriptors calculated from structures of a set of molecules with their reactivity in order to be able to predict the reactivity of unknown compounds.

Applications of QSAR can be extended to any molecular design purpose, including prediction of different kinds of biological activities, lead compound optimization and prediction of novel structural leads in drug discovery. QSAR consists of several steps which hopefully lead to the design of new compounds with the desired activity profile.

The QSAR approach follows these steps. The first step of building a QSAR model is to select a training set consisting of compounds with their experimental biological activities. The next step is to optimize the molecular structure by a proper technique. Afterwards, one should compute descriptors that contain sufficient relevant information about the biological phenomenon. Once descriptors have been calculated, it is necessary to pick which should be included in the QSAR model. Therefore, feature selection techniques are used to select the most relevant descriptors from a pool of descriptors. One way is simply to use the correlation coefficient method to select the descriptor with the highest correlation coefficient. Next step, a data analysis is needed to calculate the best mathematical expression linking together the descriptors and biological activities, In the final step, validation and predictions for non-tested compounds will take place. However, the predictive capability of the model first is verified using an external set of compounds which are not used in calibration. This is talented by biological testing of some additional compounds (test set) in the same way as the training set and then comparing the experimental finding with the values predicted by the QSAR model. If the QSAR predicts within acceptable restrictions, it may be used for a more extensive prediction of more compounds.

Hansch equation (Hansch, 1969) was developed to correlate physicochemical properties (descriptors) with biological activities and is given in a general form by the following equation (1):

$$\log \frac{1}{C} = a(\log P)^2 + b\,log\,P + cs + \cdots k \tag{1}$$

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

where *C* is the molar concentration that produces the biological effect; *P* is the octanol/water partition coefficient and *s* is the electronic Hammett constant.

Descriptors

A common question in QSAR is how to describe molecules and their physicochemical properties (descriptors). The nature of the descriptors used and the extent to which they instruct the structural properties related to the biological activity is a critical step in a QSAR study It has been estimated that over a thousand of molecular descriptors can now be calculated from a given molecular structure (Devillers & Balaban, 1999; Karelson, 2000;Todeschini, Consonni & Pavan, 2001). Most of those descriptors can be calculated by using commercial software packages such as CODESSA (Katritzky, Lobanov & Karelson, 1994), DRAGON (Todeschini, Consonni & Pavan, 2001) and others. The various descriptors in use can be largely categorized as being constitutional, topological, electrostatic, geometrical, or quantum chemical.

Statistical Methods

Many different statistical methods are available in the literature and the selection of the appropriate method is critical (Xu & Zhang, 2001). However, we will try to mention some basic techniques, one linear and one non-linear, which were extensively used in QSAR/QSPR studies.

Multiple Linear Regression (MLR) (Montgomery & Peck, 1992) can be considered as an easy interpretable linear regression method. Regression analysis correlates independent X variables or descriptors with dependent Y variables (biological data). The regression model assumes a linear relationship between *m* molecular descriptors and the biological activity variable. This relationship can be expressed with the single multiple-term linear equation as follows:

$$y = b_0 + b_1 x_1 + b_2 x_2 + \cdots + b_m x_m + e \tag{2}$$

The MLR analysis calculates the regression coefficients, b_i, by minimizing the residuals, **e**, which quantify the deviations between the data (Y) and the model (Y'), as in the case of simple linear regression.

Artificial Neural Networks (ANN) method (Duprat, Huynh & Dreyfus, 1998; Tetko, Alessandro, Villa & Livingstone, 1996;) is a non-linear technique inspired in the human brain, composed of many simple processing units called neurons. This method is also recognized as learning algorithms. The aim is to simulate the various shells of the neurons, where each neuron is connected to a number of neighboring neurons with variable coefficients of connectivity that signify the strength of these associations. Several examples of this methodology are explained in Montañez-Godinez *et al* (2014).

Validation of QSAR Models

After the model equation is obtained, or it is also significant to estimate the power and the validity of the model before using it to predict the biological activity. Validity is to establish the reliability and significance of the method for a particular use. For that reason, validation of a QSAR model must be done. There are two validation methods used for a QSAR model: internal and external validation techniques to establish the confidence and strength of the model.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Internal validation uses the data set from which the model is built and checks for internal stability. *Cross-Validation (CV) technique* is widely employed as an internal validation method of statistical models (Wold, 1991). External validation evaluates how well a built model is generalized. If a sufficiently large series of compounds with known activity are obtainable, the original data set can be divided into two subgroups, the *training set* and the *test set.* The training or calibration set is used to derive a calibration model that will be used later to predict the activities of the test or validation set compounds.

STRUCTURE BASED DESIGN METHOD

Molecular Docking

It is widely accepted that drug activity is obtained through the molecular binding of one ligand to receptor. In their binding conformations, the molecules exhibit geometric and chemical complementarity, both of which are essential for successful drug activity. The computational process of searching for a ligand that is able to fit both geometrically and energetically the binding site of a protein is called molecular docking. The docking process involves the prediction of ligand conformation and orientation within a targeted binding site. In general, there are two aims of docking studies: accurate structural modeling and correct prediction of activity.

The docking program is used to place computer-generated representations of a small molecule into the active site of an enzyme in a variety of positions, conformations and orientations. Each such docking mode is called a 'pose'. In order to identify the energetically most favorable pose each pose is evaluated or simply 'scored' based on its complementarity to the target in terms of shape and properties such as electrostatics. A good score for a given molecule indicates that it is potentially a good binder. This process is repeated for all molecules in the collection, which are subsequently rank-ordered by their scores (or their predicted affinities). Assuming that both the poses and the associated affinity scores have been predicted with reasonable accuracy, this selection will contain a relatively large proportion of active molecules

The prediction of the protein–ligand complex is usually done by searching the translational and rotational degrees of freedom of the ligand within the receptor binding site, and by searching the conformational degrees of freedom of the ligand itself. Binding conformations generated by docking programs are thus defined by both a position of the ligand on the receptor surface and a particular ligand conformer. The first docking algorithm for small molecules was developed by the Kuntz group at UCSF in 1982 (Kuntz *et al*., 1982). Before ligands can be docked against a receptor, generally the binding site has to be identified first. This is done to limit the search space on the receptor surface and thus minimize the degrees of freedom that have to be searched. The active site is often known from crystal structures of ligand-bound receptors, but it can also be predicted. The largest cavity on a protein surface is frequently the active site, but this is not always the case and different active site prediction and analysis methods have been developed. In the absence of knowledge about the binding sites, cavity detection programs such as GRID (Goodford 1985; Kastenholz, Pastor, Cruciani, Haaksma & Fox 2000), POCKET (Levitt & Banaszak 1992), SurfNet (Laskowski 1995; Glaser, Morris, Najmanovich, Laskowski & Thornton. 2006), Docking without any assumption about the binding site is called blind docking. Various excellent reviews on docking have been published in the past (Kitchen, Decornez, Furr & Bajorath 2004; Halperin, Ma, Wolfson & Nussinov 2002; Coupez & Lewis 2006; Kontoyianni, Madhav, Suchanek & Seibel 2008;

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Brooijmans & Kuntz. 2003). In the following sections, we will give more details about the docking theory including search algorithms, scoring functions, docking software's as well as docking methods.

DOCKING ALGORITHMS

Docking algorithms generally contain two search engines; one is responsible for the placement and exploration of the ligand in the binding site, while the other searches the internal degrees of freedom of the ligand. For ligands without any degrees of freedom, it is feasible to search the six translational and rotational degrees of freedom in the receptor binding site. However, as the number of rotatable bonds of the ligand increases, the number of degrees of freedom increases exponentially when finding solutions to fit into the binding site. Different algorithms are available and can be divided into three major categories. The first algorithm is a grid search that comprehensively searches the binding site by moving the rigid ligand through the available six degrees of freedom in a systematic fashion in the binding site. The original algorithm only looked for surface complementarity (Katchalski-Katzir *et al*., 1992), but later implementations also use electrostatic complementarity, as in FTDOCK (Gabb, Jackson, & Sternberg, 1997) for example. The second algorithm and significantly more efficient algorithm place ligands in the binding site by descriptor matching (Ewing & Kuntz, 1997). Descriptors to find a solution are generally points, sometimes with properties associated to them, placed in the receptor site. Ligand atoms are matched with the receptor descriptors with some tolerance. The descriptor matching algorithm orients the ligand in the binding site, which subsequently has to be optimized and scored. Usually a large number of orientations are possible, and they all have to be explored and optimized. When binding site descriptors are associated with physical– chemical properties, such as hydrophobicity and hydrogen-bonding capabilities, the ligand atoms have to match geometrically as well as chemically. DOCK (Shoichet & Kuntz, 1993; Moustakas *et al*., 2006) and FlexX (Rarey, Wefing & Lengauer, 1996) use descriptor matching to orient the ligand in the binding site. The third algorithm is an energy-based search method using molecular mechanics force fields to explore the energy surface of the ligand with molecular dynamics (MD) or energy minimization algorithms. The minima of the ligand on the surface have to be located and assessed in terms of their complementarity to the receptor. Energy minimization is a local search, and is only used to optimize binding conformations generated by other search engines. MD searches are global searches in principle, but also tend to get stuck in local minima. This search strategy generally explores all degrees of freedom simultaneously, and is therefore not strictly considered as orientation algorithms.

In summary ligand search algorithms are divided into three types of methods, namely systematic, stochastic, and deterministic. Systematic search methods are frequently used in rigid protein-ligand docking, where there are only six degrees of freedom, while genetic algorithms and Monte Carlo are stochastic search algorithms, and molecular dynamics and energy minimization are deterministic algorithms.

Scoring Functions

The search algorithm of a docking method generates a set of candidate dockings for a particular ligand, but some mechanism is needed to decide which ligand placements are better than others, and thereby rank conformations against each other. This mechanism is called a scoring function. Scoring functions can be classified into three categories: knowledge-based, empirical and force field-based. Knowledge-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

based scoring functions rely on statistical means to extract rules on preferred, and non-preferred atom pair interactions from experimentally determined protein-ligand complexes. The rules are interpreted as pair-potentials that are subsequently used to score ligand binding poses. The PMF score (Muegge & Martin 1999), for example, is a well-known knowledge-based scoring function. Empirical scoring functions sum enthalpic and entropic interactions with the relative weights of the terms based on a training set of protein-ligand complexes. The interaction terms often include Van der Waals, electrostatic interactions and hydrogen bonds. Examples of empirical scoring functions include ChemScore (Eldridge, Murray, Auton, Paolini & Mee 1997) and the FlexX (Rarey, Wefing, & Lengauer, 1996) scoring function. Force field scoring functions are similar to empirical scoring functions in that they predict the binding free energy of a protein-ligand complex by adding up individual contributions from different types of interactions. However, they differ from empirical scoring functions in that the interaction terms are derived from physical chemical phenomena as opposed to experimental affinities. Examples of force field scoring functions in docking programs include the energy score in DOCK (Shoichet and Kuntz, 1993; Moustakas *et al*., 2006), the score function used for single ligand docking in GOLD (Jones, Willett, Glen, Leach and Taylor 1997). Several reviews on the use of various scoring functions employed in docking calculations have been published (Tame, 1999; Halperin, Ma, Wolfson & Nussinov 2002; Gohlke & Klebe 2001).

Docking Software

A large number of docking programs have been published. Each program applies a certain algorithm that explores the way the ligands are treated during docking. For example, programs that follow the algorithm in which the ligand is built up incrementally, starting from a docked 'base fragment' are DOCK (Shoichet & Kuntz, 1993; Moustakas *et al*., 2006), and FlexX (Rarey, Wefing & Lengauer, 1996). In other programs, such as AutoDock (Morris *et al*., 1998; Osterberg, Morris, Sanner and Olson, 2002), Genetic Optimization for Ligand Docking (GOLD) (Jones, Willett, Glen, Leach & Taylor 1997) the ligand is treated in its entirety. Few docking programs allow protein flexibility such as AutoDock (Osterberg, Morris, Sanner & Olson, 2002), FlexE (Rarey, Wefing, & Lengauer, 1996) and QXP (McMartin and Bohacek, 1997). Another measure to classify docking programs would be according to the search strategy employed. For example, DOCK (Shoichet & Kuntz, 1993; Moustakas *et al*., 2006) and FlexX (Rarey, Wefing, & Lengauer, 1996) trying to maximize shape complementarity while AutoDock (Morris *et al*., 1998; Osterberg, Morris, Sanner & Olson, 2002), QXP (McMartin & Bohacek, 1997) and GOLD (Jones, Willett, Glen, Leach & Taylor 1997) programs incorporating an energy-driven or stochastic algorithm.

DOCKING METHODOLOGIES

Rigid Ligand and Rigid Receptor Docking

In this type of docking, the ligand has six degrees of freedom, three translational and three rotational in which the search space is limited. Only one conformation of the ligand is considered. No internal rotations about bonds are permitted in either molecule. Although no modern docking program relies exclusively on this type, they remain an integral component of many other techniques. DOCK (Shoichet & Kuntz, 1993; Moustakas *et al*., 2006) and FTDOCK (Gabb, Jackson & Sternberg, 1997) adopted this type docking. This method is divided into three types: Clique search, geometric hashing and pose clustering. All

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

are based on finding complementarity between the geometry of the binding site and that of the ligand. Some early docking programs used clique detection to find docked positions of rigid ligands, and clique detection remains an element of several modern, flexible-ligand docking programs, including recent versions of DOCK. In DOCK, to place a given conformation of the ligand, the unoccupied space in the binding site of the receptor is broken down into spheres, and the docking problem is solved by matching the centers of heavy atoms in the ligand to sphere centers in the binding site using clique detection.

Flexible Ligand and Rigid Receptor Docking

Most small molecules have one or more freely rotatable bonds, allowing them to assume a variety of stable conformations, so the next logical step in the evolution of docking methods was to allow for ligand flexibility. Considering multiple ligand conformations makes it less likely that a ligand will fail to dock simply because the conformation chosen was incompatible with the receptor. Almost all the docking programs such as AutoDock (Morris *et al*., 1998) and FlexX (Rarey, Wefing, & Lengauer, 1996) have adopted this methodology of treating the ligand as flexible while the receptor is kept rigid during docking. AutoDock incorporates Monte Carlo simulated annealing, evolutionary, genetic and Lamarckian genetic algorithm methods to model the ligand flexibility while keeping the receptor rigid. The scoring function is based on the AMBER force field, including van der Waals, hydrogen bonding, electrostatic interactions, conformational entropy and desolvation terms. Each term is weighted using an empirical scaling factor obtained from experimental data. FlexX uses an incremental construction algorithm to sample ligand conformations. The base fragment is first docked into the active site by matching hydrogen bond pairs and metal and aromatic ring interactions between the ligand and receptor. Then the remaining components are incrementally built-up in accordance with a set of predefined rotatable torsion angles to account for ligand flexibility. The current version of FlexX includes terms of electrostatic interactions, directional hydrogen bonds, rotational entropy, and aromatic and lipophilic interactions. The interactions between functional groups are also taken into account through assigning the type and geometry for groups. In summary, molecular simulations such as molecular dynamics and Monte Carlo as well as ligand fragmentation will be the approach to treat flexible ligand and rigid receptor docking methodology.

Flexible Ligand and Flexible Receptor Docking

Most proteins of pharmaceutical interest are flexible objects, constantly shifting from one stable conformation to another. When they bind a ligand, many proteins undergo a conformational change in order to better accommodate the ligand and its physical properties in their binding site. This phenomenon is called ‘induced fit’. It has been demonstrated that rigid receptor methods have a high probability of failing to dock ligands to some flexible proteins when the wrong protein conformation is used (Österberg *et al.*, 2002). While some ligands readily bind to a variety of conformations, others are highly selective. Thus, in drug discovery, failure to allow induced fit and conformational change may translate into passing over viable leads. Docking methods allowing protein flexibility are therefore an active area of research (Teodoro & Kavraki, 2003; Kokh *et al.*, 2011). Incorporating the receptor flexibility is significant challenge in the field of docking. Ideally, using MD simulations could model all the degrees of freedom in the ligand-receptor complex. But MD has the problem of high computational expense, which prevents this method from being used in the screening of large chemical database. Various methods are currently available to implement the receptor flexibility. The simplest one is so-called “soft-docking” (Jiang,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Kim, 1991) decreases the van der Waals repulsion energy term in the scoring function to allow for a degree of atom-atom overlap between the receptor and ligand. AutoDock 4 (Morris *et al*., 2009) adopts a simultaneous sample method to deal with side chain flexibility. Several side chains of the receptor can be selected by users and simultaneously sampled with a ligand using the same methods. Other portions of the receptor are treated rigidly with a grid energy map during sampling.

An extensive list of commonly used molecular docking programs, algorithms and scoring functions, can be found in Table 1 and Table 2 of the recent Review paper by Ferreira, dos Santos, Oliva & Andricopulo, (2015). Another source of the latest developments in docking programs, docking web servers, screen software, and screen webservers are listed in Table 1 of Chen's paper (2015).

APPLICATIONS OF 3D-QSAR AND DOCKING

Since (Cramer, Patterson & Bunce, 1988) introduced the 3D-QSAR concept and methodology, it has proven to be an invaluable tool in the field of drug design and activity prediction. Its impact is measured in the thousands of reports dealing with 3D-QSAR successful applications to many data sets of enzyme and receptor ligands. Excellent reviews have been written on this field (Kubinyi, Folkers & Martin, 1998, 2006; Melo-Filho, Braga and Andrade, 2014; Verma, Khedkar and Coutinho, 2010).

3D-QSAR is rooted on the hypothesis that ligands interact with their biological targets in a specific conformation, where it is assumed that identification of steric, electrostatic, and hydrophobic structural features of various drugs acting on their biological receptors can be used to explain their biological activity as well as in assisting further work on molecular design and modification.

Initially most of the research work done in this field was oriented in finding the geometric similarity among ligand and receptor. Later on, calculations of stereoelectronic properties in the binding conformation, such as comparative molecular field analysis (CoMFA) and comparative molecular similarity indices analysis (CoMSIA), along with the development of complex sophisticated docking methodologies, have allowed more accurate prediction of the biological activity of biomolecules. In the last decade there has been an explosion of reports on combining 3D-QSAR and Molecular Docking (M/D) for establishing the active conformation of a ligand in the presence of a receptor.

In 1997 a couple of articles were published on the methodology and applications of 3D-QSAR in drug design (Kubinyi, 1977a, 1977b). In 1998 (Vedani, Dobler & Zbinden) performed the first attempt to build a three dimensional receptor surface populated with atomistic properties mapped onto it. Soon after (Santos-Filho & Hopfinger, 2002) applied the 4D-QSAR idea to both receptor-independent (RI) and receptor-dependent (RD) problems. In the first method, the geometry of the receptor is not part of the data available to perform the analysis while in the second method the geometry of the receptor is available.

The first documented report of 3D-QSAR/Docking application to drug development was conducted in 2002 by (Buolamwini & Assefa) who proposed a binding mode for the cinnamoyl inhibitors at the active site of HIV-1 integrase.

In 2003 (Wu, Robertson, Books & Vieth) proposed a combined strategy involving grid docking and full force field minimization via a molecular dynamics (MD) simulated-annealing-based algorithm in order to improve docking accuracy. In their docking studies of a test set of 41 diverse protein-ligand complexes selected from the PDB, the protein was kept rigid while the ligands were treated as fully flexible and a final minimization step was used to refine the docked poses. Their results indicated that final minimization of docked structures improved the docking accuracy up to 10%.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

In 2004 (Erikson, Jalaie, Robertson, Lewis & Vieth) studied the effects of ligand and protein flexibility on M/D accuracy. To examine ligand flexibility, in a test set of 41 X-ray ligand-protein complex structures they applied several docking algorithms, finding that docking accuracy decreased substantially for ligands with eight or more rotatable bonds. To examine how protein flexibility influences docking accuracy, they applied the best docking algorithm to X-ray structures of trypsin, thrombin, and HIV-1-protease in the unbound (apo) form and also bound to several ligands. For the docking experiments they positioned each ligand to one average protein structure and to the apo form as well, and compared the results to those of docking each ligand back to its original structure. The outcome indicates that the docking accuracy falls off drastically for the average or apo structure reflecting the degree to which the protein moves upon ligand binding.

Due to the impossibility of accounting for all the research papers published in the last decade that combine M/D and 3D-QSAR to propose the best pharmacophore model, below we list a number of recent reports that we have considered most relevant in accomplishing this task. Most of the research done in this area has been focused in designing potent and effective inhibitors to HIV-1 proteins, and anti-cancer drugs. However, we must give credit to other studies in drug design such as antinociceptives, anti-tuberculosis, metabolic diseases, inflammatory and allergic processes, insecticides, osteoarthritis, antivirals, anticoagulants, anti- amyloid therapies, anti-malarial and antimicrobials.

Tubulin is an αβ heterodimer protein that forms part of microtubules essential in the cell cycle. Microtubules are involved in cell division, motility and shape and when they are compromised cell division is altered or blocked. Therefore, tubulin is the target of numerous small-molecule ligands used in cancer treatment among which is colchicine extracted from the poisonous meadow saffron *Colchicum autumnale L.* In order to construct binding models for a set of structurally diverse colchicine site inhibitors (CSIs) (Nguyen *et al*. 2005) reported docking and MD studies using the αβ-tubulin:DAMA-colchicine X-ray structure as the template. The docking studies helped in determining the binding modes of the colchicine site inhibitors. They used annealing via MD to compensate for pose inaccuracies arising from target X-ray structure resolution. They also used constrained MD simulations to undock the CSIs from the colchicine site in the binding models and to reverse the resulting trajectories to produce better models of the binding event. From these results they proposed a common structure-based pharmacophore model that accounts for the multiple structural classes of CSIs.

In order to accelerate *in silico* High Throughput Screening (Cherkasov, Ban, Li, Fallahi & Hammon, 2006) reported a progressive docking method based on "inductive" QSAR descriptors which cover a broad range of molecular properties that can be used effectively to create various binary inductive QSAR classifiers. In their approach, they used previously generated docking scores of already processed compounds in order to build predictive QSAR models that could assess hypothetical target binding affinities for yet undocked items. They tested this methodology on drug-like substances from the National Cancer Institute database that have been docked into several unrelated targets. They affirm that their approach can save hundreds of hours in terms of the docking time required to process ~90 000 potential ligands, while maintaining 80-100% hit recovery rates.

In 2007 (Markus A. Lill) questioned the usefulness of 3D-QSAR alone and use of the induced fit in determining the free energy of binding and in identifying the bioactive conformation of ligand molecules, particularly in the absence of structural information of the target protein. He reviewed the predictive power of multidimensional QSAR (mQSAR), particularly 4D-QSAR, in quantifying additional contributions to the binding energy. The concepts inherent in 4D-QSAR treat the alignment issue by incorporating molecular and spatial variety by representing each molecule in different conformations, orientations,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

tautomers, stereoisomers or protonation states. He affirmed that in classical 3D-QSAR, even those that include CoMFA or CoMSIA, one cannot sample the entire conformational space around the binding mode due to a combinatorial explosion in the number of required QSAR simulations. Since only if the 3D structure of the target protein is known, it can be used for predicting purposes using docking for example; therefore, 4D-QSAR can be interpreted as a feasible extension of 3D-QSAR to address the uncertainties during the alignment process.

In 2008 (Santos-Filho & Cherkasov) proposed a drug design approach which included docking, molecular fingerprints-based cluster analysis, and 'induced' descriptors-based receptor-dependent 3D-QSAR. They claimed that unlike other 3D-QSAR receptor-dependent, in their approach no ambiguous alignments are required for the construction of the models and that the computational cost is relatively lower. The induced descriptors presented are R_s that defines the steric influence of a group of atoms that compose a substituent G onto a single atom j, and σ^* that defines the inductive effect of G onto the reaction center j. They suggested that induced descriptors capture intermolecular interactions between ligands and receptors. This methodology was tested in eight data sets sampled from the literature and from public databases such as: human sex hormone-binding globulin, human corticosteroid-binding globulin, anthrax lethal factor, HIV-1 reverse transcriptase, neuraminidase A, thrombin, trypsin, and *Pneumocystis carinii* dihydrofolate reductase data sets. They concluded that although the presented models are interpretable, with high statistical and predictive significance, the usage of the receptor structure is not always enough for the development of significant models.

In 2009 (Pasqualoto & Ferreira) built RD 3D-QSAR models for a set of thirty seven isoniazid (INH) derivatives bound to the enoyl-acp reductase from *M. tuberculosis* (InhA). The molecular geometries of hypothesized active conformations of each ligand, resulting from a RI 4D-QSAR analysis, were used in their study. They used the 2.7 Å X-ray structure of the complex InhA-NAD-INH as starting model for the receptor geometry, and the energy-minimized structure was used as initial structure in MD calculations. Furthermore, they used the lowest energy conformation of the InhA-NAD-INH model to dock the energy-optimized structures of all ligands. They also performed MD simulations on each complex InhA-NAD-analogue. From the MD simulations these authors found that the following energy contributions were very important to the binding process: the bound ligand solvation energy, the sum of electrostatic and hydrogen bonding energies of the unbound ligand, the bending energy of the unbound ligand, the electrostatic intermolecular ligand-receptor energy, and the change in hydrogen bonding energy upon binding.

Human serum albumin (HSA), the most abundant protein in human blood plasma, binds to different types of ligands at multiple sites. Albumin is of medical importance since it transports hormones, fatty acids, metabolites, buffers pH, and maintains osmotic pressure, among other functions. To explain the high ligand promiscuity of HSA in 2010 (Deeb, Rosales-Hernández, Gómez-Castro, Garduño-Juárez, & Correa-Basurto) performed a 5 ns MD simulation on HSA. Those HSA structures sampled every 0.5 ns were subjected to a 3D-QSAR/Docking study on 94 well known HSA ligands, including warfarin and ketoprofen, known to bind HSA sites I and II. This study provided evidence that HSA binding sites I and II interact specifically with a variety of compounds through conformational adjustments of the protein structure in conjunction with ligand conformational adaptation to these sites.

In 2011 (Taha *et al*.) proposed a docking-based comparative intermolecular contacts analysis (db-CICA) as a new 3D-QSAR concept for validating docking solutions. Their approach evaluates the docking configurations based on the observations that a set of ligands inside their corresponding binding pocket interact in such a way that potent ligands contact the binding site spots in a different way than

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

those ligands with low affinity. Within this framework optimal dbCICA models can be transformed into valid pharmacophore models that can be used for 3-D search of new bioactive compounds. These authors applied dbCICA methodology to search for new inhibitors of candida N-myristoyl transferase as potential antifungal agents and glycogen phosphorylase (GP) inhibitors as potential antidiabetic agents.

In in an elegant study (Deeb, da Cunha, Cormanich, Ramalho & Freitas, 2012) used a multivariate image analysis applied to QSAR (MIA-QSAR) method. MIA-QSAR is a 2D image-based approach in which images are chemical structures and, where the combination and arrangement of pixels (descriptors, binaries) provide chemical information. For this work they took 60 compounds obtained from two series of non-peptides such as HIV-1 protease inhibitors reported elsewhere. Their premise was that the sum of the substructures of two compound classes can give rise to new actives can cause synergistic effects on bioactivities and enhanced pharmacokinetic parameters. The interaction modes of the ligands with the HIV-1 protease crystal structure active site were obtained with the Molegro Virtual Docker (MVD) program using the MolDock scoring function. The MIA-QSAR models were validated through LOO-CV and Y-randomization tests. The best MIA-QSAR model was the one with the lowest RMSECV value and able to predict pIC_{50} values of new compounds that have comparable to higher HIV-1 protease inhibitory activity when compared to the existing compounds used in the study. They concluded that the MIA-QSAR method is useful in showing the synergistic effect of mixing substructures to give rise of a new compound.

In 2013 (Jimenez-Botello *et al*.) performed QSAR studies on a set of experimentally tested ligands to validate a homology built 3D model of the rat adenosine receptor (rA2AR). The rA2AR model was refined by MD, in which the initial and refined 3-D structures were used for M/D simulations. The results showed that there is a hindrance effect caused by a ribose moiety attached to agonists which plays an important role in activating the receptor via formation of several hydrogen bonds; while the lack of this moiety allows blocking of the receptor. They showed that their theoretical affinity estimation had good correlation with reported experimental data.

To improve the (Nguyen *et al*., 2005) not correctly predicted binding conformations of a few colchicine site inhibitors (CSIs), in 2013 (Da, Mooberry, Gupton & Kellogg, 2013) performed an elegant study to definitively map the αβ-Tubulin colchicine site by using 3D-QSAR, ensemble-docking and hydropathic analysis. They concluded that a combination of these techniques reveals a more detailed pharmacophore model for CSIs with a higher resolution than the ∼3.6 Å available for αβ-tubulin.

In 2013 (Ul-Haq, Usmani, Shamshad, Mahmood & Halim, 2013) performed 3D-QSAR and docking studies on Danuravir derivatives, the most potent HIV-1 protease inhibitor known so far. They applied a combined study of 3D-QSAR unto the Danuravir derivatives using ligand-based and receptor-based protocols to generate CoMFA/CoMSIA models. To align a series of 102 Darunavir derivatives in the receptor-based method, they used the bound conformation of Darunavir in the crystal structure of HIV protease as a template. To validate the 3D-QSAR results, they performed docking simulations with the most active compound and with the least active compound, and to evaluate the quality of interaction as HIV-1 protease inhibitors they were docked with the wild type and mutated proteins.

In 2013 (Contreras-Romo *et al*.) used a combined approach of protein folding, MD simulations, docking, and QSAR to elucidate the detailed interaction of the vasopressin receptor V1a (V1aR) with some of its blockers. The V1aR model was constructed by I-TASSER and refined through MD simulations. For this study 134 compounds that are structurally related to benzodiazepines were used. The energy minimized 3D chemical structures of the compounds were docked at the binding pose of conivaptan on the refined V1aR structure at the 5-ns snapshot of the MD simulations. The QSAR analysis was

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

performed upon the best binding poses of the ligands, and the accepted linear models were subjected to cross-validation (CV) analysis by the leave-one-out (LOO), leave-a-group-out (LGO) procedures and Y-scrambling test. The scrambled data set was re-examined by the MLR method. The accepted MLR models were further optimized using a feed-forward neural network (NN) with back propagation of the error algorithm. Their results suggest that ligand recognition of V1aR is mediated by π-π and π-cation interactions with aromatic residues at the binding pocket of this receptor. Other nearby residues engage in hydrogen bonds and hydrophobic interactions and that a hydrogen bond interactions with the N atom of side chain of R214 is needed for a high affinity to V1aR.

It is known that protein kinase C Related Kinase 1 (PRK1) is involved in the regulation of androgen receptor signaling and has been considered as a novel potential drug target for prostate cancer therapy. Since there is little known about the PRK1 structure and its inhibitors, in 2014 (Slynko *et al*.) used the kinase domain of the protein kinase c theta (PKC-theta), with high homology to PRK1, as template in order to generate six PRK1 homology models (hm-prk1). From a group of 84 known active kinase inhibitors obtained from *in vitro* screening, they chose six compounds among which there were potent PRK1 inhibitors as well as some moderately active inhibitors. The refinement of the hm-prk1 conformations on the binding pocket and ligand was done via receptor-based docking. They observed that an inaccurate prediction of ligand binding poses occurred when using only one protein conformation and, subsequently, in low enrichment factors. To overcome this problem they docked all six chosen compounds in all six PRK1 homology models. They used MM-PB(GB)SA, QM/MMGBSA approaches to re-score the docking solutions by calculating binding free energy scores through simple QSAR models based on descriptors such as ligand charge or number of rotatable bonds. However, their results indicate that the MM-PB(GB)SA, QM/MM-GBSA rescoring approach is not accurate enough to distinguish the compounds with similar binding affinities, but it can be used to separate strong PRK1 inhibitors from moderate or weak binders. They also demonstrate that using only one snapshot derived after the minimization is sufficient to provide a reasonable prediction of the binding free energy, but only if the correct starting conformation is used.

Due to its narrow therapeutic index the CSI colchicine has limited its applications in clinical trials as antitumor agent. As a large number of small molecules possessing significant structural diversity, have been reported to bind the colchicine site in microtubules, in 2015 a hierarchical strategy was developed for structure-based virtual screening (VS) by integrating different computational methods such as M/D, 3D-QSAR, and pharmacophore model. With this procedure, based on SAR analysis, 691 novel small molecules were designed and the binding poses were predicted by a M/D into the three-dimensional X-ray structure of human tubulin complex and generated 6920 binding poses. The binding energy of the poses was calculated by MM-GBSA. Use of 3D-QSAR modeling helped in correlating correlate compound activities with interaction fields calculated based on protein crystallography or molecule superimposition. By means of the VS strategy, sixteen novel compounds with various structural features were obtained and synthetized (Li *et al*., 2015).

A CASE STUDY OF MOLECULAR DOCKING AND QSAR

In the last year, several studies have been performed using Molecular Docking-Molecular Dynamics and QSAR methodologies. For example, (Mei *et al*, 2015) have used the computational tools to study ROCK/PKA inhibitors. The 3D-QSAR results showed that the substitution containing positive charge

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

attached to the phenyl ring was favored for activity and selectivity. Specially, two compounds show theses characteristics but PKA protein (PDB: 3POO) inhibitory activities were quite different. To understand this behavior, docking methodology (using Surflex-Dock module in Sybyl 2.0) were used to explain the interaction of these molecules with ROCK2 protein (PDB: 4L6Q), and finally to validate the docking results, the Molecular Dynamics (using Sybil 2.0) simulations were carried out for 5 ns.

In the same way, (Abbasi *et al*, 2015) have performed QSAR and molecular docking (AutoDock 4.2) methodology to examine 30 L-tyrosine derivatives as metalloproteinase (MMP-2, PDB: 3AYU) inhibithors. They proposed that their results could be used to design new inhibitors.

(Vats *et al*, 2015) have studied several novel flavonoid analogues as potential AChE (PDB: 4M0E) inhibitors by QSAR, Docking and MD analysis. QSAR methodology was applied by the G-QSAR module from the VLife MDS version 4.3, the docking and molecular dynamic methodologies were applied by Glide module of Schrodinger and the force field 2005 respectively, the docking was carried out only around the active site in the protein. They selected the most favorable compounds from the QSAR analysis to perform the docking and MD studied. They concluded that the stability of the complex in vivo conditions depends on the two best compounds.

(Sepehri *et al*, 2015) and (Fatemi *et al*, 2015) established a methodology, QSAR and Docking (AutoDock 4.2), to evaluate of gp41 as possible target for anti-HIV-1 (PDB: 1A1K) activity and HIV-1 protease (PDB: 4DJP) respectively. In general, docking methodology is carried out to establish the interaction between the active site and several compounds. On the other hand, (Saleh, 2015) has studied several fullerenes derivatives as HIV-1 protease (PDB: 4DJO) inhibitors. After theoretical descriptors analysis, It is concluded that the characteristics of a compound such as solubility and reactivity with the surrounding system could be sufficient to interact with the HIV-1 protease, however the docking results showed that other compounds should be more active.

(Kang *et al*, 2015) studies 36 compounds that showed inhibitory activity toward human recombinant protein of VEGFR-2 tyrosine kinase (PDB: 2IVU) by QSAR and docking (AutoDock 4.2) methodologies. Their results permitted to design seven new molecules with high predictive biological activities.

The last papers discussed before have applied the same methodology, first QSAR analysis and then molecular docking and finally, in some cases, molecular dynamic analysis. The QSAR analysis was carried out to obtain the best descriptors in the series analyzed and, in some cases, the QSAR model was used to predict new molecules with activity. The docking and molecular dynamic studies were carried out to establish the active site and the interactions between this site and the compounds.

The histone deacetylase 2 (HDAC) inhibitors are used as a new therapy for neurodegenerative diseases. Several inhibitors are in the market such as trichostatin, valproic acid, sodium butyrate, phenylbutirate, vorinostat (SAHA) (MCQouwn *et al*, 2011), however some side effects are present in its treatments. For this reason, a new compounds as HDAC2 inhibitors are required.

Our group (Martínez-Pacheco, 2012; Martínez-Pacheco, 2015; Martínez-Pacheco *et al*, 2015) has established a different methodology to find new compounds with some biological activity. First, a docking study of a series of compounds having certain biological activity took place, these compounds are exclusive of the catalytic site. In this docking analysis some new hypothetic compounds are included to identify the most probable molecules with good biological activity. After this analysis, the QSAR analysis is performed to predict the best candidate as new molecule with good biological activity.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Results

The histone deacetylase 2 (HDAC2, PDB: 4LXZ) in complex with SAHA was used in this methodology. To prepare protein input, PyMOL Molecular Graphics System was used to remove ligands and cofactors. In this case, the HDAC2 is a trimmer and only the monomer A was used. Polar hydrogens and Kollman charges were added to monomer A. In this case, a grid box of 96Åx96Åx96Å was used as search space.

From the docking results, an occupation probability was calculated by applying the following steps:

- Selecting only the catalytic sites and the Gibbs free energy
- Consider the temperature as (298 K) and the ideal gas constant (1.98 cal/mol)
- Use the occupation probability of the results obtained in order to establish a relationship between the occupation probability and Gibbs free energy.

The following equation calculates the probability of occupation considering the Gibbs free energy:

$$p_i = \frac{e^{-\frac{\Delta G_i}{RT}}}{\sum e^{-\frac{\Delta G_i}{RT}}} \tag{3}$$

where T is the temperature at 298 K, ΔG is the difference in Gibbs free energy; R is the ideal gas constant (1.98 cal/mol).

Taking ΔE *as*:

$$\Delta E = RTln\frac{p_1}{p_2} \tag{4}$$

- Establish a p> 0.7, where $p_1 = 0.7$ and $p_2 = 0.3$

Select only those catalytic sites with higher probability of success (ex ΔG>0.499 kcal/mol).

- Analyzing the catalytic sites with a p> 0.7

Using the most stable conformation of a molecule in the catalytic site with higher probability of success and the Gibbs free energy calculated previously, it is possible to perform a QSAR study and to validate the models.

Although, many authors consider a high q^2 (for instance, $q^2>0.5$) as an indicator, or even as the ultimate proof that the model is highly predictive (Golbraikh & Tropsha, (2002)), to define the relative importance of the QSAR models, we have also performed several other tests beyond the q^2. These include the Akaike's information criterion (AIC, Akaike, (1974)), the Kubinyi fitness function (FIT, Kubiny, (1994)) and calculations of the correlation coefficient for regression through the origin (RTO, R_0^2), all of which were performed for the training and predicted activity according to (Anderson and Legendre, 1999).

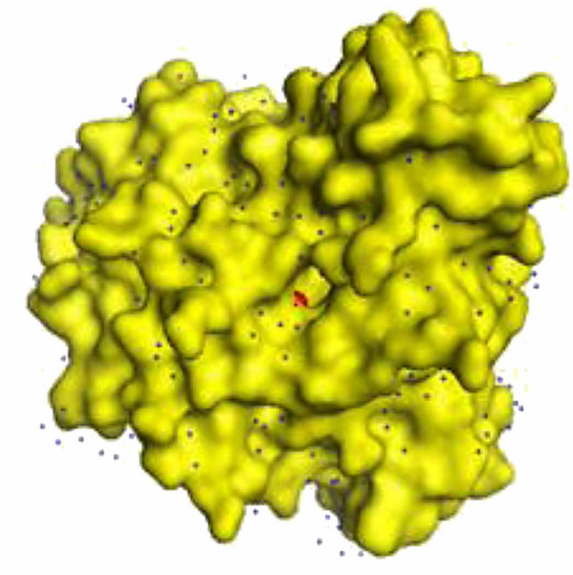
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

The tridimensional structure of HDAC2 used in this study was the PDB: 4LXZ, this structure correspond a trimmer, however, only a monomer was used in the molecular docking processes (Figure 1).

The monomer and Zn^{2+} ion (Figure 1) were used in the molecular docking by AutoDock 4.2 software, in a grid box of 96X96X96 Å, it is important to mention that the catalytic site is formed for the Zn2+ ion, Tyr306, His142, His143, Phe152 and Phe207

One hundred fourteen molecules were used in the docking and QSAR analysis; fifty four molecules (hydroxamic acid compounds, Figure 2) were taken as training set, fifty molecules (carboxylic acid compounds) as prediction set and ten commercial inhibitors of HDAC as validation set.

Figure 1. HDAC2 structure, only a monomer of HDAC2 and a Zn^{2+} ion (red sphere) were used in the study



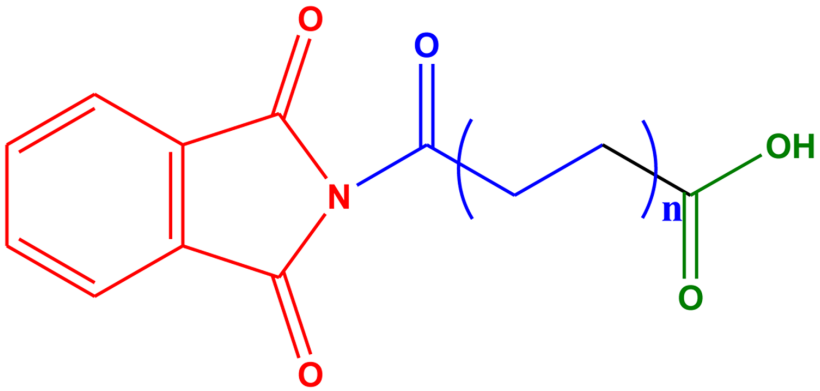


Figure 2. General structure of hydroxamic acid compounds (red color represents the lipophilic group, blue color represents the linker and the green color represents the coordination group of Zn^{2+})

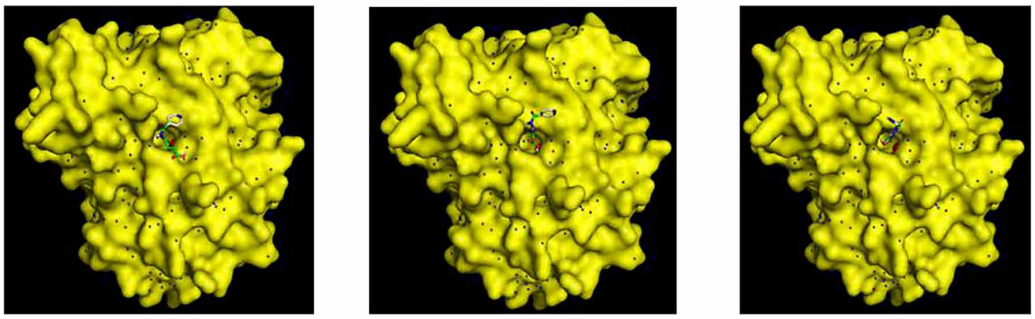
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

All compounds of the training set were docked into the catalytic site, and only fourteen compounds of the predicted set were docked into the catalytic site, they showed several conformations around the catalytic site. Figure 3 shows three differents conformations of a carboxyl acid derivative (14) around the catalytic site on the HDAC2 monomer.

Interactions between the compound 14 and the catalytic site were studied. The binding energy, the population distribution was calculated and only the interactions with probability higher than 0.7 were taken for QSAR analysis. The docking results showed that the active site is open when the lysine 36 is deacetiled from the histone, or close when this amino acid is acetiled. All our calculations were taken in the deacetiled system.

The QSAR model for the training set was built from 1239 molecular descriptors calculated by Dragon software. After statistical procedure, 151 molecular descriptors were used as a pool of descriptor. The best Multi-Lineal Regression (MLR) model (Figure 4A) is:

$pIC_{50}^{Exp} = -0.967\ (\pm 0.583) + 0.541\ DP06\ (\pm 0.097) + 3.317\ MATS5e\ (\pm 0.963) + 0.721\ Mor18e\ (\pm 0.224) - 1.349\ Mor13p\ (\pm 0.326) + 1.433\ GATS1e\ (\pm 0.512) + 1.015\ GATS8p\ (\pm 0.421)$



$R=0.94524$, $SD=0.23065$, $p<0.0001$, $N=52$, $SEE=2.7986$, $q^2_{LOO}=0.8498$, $q^2_{LGO}=0.7598$, $FIT=1.791$, $AIC=0.0608$, $F=60.9553$.

It is very interesting that the two commercial inhibitors as valproic acid (it does not present a bulky group) and AGK2 compounds are considered as outliers, this could be interpreted that these compounds are specific to HDAC8 and class III HDAC, respectively.

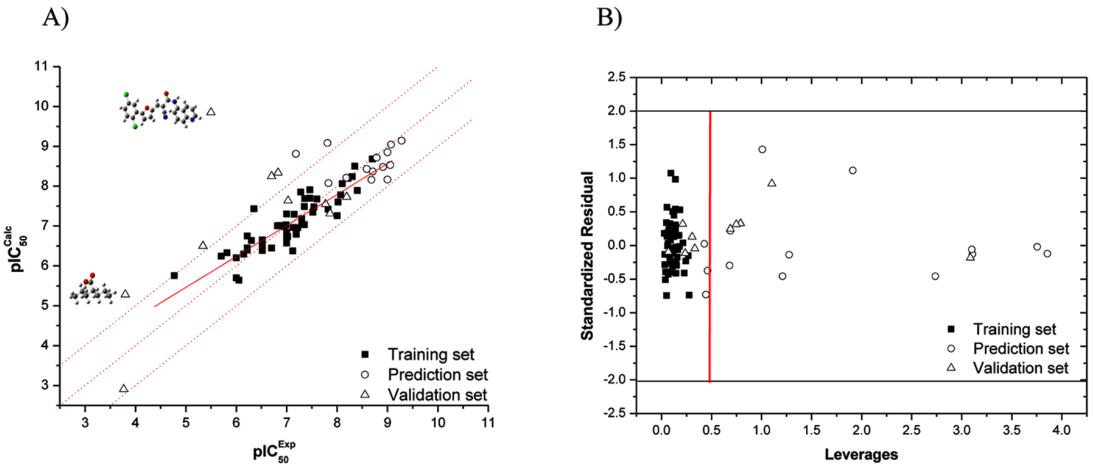
The Williams plot (Figure 4B) showed that three molecules of the prediction set are including into the region of description. These three molecules (Figure 5) were synthesized and tested as HDAC2 inhibitors (Martínez-Pacheco, (2015)), and they show potential experimental activity as theoretical prediction proposed.

Our results suggests that compoud 4 is a HDAC inhibitor with activity similar to phenylbutirate, whereas compound 14 is a HDAC inhibitor as phenylbutirate and trichostatin. Finally, compound 1 activated the HDAC2, however, theoretical results of this compound suggests the HDAC2 activation because its molecular docking is in a site different as the other two compounds.

Figure 3. Three different conformations of the carboxyl acid derivative (14), of all them are probable into the catalytic site

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 4. A) MLR of 52 inhibitors of HDAC2 as training set, 14 compounds proposed from molecular docking as predicted set and 10 commercial inhibitors as validation set. There are two compounds in the validation set that are a big outliers (Valproic acid and AGK2). B) Williams plot. There are three compounds of the predicted set that are including of the description region (compounds 1, 4 and 14). These compounds are very close to the leverage limit (h).*



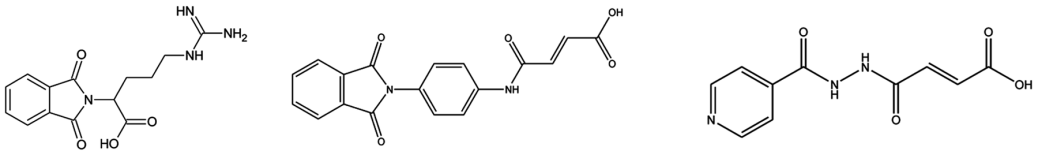


Figure 5. Compounds 1, 4 and 14. They are predicted by molecular docking and QSAR analysis as best HDAC2 inhibitors.

CHALLENGES AND FUTURE DIRECTIONS FOR CURRENT DOCKING METHODS IN DRUG DESIGN

Despite that M/D is routinely used in virtual screening or lead optimization for drug screening and design, frequently many problems arise. These issues are related to use of the wrong binding site of the target protein, use of an inappropriate small-molecule database, the method to choose the docking pose, or even a high dock score that fails in MD simulations. Sometimes docking analysis alone can generate erroneous poses of ligand binding, and occasionally the ligand will fly away during the MD simulation, in spite of having a high dock score. Such problems have been addressed by (Chen, 2015) who has given a word of caution regarding docking results.

Sampling and scoring are two of the fundamental weaknesses in simulating the binding of proteins and small ligand molecules. Protein-ligand interactions implicate a delicate balance of competing forces that occur between flexible moieties generating far too many conformations to be sampled exhaustively. These interactions are also affected by the surrounding water molecules and ions. In order to calculate the total free energy of binding, there is the need of designing accurate force-field-based approaches able

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

to model the many types of interactions using physics-based parameters derived either from experiments or quantum mechanical calculations. These force fields must be able to model the entropic freedom of nearby water molecules in the vicinity of a ligand-receptor, a computationally expensive process when simulating explicit water molecules, and the water screening of the electrostatic forces between charged atoms. Such scoring function, however, will add substantial computational cost in order to estimate the favorability of a protein-ligand complex. Other qualities than one may want to score for practical reasons are toxicity and properties related to absorption, distribution, metabolism, and excretion. Since it is well-recognized that drugs may bind to different targets with significant affinities, known as drug promiscuity, another challenge is to model this tendency of ligands to bind to several sites of the protein receptor. Mainly because if a ligand binds tightly somewhere, even near the desired binding site, this does not mean that it will affect substantially the drug action, particularly important for non-traditional drug targets, such as a target found inside the interface of protein-protein interactions.

Nevertheless, some recent efforts have been oriented to help in solving the challenges mentioned above. Among these the technique known as Protein Energy Landscape Exploration (PELE) is a good example (Borrelli, Vitalis, Alcantara & Guallar, 2005) since it combines protein structure prediction algorithms and Metropolis Monte Carlo techniques in order to explore ligand diffusion on the protein energy landscape.

CONCLUSION

Computational-based rational drug design has become more common over the past decade. Most of the approaches involved in this type of design focus on ligand based drug design such as Quantitative Structure–Activity Relationship (QSAR) studies that use various molecular descriptors for chemical information training. Another branch is structure based drug design method which is molecular docking.

In this chapter, we have summarized the two methods including QSAR and Molecular Docking methodologies. Also the efforts done in 3D-QSAR and docking were presented followed by a case study.

KEY TERMS AND DEFINITIONS

Computer Aided-Drug Design (CADD): The effective design of chemical structures with the desirable therapeutic properties, it is a well-established area of computer aided molecular design (CAMD).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Docking Algorithm: Mechanism that two search engines; one is responsible for the placement and exploration of the ligand in the binding site, while the other searches the internal degrees of freedom of the ligand.

Molecular Docking (M/D): The computational process of searching for a ligand that is able to fit both geometrically and energetically the binding site of a protein.

Molecular Dynamics (MD): This computational method calculates the time dependent behavior of a molecular system based on Newton's second law or the equation of motion.

Quantitative Structure Activity Relationships (QSAR): A way of finding a simple equation that correlates structural molecular features (descriptors) with physicochemical properties, such as biological activities for a set of compounds by means of statistical methods.

Rigid Ligand: A drug that has no degrees of freedom to rotate around bonds.

Rigid Receptor: Protein that has only one conformation and cannot shift to another.

Scoring Function: The mechanism that is needed to decide which ligand placements (scores) are better than others, and thereby rank conformations, or candidate dockings, of a particular ligand.

ABSTRACT

Sequence-structure deficit marks one of the critical problems in today's scenario where high-throughput sequencing has resulted in large datasets of protein sequences but their corresponding 3D structures still needs to be determined. Homology modeling, also termed as Comparative modeling refers to modeling of 3D structure of a protein by exploiting structural information from other known protein structures with good sequence similarity. Homology models contain sufficient information about the spatial arrangement of important residues in the protein and are often used in drug design for screening of large libraries by molecular docking techniques. This chapter provides a brief description about protein tertiary structure prediction and Homology modeling. The authors provide a description of the steps involved in homology modeling protocols and provide information on the various resources available for the same.

INTRODUCTION

Knowledge of the protein structure is an important step towards rational structure based drug design and virtual screening of large molecular libraries. Sequence-structure deficit marks one of the critical problems in today's scenario where high-throughput sequencing has resulted in large datasets of protein sequences, but their corresponding 3D structures still need to be determined. Currently there are about 2 million protein sequences in Swissprot and TrEMBL, among them about 30,000 proteins have had

their structures solved experimentally. Although the rate of experimental structure determination will continue to increase, the number of newly discovered sequences grows much faster than the number of structures solved. Since experimental structures can only be determined for a small fraction of proteins, computational methods for protein structure modeling play an increasingly important role yielding models suitable for a wide spectrum of applications.

The term "homology modeling", also called comparative modeling refers to modeling of 3D structure of a protein by exploiting structural information from the known configurations of similar proteins. The method is based on the fact that structural conformation of a protein is more highly conserved than its amino acid sequence, and that small or medium changes in sequence normally result in little variation in the 3D structure. The necessary condition for successful homology modeling is a sufficient similarity (>30%) between the protein sequences. The importance and applicability of homology modeling is steadily increasing with the increase in the number of known structures in the protein structure database. Homology models contain sufficient information about the spatial arrangement of important residues in the protein, enabling us to study the binding site and design/dock drugs suitable for binding to the molecule. Stable and reliable repositories have been developed to give access to these annotated and evaluated models.

With the advent of new modeling softwares and algorithms, homology modeling is rapidly becoming the first choice for obtaining the 3D structure coordinates as well as other valuable structural and functional insights. The recent advancements in homology modeling, particularly in detecting and aligning sequences with Template structures, loop and side-chain modeling, model validation and evaluation have largely contributed to the prediction of more accurate models of protein structure, which was not possible several years ago. Improvement in sequence search/analysis, scoring systems and tertiary structure prediction methods allows development of models robust, error free models with high statistical significance. Publicly available, easy to use modeling servers and structure validation tools have further assisted the development of this technique.

Homology modeling is a multistep process, that can be summarized in following steps 1) Template identification and alignment, 2) alignment correction, 3) model generation, that includes backbone, loop and side chain generation 4) model optimization, and ; 5) validation. The first and foremost step is to fetch the Target protein sequence from various freely available databases. This is followed by Template identification, where, a protein Template whose 3D coordinates is known and that shares the maximum similarity with the Target sequence is selected. Similarity check between the Target and Template protein sequence is done by sequence alignment. The most widely used algorithm to run alignment is BLAST (Basic Local Alignment Search Tool). For a good alignment between both Target and Template sequence, the Template should not possess an E-value larger than 1. Sometimes it may be difficult to align two sequences in a region where the percentage sequence identity is very low. To resolve this issue, multiple Templates homologous to the Target protein are used, and an alignment correction is performed manually. After obtaining a good alignment, model generation starts. Quality of the model generated largely depends upon the correctness of the Template identified and accuracy of the alignment generated. If the alignment is accurate, there are less chances of the model being inaccurate. In Model generation, if the sequence alignment is good, the coordinates of those Template residues that show up in the alignment with the model sequence can be copied. If two aligned residues differ, only the backbone coordinates (N, Cα, C and O) are copied. The Target-Template alignment may contain gaps due to insertions and deletions of amino acids or bases. These loops are modeled using commercially available or manually generated loop libraries. There are generally two methods of loop modeling: 1) by

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

finding similar loops in similar proteins and 2) by generating the segment *de novo*. Finding loops from similar proteins is done by taking some residues before and after the insertion as "anchor" residues and performing the loop search against databases like PDB with similar anchor residues. The best fitting loop is copied to the model. This has an advantage that all the loops are guaranteed to have reasonable internal geometries and conformations but again, they may not fit properly into the given model protein's framework. Loop selection must be done by carefully examining it for steric overlaps, and by checking loop atoms against rest of the protein's atoms. Structurally similar proteins have similar torsion angles about Cα-Cβ bond (psi angle) when comparing the side chain conformations. Therefore, in this step, the torsion angle between Cα and Cβ of the other residues can also be copied to the model because these rotamers tend to be conserved in similar proteins and many backbone configurations strongly prefer a specific rotamer. The modifications in the side chain can affect the backbone causing steric hindrance between atoms. Thus, optimization or idealization of the modeled structure using suitable a force field must be performed in order to obtain a refined model. Every homology model contains errors. Once the full scale 3D model is generated, model is validated for its authenticity, the overall correctness of the fold/structure, stereochemical parameters like bond lengths, torsion angles and bond angles, bump check etc. Moreover Ramachandran plot to visualize backbone dihedral angles (Phi)ψ against (Psi)φ of amino acid residues in protein structure have to be analyzed that whether the torsion angles fall into the allowed and the generously allowed region of the Ramachandran plot or not. Both the internal and external validation procedures need to be performed to verify that the generated model is precise and accurate. In spite of the tremendous growth in homology modeling procedures and algorithms, still there are several challenges in the technique of homology modeling which require further elucidation.

This chapter provides a brief description about the different approaches undertaken for protein tertiary structure prediction in order to lend statistical robustness to the problem of structure prediction. It provides a detailed overview of protein structure prediction, need of prediction methods and an introduction to various structure prediction approaches along with the challenges in protein structure prediction. Insights into the general features of the protein family, degree of conservation, the consensus sequence, Template identification and know-how of a correct alignment are also covered in the chapter. Recent developments in the field of protein structure prediction e.g. Comparative modeling and Threading algorithms have been discussed. Comparative modeling involves sequence-profile alignments while threading algorithms involves profile-profile alignments for identifying Templates against the query protein. Empirical techniques like *ab initio* structure prediction are also used when sufficient similarity of the Target protein to known models is not obtained. *Ab initio* strategy includes predicting the protein structure from its sequence from first principles. In different methods, this may entail calculating the physicochemical properties of proteins, evolutionary information etc. The information obtained is further used for generating spatial restraints or for identifying local structural building blocks.

Recent community-wide blind test like Critical Assessment of Protein Structure Prediction(CASP) have demonstrated significant advantages of composite (hybrid) approaches in protein structure prediction, which combine various techniques i.e Threading, *ab initio* methods, homology modeling and atomic level structure refinement. A variety of software tools, servers and meta-servers are now available for performing homology modelling. In spite of tremendous developments in structure prediction approaches, several challenges like modeling of proteins with very low similarities like GPCRs and better optimization methods still need further elucidation. The ongoing efforts in solving protein structures will continue to spur the development of novel algorithms and computational approaches to solve the problem of sequence-structure.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

BACKGROUND

Functional classification requires structural information which relies on the primary sequence of the protein. Owing to the commendable efforts in genome sequencing, there has been an overwhelming flood of sequential information. Approximately 2000 nucleotide sequences are deposited per day in publicly available databases (Kulikova et al., 2004). However, while the structural genomics efforts succeeded in determining a large number of new protein structures, there are only about 109822 protein structures deposited in the Protein Data Bank (till June 2015), the repository of protein 3D structures. The thumb rule says that more the protein structures are determined experimentally, more would be the probability to find close structure analogues in the databases of known structures for almost any protein sequence in the near future. Due to the inability of experimental procedures for determining structural coordinates for most of the proteins, a major issue of sequence-structure deficit has arisen. This huge gap between the number of available sequences and experimentally solved protein structures can only be resolved by computational prediction methods.

Structure prediction methods can be divided into two broad categories: *ab initio* method (Lesk, 1997) and homology modeling(Kolinski, Rotkiewicz, Ilkowski, & Skolnick, 1999; Rost, Fariselli, & Casadio, 1996). The first approach has prediction from physical chemistry principles while the second method predicts the three-dimensional structure of the Target sequence based on its similarity to one or more proteins of known structures. In the early 1990s, fold recognition was considered as a separate field until recently CASPs (Critical Assessment of Structure Prediction) demonstrated that Fold recognition or threading is a combination approach combining the two extremes, in which remote homologues are detected by sampling the known protein PDB conformations with scoring energies(Venclovas, Zemla, Fidelis, & Moult, 2003; Xu, Xu, & Uberbacher, 1998).

Homology modeling, also called comparative modeling or Template based modeling refers to the construction of an unknown atomic resolution model of the 'Target' protein from the amino acid sequence of the Template protein. Homology modeling approach serves well if the sequence identity between the Target and the Template sequence is sufficiently high (>30%). The quality of the homology model generated depends largely on the extent of sequence conservation between the Target and the Template sequence (Chakravarty, Wang, & Sanchez, 2005; Marti-Renom et al., 2000). This type of modeling is based on the concept that protein's structural information is more conserved than the amino acid sequence.

Besides the increasing importance of homology modeling in the recent years, there still exists a cascade of challenges in front of the scientific community. The inaccuracy of force field makes conformation sampling much more difficult, since it could guide energy minimization to the conformation of global energy minimum that is totally different from the true conformation. Homology modeling is a technique whose stringent requirement is a good and accurate force field and completeness of the conformation searching.

In an era when the rate of experimental structural determination is approximately 6000 proteins per year, homology modeling has already saved hundreds of years of human effort. Even if homology modeling produces less accurate models than experimental methods, it can be of prime importance in proposing and testing hypothesis in molecular biology, function annotation, and drug design (Francoijs, Klomp, & Knegtel, 2000; Ginalski, Rychlewski, Baker, & Grishin, 2004; Takeda-Shitaka, Takaya, Chiba, Tanaka, & Umeyama, 2004; Zhou & Johnson, 1999). It can also provide good starting models for solving structures by experimental methods (Ceulemans & Russell, 2004; Talukdar & Wilson, 1999). Structural models generated by homology modeling can be of direct medical and biological relevance. Homology-based

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

structural models are widely used in predicting the effects of single nucleotide polymorphisms, *in silico* drug designing. Structural models can also be used to design mutations that lead to specific changes in the function or stability of the modeled protein in the biological system. It is approximated that within the next 10 years, structural genomics might discover all distinct protein folds in nature, making homology modeling applicable to almost any protein sequence(Vitkup, Melamud, Moult, & Sander, 2001).

MAIN FOCUS OF THE CHAPTER

After studying this chapter, you shall be able to

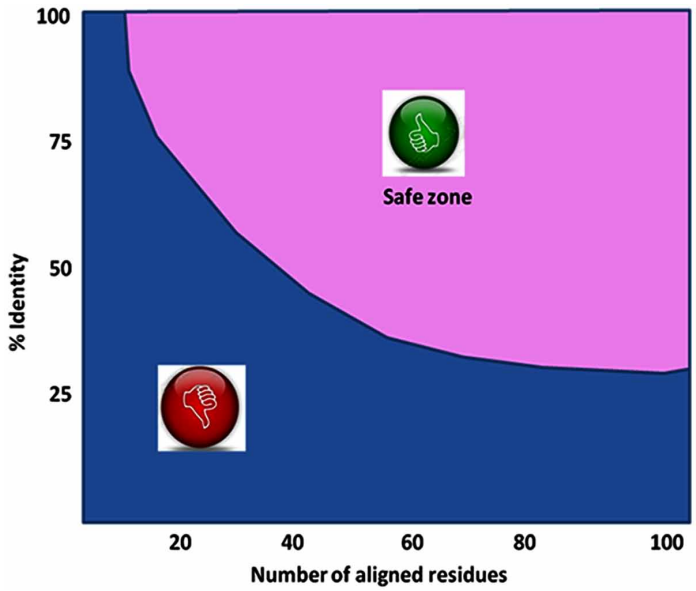
1. **Know:** The basics of protein structure prediction, need of prediction methods and an introduction to various structure prediction approaches along with the challenges in protein structure prediction.
2. **Learn:** The method of comparative modeling in a detailed step by step manner.
3. **Identify:** The various checkpoints in comparative modeling where more emphasis has to be laid on, along with the type of errors that can emerge in the building of the model.
4. **Evaluate:** The modeled protein for its accuracy.
5. **Analyze:** The modeled protein for its structure-function relationships and annotate it.

Issues, Controversies, Problems

The biological role of a protein is determined by its function, which is in turn is determined from its 3D fold. Thus, there is enormous benefit in knowing the three dimensional structures of all the proteins. Although more and more structures are determined experimentally at an accelerated rate, but the gap is still huge. As more and more protein sequences are determined, there is pressing need for predicting protein structures computationally.

1. The main reason for modeling of protein structure is the sequence-structure deficit. While the sequence is available for many proteins, the structure has been determined for very few. This is largely due to the fact that structure determination techniques are time and resource intensive exercise. Also, experimental difficulties in purification and crystallization of proteins make the structure determination a lengthy process.
2. Additionally, homology modeling is not possible for proteins that do not share sufficient sequence-structure similarity with any of the available proteins in the public databases like PDB.
3. Even if the structural information has been obtained by experimental techniques, there are gaps in the structure due to experimental limitations. Especially, disordered structures may be refractive to X-ray crystallographic structure determination. On the other hand, NMR techniques can not handle very large structures.
4. A third issue is that of movement leading to conformational transitions. It is well known that a protein can occur in both global and local conformations, global conformations are undoubtedly the stable conformation but it's very likely that the local conformations are biologically relevant and plays an important role in disease prognosis. Thus, it is vital to gather the structural information from the literature, mutagenesis studies and binding assays to give us more insights to elucidate a more rational model that can be taken up for further drug designing.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



5. Accurate protein tertiary structure prediction is essential for many bioinformatics applications, including studying catalytic mechanisms of the protein, mechanism of activation, and ligand docking in drug design.
6. Protein structure prediction also assumes a critically important role for exploration of mutations and mutagenesis on the function of the molecule.

Protein Tertiary Structure Prediction

There are three methods for protein structure prediction namely 1) *ab initio* methods 2) Template based Homology modeling 3) Fold recognition or threading. As the name suggests, *ab initio* methodology calculates the protein structure from its sequence from first principles or from the beginning. A range of *ab initio* methods rely on accurate energy functions and conformational search strategies to identify the most native-like model. However, *ab initio* methods require vast computational resources and have only proved successful for small proteins. Homology Modeling and Fold recognition, on the other hand, require the identification of homologues with known structure for the protein to be modeled (Target protein).

Homology modeling is one of the easiest ways to predict the structure of a protein and is based on the observation that during evolution, the structure of a protein changes much more slowly as compared to the sequence (Chothia C, 1986; Sander & Schneider, 1991). Thus, proteins with similar sequences adopt almost identical structures while proteins with lower sequence similarity still fold into overall similar structures. It was shown that as long as the identity between two sequences and the length of the overlap fall in the "safe" region (Figure 1), two sequences will almost certainly adopt the same fold (Rost, 1999). Typically, given that sufficient number of residues between two sequences aligns, a homolog with sequence identity above 40% can be used for homology modeling of the Target protein.

Figure 1. Safe zone: schematic representation of relationship between sequence identity, overlap, and confidence in structure
Source: Authors.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

If the sequence similarity is less than 40%, the prediction can be done thorough fold recognition or threading. These methods differ from that of comparative modeling only at the level of Template selection and prediction. Here, sensitive sequence searching methods are used to align or thread the Target sequence to that of a protein with the same fold. The alignment can then be evaluated by statistical methods as well as manual inspection. If no suitable homolog is found in the database then the 3D structure is predicted through *ab initio* predictions. Typically, two or more Templates and methods of recognition are used to lend confidence to the modeling based on fold prediction.

1. **Template-Based Predictions:** Template based protein structure prediction (either Homology/ Comparative modeling OR threading based methods) uses knowledge of solved structures to model a protein sequence's native fold. First, sequence information is fetched for protein of interest (i.e. Target protein) from Expasy. BLAST (Basic Local Alignment Search Tool) search of Target protein against PDB will give us a rough idea of all the homologous protein with known 3D coordinates (Templates). Best hits may be selected from a BLAST run on the basis of low e-values (denoting statistically significant sequence similarity) or identified automatically by Homology modeling servers. Once the Template structure is found, the Target protein 3D structure is built by mapping the Target sequence onto the Template structure. This putative structure is refined using a combination of backbone moves, side-chain packing, and loop modeling. Template based protein structure prediction has always held great promise to produce atomically accurate models close to the native conformation. Comparative modeling techniques are extremely popular, reliable and fast where sequence homologues exist in the database. With increasing structural information, these techniques should prove more useful. But the major limitation with Template based selections is that it is highly dependent on the sequence identity between query and Templates. A sequence identity above 50% leads to accurate models. The Model obtained is error prone if the identity range is less than 40%. Also, at times the side chains and loops may require remodeling in order to improve the modeled protein.
2. **Fold Recognition Methods:**
    a. **Template Structure Identification Using Threading Programs:** Threading is carried out when there is not sufficient sequence similarity between the Target and Template to carry out Comparative modeling. The recognition of the Template is a problem by itself and hence it is also called fold recognition. Threading involves steps similar to Comparative modeling. It differs in the fold identification and fold fitting step. There are many approaches, but the main theme is to find "folds' from a library of folds of known protein structures (Lu, Lu, & Skolnick, 2002; Skolnick, Kihara, & Zhang, 2004). Threading algorithm for protein structure prediction uses a database of known three-dimensional structures to match sequences without known structure with protein folds. A library of different protein folds is derived from the database of protein structures. Threading methods compare a Target sequence against a library of structural Templates. The query sequence is then optimally fitted to each library fold, allowing for relative insertions and deletions in loop regions. A scoring function is assigned to assess the fit of a sequence to a given fold. These functions are database driven and generally include a pairwise atom contact and solvation terms. The 'energy' of each possible fit is calculated by summation of the proposed pairwise interactions and solvation energy. The fold library is then ranked in the order of total energy, with the lowest energy fold being taken as the most suitable match. The best score is assumed to be the one adopted by the query sequence. The

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

basic assumption of the threading algorithm is that the tertiary structure is more conserved than the secondary structure and secondary structure is more conserved than the sequence. This method takes the advantage of knowledge of existing structures in the database and the physical properties they are stabilized with. Fold assignment and alignment are achieved by threading the sequence through each 3D structure in the fold library. Therefore structural modeling can be better detected through 2D or 3D structural homology instead of sequence homology. Two main kinds of Threading algorithms are available, namely:

i. **2D Threading or Prediction Based Methods:** These methods involve prediction of secondary structure (SS) or ASA (Accessible Surface Area) of the query protein. 2D Threading Algorithm also converts the coordinate information from PDB to a database containing sequence, SS and ASA information. Next, dynamic programming alignment of the query against the database is performed. These alignments are then evaluated on the basis of known SS and/or ASA matches with the Template structure. Lastly, it ranks the alignments and selects the most probable fold. Examples of 2D Threading servers are PredictProtein, 123D and GenThreader (Alexandrov & Shindyalov, 2003; Jones, 1999; Yachdav et al., 2014)

ii. **3D Profile Method:** This technique involves the alignment of the sequence to a string of descriptors that describe the 3D environment of the Target structure e.g. whether it is polar or non-polar. Other parameters could include α-helix, β-sheet or a turn conformation. Information whether a residue is fully buried, exposed or partially buried can also be considered. Here, each known fold is represented as a 2D matrix of inter-residue distance. An energy potential describes these distance dependent pair wise interactions for all possible combinations of amino acids. These are later compared with the 2D matrix of known protein structures. The trained set of contact potentials are then used to align an unknown protein sequence against a group of fold*s*. The top scoring alignments are considered as possible Templates. In order to gain confidence and to increase the accuracy of the results, it is recommended to use more than one Template. Some of programs that predict through fold recognition are Loopp (version 2), 3DPSSM, PROSPECT, ProSa etc (Kelley, MacCallum, & Sternberg, 2000; Kim, Xu, Guo, Ellrott, & Xu, 2003; Teodorescu, Galor, Pillardy, & Elber, 2004; Wiederstein & Sippl, 2007). The widely used Loopp program models the protein through a library of folds derived from CATH and SCOP. It aligns by optimizing the interaction partners for each pair of residues in contact with the structure. It uses secondary structure predictions tools like Psipred to constrain the threading. ProSa uses contact potentials while 3DPSSM is used for position specific scoring matrix to align the Target with the Template. 3DPSSM is a hybrid method that combines optimization of alignment to a family with optimization of threading energy (Hong et al., 2011; Wang et al., 2014).

3. **Ab Initio Prediction:** *Ab initio* prediction is carried out when there is no suitable homolog found in the database. It is based on Anfinsen's hypothesis that the native state of the protein represents the global free energy minimum. *Ab initio* methods try to find these global minima of the protein. Finding the correct native-like conformation requires an efficient search method to explore the conformational space in the free energy landscape to get the global minima. To simplify the computation and to reduce the search space, the following models are used:

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

a. **Lattice Model:** This represents peptide chain as lattices. However, it fails to represent geometric attributes like str**a**nd twist. Also, its backbone prediction is error prone.
b. **Discrete State Off-Lattice Model:** This is an improved version of the lattice model. Off-lattice method are versatile than lattice method. It is able to represent subtle geometric considerations (strand twist, secondary structure propensities and packing) and can reproduce the backbone with greater accuracies (Park & Levitt, 1995).
c. **Using Local Structure Prediction:** Local structures can be excised from proteins that can fold independently from rest of the protein; this implies that there is a strong correlation between local structural information (biases) for short sequence segments. The strength and multiplicity of these local biases are highly sequence dependent.

The fitness of the model generated is calculated using a scoring function. There are two types of scoring functions in use, namely; knowledge based scoring function and force field based function. Former is an energy function derived from an analysis of known protein structures in the Protein Data Bank. This methodology relies on basic principle of free energy i.e. most stable conformation of a protein will be the lowest energy conformation. Force field based scoring function uses physics-based all-atom scoring function for protein structure prediction. This is analyzed with several widely used all-atom decoy sets. Currently there is not a single reliable scoring function or search method as both the scoring function are unable to explore the entire conformational space.

There is a new fully automated *ab initio* prediction method in which the Monte Carlo fragment insertion method (ROSETTA) and HMMSTR server are available, but with a limitation to model only small protein (>1000 residues) (Bystroff & Shao, 2002). The input sequence, after filtering out the low complexity region, is submitted to PSI-BLAST, and then converted to a sequence profile. The sequence profile is compared in a sliding window with each of the scoring matrices. Rosetta searches the conformational protein space using fragment insertion moves and by applying the Monte-Carlo acceptance criteria. The point where the fragment is inserted is selected at random and then a fragment of length 3 or 9 residues is selected at random from the move set. The backbone angles are changed to that of the fragment and the coordinates are then calculated. The move is accepted or rejected based on Monte Carlo criteria. The energy function is a structure based Bayesian conditional probability drawn form same PDB select database. For HMMSTR, the profile was submitted to each of the HMMSTR models namely HMMSTR-r for prediction of backbone angles, HMMSTR-d for the prediction of secondary structure and lastly HMMSTR-c for the prediction of super secondary structure.

Critical Assessment of Structural Prediction (CASP)

The biannual CASP (Moult, Fidelis, Kryshtafovych, Schwede, & Tramontano, 2014) experiments are carried out to test the different prediction methods/tools, which enables a direct comparison of a protein model to its X-ray structure. CASP is held every two years and the next one, CASP12, is to be held in mid 2016. In 2014 CASP Target list was of ~ 200 sequences with unknown 3D structures. Contestants are to predict the structure of protein using different algorithms and different methods - homology, fold recognition and *ab initio*. Subsequently, an assessment of the accuracy of the predictions is carried out. CASP concludes with a meeting to discuss the results that are published in CASP proceedings.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Servers

There are various servers available for modeling as summarized in Table 1. This actually depends on the Templates chosen, the alignment of the query protein with the Template and also the algorithm or the method used in their prediction. It is a continuous benchmarking program and weekly evaluates the sensitivity and specificity of the different servers. Some of the servers that did well in both comparative and fold recognition modeling in CASP10 and CASP11 were 3DPSSM and Mgenthreader. Servers that outperformed in Template based modeling were I-Tasser and SwissModeller (Arnold, Bordoli, Kopp, & Schwede, 2006; Zhang, 2007).

Meta servers are servers that make their predictions based on the results of two or more different methods. Some simply look for consensus prediction between several methods while others calculate their own scores based on the results from the server. Some of the meta servers are Pcons, Pmodeller etc. The latest Live Bench experiments have demonstrated that meta servers clearly outperform the individual, autonomous servers.

Homology Modeling

Steps for Comparative Modeling

With the advent of automated protein modeling servers, submitting a sequence and obtaining its model has become a black box technique. However, all modeling protocols share certain steps, the understanding of which allows us to determine the quality of the model and the inherent errors in the system.

1. **Template Identification and Alignment:** For prediction of protein structure with reliably good accuracy, two conditions need to be fulfilled. First, the Target sequence must have significant similarity to the Template sequence. Second, computation of an accurate alignment must be feasible between the Target sequence and the Template structure. Overall model accuracy can be predicted by the degree of sequence similarity between the Target and the Template. The more the similar-

ity, more accurate is the model. However, while high accuracy models are more informative, low accuracy models may also provide coarse structural and functional annotation. Figure 2 shows a multiple sequence alignment of the Target (MoxT or the *B.anthracis* toxin) to the Template protein (*B. subtilis* YdcE) and *E.coli* Kid Toxin. The multiple sequence alignment was created using ClustalW(Thompson, Gibson, & Higgins, 2002) in Bioedit (Hall, 1999). The primary cause of errors in the final model is due to mistakes in the Target-Template alignment. Errors may also include incorrect loop building or side chain modeling. No modeling program can generate a good model from an incorrect starting alignment. Thus, good sequence-structure alignment must be ensured to improve the accuracy of the final model. Recent years mark the tremendous progress in the development of alignment methods e.g. HMMER, PSI-BLAST, HMM, SAM, HHsearch etc. Alignment can be pairwise or multiple alignments. Multiple alignments are usually heuristic, working on the principle of progressive alignment allowing large alignments of distantly related sequences eg ClustalW, ClustalX, T-Coffee. Probabilistic-based program like PROBCONS uses BAliBASE, which is a most accurate method available for multiple alignments. PROBCONS uses probabilities instead of the heuristic algorithms. HOMSTRAD is based on sequences with known 3D structures and PDB files.

2. **Alignment Correction:** An alignment is calculated by proper optimization of the scoring function. A scoring function includes gap penalty function and a substitution score matrix for matching residues in the Target and the Template sequence. Using a multiple sequence alignment program, structurally conserved region (SCRs) are searched. Insertions and deletions can be made in widely divergent parts of the molecule using multiple sequence alignment. Gaps have to be shifted to make them as small as possible. Gap is one or more empty spaces in one sequence aligned with letters in the other sequence. Gaps may or may not be treated as gap penalties. Gap penalty can be gap opening penalty or gap extension penalty. Gap penalties must be judiciously and carefully assigned as both the higher and the lower deviating from the optimum may lead to a poor alignment score. Precise importance has to be focused on residue-specific gap penalties which are responsible for

Figure 2. Multiple sequence alignment of MoxT (target) from B. anthracis with YdcE (template) from B. subtilis and Kid toxin from E. coli; the annotation of the catalytic residue E78(*) was derived by similarity from Kid.

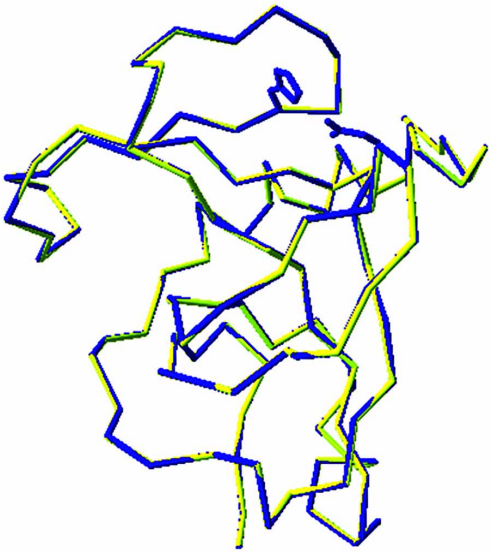
gaps in potential loop regions. Alignment score is a sum of gap penalties and the pair wise substitution scores which depend on the gap lengths and the residues matched. Despite inserting or deleting a gap and imposing gap penalties to correct the alignment, manual intervention may still be needed (Krieger, Nabuurs, & Vriend, 2003). In order to ensure a good alignment, it is recommended to choose to model only that part of the sequence which aligns without a large number of gaps in the alignment. Further, alignment errors are the main cause of deviations in comparative modeling even when the correct Template is chosen. In the alignment, gap positions should lie outside the secondary structures and in the loop areas. It is also recommended to integrate accessory information about secondary structures, conserved family residues, transmembrane helices, active site residues, etc. into the alignment in order to improve its accuracy. Last but not the least, no good alignment can be produced between sequences containing multiple repeats.



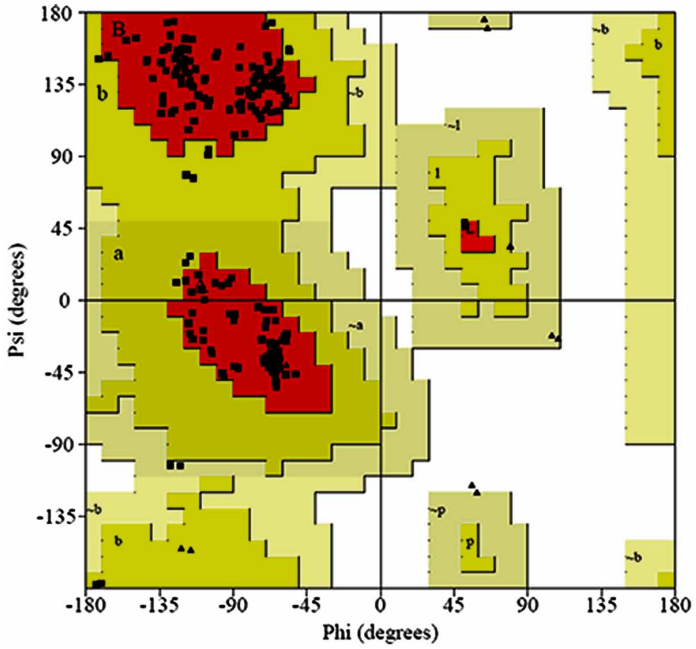
3. **Model Building:**
   a. **Backbone Generation:** When the alignment is correct, the backbone of the Target can be created. In this step, structurally conserved regions from the Template structure are used to generate the initial coordinates of the Target structure. For variable regions, the coordinates are copied from the Template structure only if the residue types are similar.
   b. **Loop Modeling:** The Target-Template alignment may contain gaps due to insertions and deletions of amino acids or bases. When the Target sequence contains a gap, the corresponding residue in the Template is deleted generating a hole. If there is an insertion in the Target, the Template will contain gap. Since, due to the gap in the Template, there will be no backbone coordinates known for these residues in the model, the Template backbone has to be cut to insert these residues. These large modifications are not feasible in secondary structural elements and therefore have to be placed in loops and strands. There are generally two methods of loop modeling: 1) by finding similar loops in similar proteins and 2) by generating the segment de novo (Li, 2013). Finding loops from similar proteins is done by taking some residues before and after the insertion as "anchor" residues and performing the loop search against databases like PDB with similar anchor residues. The best fitting loop is copied to the model. This has an advantage that all the loops are guaranteed to have reasonable internal geometries and conformations but again, they may not fit properly into the given model protein's framework. Loop selection must be done by carefully examining it for steric overlaps, and by checking loop atoms against rest of the protein's atoms.
   c. **Side Chain Modeling:** Structurally similar proteins have similar torsion angles about Cα-Cβ bond (psi angle) when comparing the side chain conformations. Therefore, in this step, the torsion angle between Cα and Cβ of the other residues can also be copied to the model because these rotamers tend to be conserved in similar proteins and many backbone configurations strongly prefer a specific rotamer. However, side chain conformations are also partially knowledge based. They are generated using rotamer libraries to select the best rotamer. To build a position-specific rotamer library, high-resolution protein structures are taken and all stretches of three to seven residues with a given amino acid at the center are collected. Prediction accuracy for side chain conformations is usually quite high for residues in the hydrophobic core (90%), while it is much lower for surface residues (50%).
   d. **Model Optimization:** The modifications in the side chain can affect the backbone causing steric hindrance between atoms. Errors in the prepared comparative model can be of different categories like: error in side chain modeling, distortions in the region correctly aligned with

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

the Template structure, drift in non-aligned regions, drift in the incorrectly aligned region, and structure misfolding due to incorrect Template. For the last case, a change of Template is required. In all other errors mentioned, optimization or idealization of the modeled structure using suitable a force field must be performed in order to obtain a refined model. A forcefield is a set of energy terms used to minimize the modeled structure. It is a collection of energy terms like energies of Van der Waals and electrostatic energy between all the atoms of the structure. For this, force fields used can be either quantum-based or self-parametrizing force fields. Bond-geometry correction and removal of bad contacts can be performed by forcefields like CHARMM (Brooks et al., 1983), AMBER (Cornell et al., 1995)or GROMOS (Scott et al., 1999). Refinement can be performed by using steepest descent, conjugate gradient or other energy minimization algorithms.

4. **Model Validation:** Homology models may contain errors. The reason may either be attributed to low percentage sequence identity among Target and Template or error in the Template. Therefore, the model must be evaluated for the overall correctness of the fold/structure, stereochemical parameters like bond lengths, torsion angles and bond angles, bump check etc. other properties like the distribution of polar/ nonpolar residues, bad contacts etc can also be compared with real structures. Models are routinely compared to Template structures to show the superposition (Figure 3) and the outcome is quantitatively expressed as root mean square deviation (RMSD). RMSD values up to 2.5Å between the Target and Template are indicative of good model quality. Validation can be of two types: Internal or External Validation.
    a. **Internal Validation:** Performed for self-consistency checks. It deals with the assessment of stereochemistry of the model like bond-lengths, bond-angles, dihedral angles, etc. it can be done by programs like WHATCHECK and PROCHECK.

Figure 3. Target template superposition; the figure highlights the superposition of the modeled MoxT (blue) upon the Template YdcE (green).
Source: Based on Agarwal S, Mishra NK, Bhatnagar S, Bhatnagar R (2010).



EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

b. **External Validation:** Based on information that was not used in calculation of the model. External validation involves the check over whether the correct Template was used (based upon identity percent). This can be predicted by comparing the Z-score of the model and the Template structure. Z-score is the measure of the compatibility between a model's sequence and its structure. Moreover Ramachandran plot to visualize backbone dihedral angles φ and ψ of amino acid residues in protein structure have to be analyzed to determine whether the torsion angles fall into the allowed and the generously allowed region of the Ramachandran plot or not (Figure 4). Thus, validation forms an indispensable part of structure modeling and must be dealt with utmost precision.

SOLUTIONS AND RECOMMENDATIONS

1. The largest improvements will come from more experimentally determined structures. This will increase the chances of modeling assignments to recognize the fold correctly, thus increasing the accuracy of the model generated.
2. Further improvement in the sequence-structure alignment can also improve the accuracy of the structure model. A better aligned profile with fewer gaps improves the accuracy of the model. One possible way of improving sequence-structure alignment might be using threading based techniques to align the sequence to structures identified in comparative modeling.
3. Protein tertiary structure prediction finds the solution to most of the issues and problems in the domain of deciphering protein structural coordinates. Multiple Template based homology modeling

Figure 4. Ramachandran plot
Source: Based on Agarwal S, Mishra NK, Bhatnagar S, Bhatnagar R (2010).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

can be applied to the low sequence similarity situations where multiple protein structural Templates can be used to model the Target protein.

4. Refinements of the modeled structure generated from homology modeling, threading, or even *ab initio* methods can be done by running molecular dynamic simulations.
5. The model is supposed to be generated on the basis of background knowledge of the protein of interest; this can be achieved by knowledge from the literature on the protein, an in-depth knowledge of the functional relevant conformation and Active site residues information. The knowledge from the literature study can help us explaining the structural and functional attributes of the protein to be modeled.

CASE STUDY

Modeling of B.anthracis Toxin MoxT: This case study is based on "Agarwal S, Mishra NK, Bhatnagar S, Bhatnagar R (2010) PemK Toxin of *B.anthracis* Is a Ribonuclease: An insight into its active site, structure, and function. JBC 285:7254–7270 (Agarwal, Mishra, Bhatnagar, & Bhatnagar, 2010). "

B.anthracis toxin-antitoxin module (MoxXT) is a TA system wherein, PemK-like toxin (MoxT) functions as a ribonuclease and thus acts as a cellular endotoxin. Under normal conditions, it exists as a dimer in complex with its cognate antitoxin and is inactive. Modeling of this toxin was used for the purpose of mutating the possible catalytic site residues.

Methodology

Homology modeling of the MoxT dimer: Homology modeling of the MoxT dimer was performed using *B. subtilis* YdcE as Template (PDB ID: 1NE8) (Gogos, Mu, Bahna, Gomez, & Shapiro, 2003) using the Swiss-Model Workspace. Figure 2 shows a multiple sequence alignment of the Target (MoxT or the *B. anthracis* toxin) to the Template protein (*B. subtilis* YdcE) and *E.coli* Kid Toxin. The multiple sequence alignment was created using ClustalW (Thompson, et al., 2002) in Bioedit (Hall, 1999) (Figure 2). Homology modeling was done using the sequence alignment with YdcE while alignment with Kid was used to infer the catalytic site residues for further mutagenesis. The modeled structure superimposed on the Template with RMSD of 0.1 Å between 232 amino acids (Figure 3). The Ramachandran plot of the predicted model revealed that 92.8% of the residues lie in the most favoured regions, and 6.2% of the residues lie in the additionally allowed regions, whereas 1.0% of the residues lie in the generously allowed region (Figure 4). The Final model was validated using Procheck (Laskowski, et al., 1993).

The residue E78 is conserved in MoxT. The other catalytic residue of Kid (R73) is replaced by a non-polar Leucine in YdcE and MoxT. However, the ribonuclease activity essentially requires the presence of a negatively charged and a positively charged (or polar group) in close proximity. In order to find the second catalytic site residue, the polar groups in the neighborhood of the conserved negatively charged E78 were identified. Interestingly, the only positively charged residue located in the close proximity of E78 was found to be H59 (Figure 5). Site directed mutagenesis of E78 and the nearby H59 resulted in abrogation of the ribonuclease activity of MoxT.

FUTURE RESEARCH DIRECTIONS

With the advancements in structural genomics projects, homology modeling methods is ought to play an attractive role in structure based drug discovery. Computational prediction methods provide a cost effective alternative in the absence of crystal structures. But the major drawback with prediction tools is to develop an accurate model. In this chapter, we report the current developments in this field, discuss *in silico* modeling limitations, and review the successful application of this technique to different stages of the drug discovery process. In-spite of the tremendous developments in the domain of protein tertiary structure prediction using homology modeling, there is still a requirement for better force fields and optimization functions. Better algorithmic approaches need to be developed to successfully incorporate divalent metal ions into the model

CONCLUSION

- Experimental macromolecular structure determination methods like X-ray and NMR methodology is expensive, exhaustive and cumbersome. Thus it cannot be always be undertaken.
- There are three basic approaches of structure prediction based upon the query-Template identity. If the identity is more than 30%, then the modeling lies in safe zone and comparative modeling approach is the preferred approach else threading and *ab initio* approach is used.
- If the query Template identity is less than 30%, then Threading is performed for protein structure prediction. This approach uses a database of known three-dimensional structures to match sequences without known structure with the protein folds.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

- *Ab initio* methods of protein fold prediction use force-field-based energy minimization to simulate the process of protein folding.
- Comparative modeling refers to the prediction of the Target protein from the identified Template protein structure.
- In comparative modeling, first a suitable Template is identified based upon the Target-Template alignment. After getting a proper alignment, real model building starts which encompass backbone generation, side-chain modeling and loop modeling. This is followed by model optimization and model validation.
- The accuracy of the model largely depends upon the Template identified and its alignment with the Target sequence.

KEY TERMS AND DEFINITIONS

Alignment: The process of lining up two or more sequences to achieve maximal levels of identity for the purpose of assessing the degree of similarity and the possibility of homology.

BLAST: Basic Local Alignment Search Tool. A sequence comparison algorithm used to search sequence databases for optimal local alignment to a query.

CASP: Critical assessment of Structure Prediction is a community-wide, worldwide experiment for protein structure prediction taking place every two years since 1994.

DDBJ: DNA Databank of Japan is a biological database that collects DNA sequences.

EMBL: European molecular biology laboratory is Europe's primary collection of all publicly available nucleotide sequences.

Fold: Arrangement of secondary structural elements like helix, sheets and coils of a protein in 3D space.

Gap: A position in an alignment that represents a deletion within one sequence relative to other at that position.

Gap Penalties: Penalty applied to a similarity score for the introduction of an insertion or deletion gap, gap extension, etc. gap penalty is the deduction from the cumulative score in alignment of two sequences.

Homology: Similarity in two sequences between individuals of the same or different species.

Modeling: Process where 3D structure of the macromolecule is generated (predicted), represented and manipulated to determine their molecular properties.

PDB: Protein Databank is an archive of experimentally determined 3D structures.

RMSD: Root mean square Deviation is the measure of the average distance between the atoms of superimposed proteins.

ABSTRACT

Antimicrobial drug resistance occurs when bacteria undergo certain modifications to eliminate the effectiveness of drugs, chemicals, or other agents designed to cure infections. To date, the burden of resistance has remained one of the major clinical concerns as it renders prolonged and complicated treatments, thereby increasing the medical costs with lengthier hospital stays. Of complex causes for bacterial resistance, there has been increasing evidence that proved the significant role of efflux pumps in antibiotic resistance. Coadministration of Efflux Pump Inhibitors (EPIs) with antibiotics has been considered one of the promising ways not only to improve the efficacy but also to extend the clinical utility of existing antibiotics. This chapter begins with outlining current knowledge about bacterial efflux pumps and drug designs applied in identification of their modulating compounds. Following, the chapter addresses and provides a discussion on Quantitative Structure-Activity Relationship (QSAR) analyses in search of novel and potent efflux pump inhibitors.

INTRODUCTION

Antimicrobial drugs have been important tools of healthcare in several decades because of their effectiveness in control of bacterial infections. Unfortunately, soon after their invention it was realized that some pathogens rapidly developed resistance to antibiotics (Neu, 1992; Wood, Gold, & Moellering Jr, 1996). People infected with antimicrobial-resistant organisms are more likely to have longer, more expensive

hospital stays, and may be more likely to die as a result of the infection. Initially, this problem was overcome by discovery of new classes of antibiotics such as aminoglycosides, macrolides and glycopeptides, but the bacteria rapidly showed an impressive array of defensive mechanisms that conferred on them, resistance to many modes of attack (Wood et al., 1996). The main mechanisms whereby the bacteria develop resistance to antimicrobial agents include enzymatic inactivation (Bush & Miller, 1998; Sabatini et al., 2012), modification of the antibiotic attack site(s) (Ruiz, 2003; Sabatini et al., 2012), and reduction of intracellular drug concentration by changes in membrane permeability (Nikaido, 2003; Sabatini et al., 2012) or by the overexpression of efflux pumps (Li & Nikaido, 2009; Sabatini et al., 2012).

One primary mechanism of antibiotic resistance is extrusion of the foreign chemical, which is termed efflux. In 1980, tetracycline was reported that it could be actively effluxed from the bacterial cell (McMurry, Petrucci, & Levy, 1980). From then on, many efflux-related mechanisms have been discovered. Overexpression of these efflux pumps may lead to antibiotic resistance. While efflux pump proteins are present in both Gram-positive and Gram-negative bacteria and also in eukaryotes, antibiotic resistance due to efflux is more of a problem in Gram-negative bacteria than in Gram-positive bacteria (Nikaido, 1996). This is because the presence of an outer membrane in Gram-negative bacteria shows comparatively lower permeability and complements the efflux activity of these pumps. Besides, studies of efflux pumps in Gram-negative bacteria have got more complicated as their double-membrane cells allow the expression of a tripartite efflux pump system such as AcrA/AcrB/TolC in Enterobacteriaceae, or MexA/MexB/OprM in *Pseudomonas aeruginosa*. One plausible practice to fight against multidrug efflux systems (MES) is the combination of conventional antimicrobial agents/antibiotics with small molecules that block MES known as multidrug efflux pump inhibitors (EPIs). An array of approaches in academic and industrial research settings, varying from high-throughput screening (HTS) ventures to bioassay guided purification and determination, have yielded a number of promising EPIs in a series of pathogenic systems (Tegos et al., 2011).

Up to now, most inhibitors of efflux pumps have been discovered through traditional random screening of synthetic compounds or natural products libraries. The assays used are very simple and easily adapted to high-throughput screening. An alternative approach is to screen libraries of known drugs. The identification of a novel mode of action in an approved drug could considerably shorten the development route and lessen the risks associated with a new chemical entity.

OVERVIEW OF BACTERIAL EFFLUX PUMPS AND ANTIBIOTIC RESISTANCE

Bacterial Efflux Pumps

Efflux pumps in Gram-positive bacteria can be categorized into four families (Handzlik, Matys, & Kieć-Kononowicz, 2013), namely ABC (ATP-binding cassette) (Higgins, 2001), MFS (major facilitator superfamily) (Saier Jr et al., 1999), SMR (small multidrug resistance) (Chung & Saier Jr, 2001) (Jack, Yang, & H Saier, 2001), and MATE (multidrug and toxic compound extrusion) (Hvorup et al., 2003).

For Gram-negative bacteria, many pump systems including *Campylobacter jejuni* (CmeABC) (Pumbwe & Piddock, 2002) (Lin, Michel, & Zhang, 2002), *Escherichia coli* (AcrAB-TolC, AcrEF-TolC, EmrB, EmrD) (Poole, 2000), *Pseudomonas aeruginosa* (MexAB-OprM, MexCD-OprJ, MexEF-OprN and MexXY-OprM) (Poole, 2000), *Salmonella typhimurium* (AcrAB) (Nikaido, 2001) have been described. These pumps basically belong to five major families, including the MFS (major facilitator superfamily),

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

MATE (multidrug and toxic extrusion), SMR (small multi-drug resistance), ABC (ATP-binding cassette) and RND (resistance-nodulation-division) families (Saier Jr, 1998). Co-expression of multiple types of efflux pumps can bring an additive or multiplicative effect on drug resistance (Lee et al., 2000).

MFS is the largest superfamily of transporters involved in symport, uniport, or antiport of various small solutes (Saier Jr et al., 1999). Examples include sugars, neurotransmitters, amino acids, Krebs cycle metabolites, and importantly, drugs. Most MFS efflux pumps have 400-600 amino acid residues and possess either 12 or 14 putative transmembrane domains. In MFS transporters, negatively charged amino acid residues located in transmembrane helices appear to play a critical role in the protonation/deprotonation step during transport. Typical MFS efflux pumps in Gram-positive bacteria include NorA, NorB, MdeA, Tet38 (*Staphylococcus aureus*), LmrB, Bmr, Bmr3, Blt (*Bacillus subtilis*), MefA (*Streptococcus pyogenes*), MefE (*Streptococcus pneumoniae*) or CmlR (*Streptococcus coelicor*) (Borges-Walmsley, McKeegan, & Walmsley, 2003; Handzlik et al., 2013; Jarmuła, Obłąk, Wawrzycka, & Gutowicz, 2010; Markham & Neyfakh, 2001; Paulsen, Brown, & Skurray, 1996; Poole, 2005).

The SMR family consists of small multidrug transporters widespread among eubacteria (Bay, Rommens, & Turner, 2008). These proteins are about 100-amino acid residues long, with four transmembrane helices. The examples of SMR efflux pumps in Gram-positive bacteria are EbrAB (*Bacillus subtilis*) or Smr, QacG, QacH (*Staphylococcus aureus*) (Jarmuła et al., 2010; Kikukawa, Nara, Araiso, Miyauchi, & Kamo, 2006; Putman, van Veen, & Konings, 2000).

All ABC transporters contain four essential modules, two nucleotide binding domains (NBDs) and two transmembrane domains (TMDs). These four modules can be encoded by four separate genes or fused pairwise in all possible combinations (Hollenstein, Dawson, & Locher, 2007; Lubelski, Konings, & Driessen, 2007). Bacterial MultiDrug Resistance (MDR) is usually homo- or heterodimers in which one NBD is fused to one TMD. LmrA (*Lactococcus lactis*) and Rv1217c-Rv1218c (*Mycobacterium tuberculosis*) (Borges-Walmsley et al., 2003; Jarmuła et al., 2010; Wang et al., 2013) belong to this transport protein family.

The RND transporters are responsible for the high intrinsic antibiotic resistance which can be seen in Gram-negative bacteria, one component of the notorious "natural superbug" phenotype. They are also found in Gram-positive bacteria where their functions are largely unknown (Tseng et al., 1999). RND transporters are homo- or heterotrimers consisting of promoters of about 1100-amino acid residues in size. Each promoter consists of the 12 transmembrance helices and a large periplasmic domain.

Most MATE transporters consist of 400-550 amino acid residue polypeptides with 12 putative transmembrane helices which share about 40% sequence similarity. An example of MATE efflux pump in Gram-positive bacteria is MepA protein found in *Staphylococcus aureus* (Handzlik et al., 2013; Omote, Hiasa, Matsumoto, Otsuka, & Moriyama, 2006; Wasaznik, Grinholc, & Bielawski, 2008). Currently, no high-resolution structures are available for this family of transporters. Secondary structure predictions showed the symmetric repetition of conserved regions in the *N*- and *C*-terminal halves of the proteins suggesting a gene duplication event.

Bacterial Efflux Pump Inhibitors

For Gram-positive bacteria, the search for new EPIs performed in the last decade was mostly focused on the NorA of *S. aureus* (Handzlik et al., 2013). Many approaches have been made to explore new EPIs. EPI activity is often found by antibiotic–EPI combination assays using efflux-proficient and -deficient *S. aureus* strain pairs. Efflux inhibition is verified with fluorometric efflux assays using ethidium bro-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

mide, a nonspecific DNA intercalator. A number of EPIs targeting *S. aureus* NorA have been identified including current chemotherapeutic agents used as EPIs (e.g. reserpine, P-gp inhibitors, verapamil, proton pump inhibitors, phenothiazines, thioxanthenes, paroxetine and COX-2 inhibitors), naturally occuring EPIs (e.g. 4',5'-*O*-dicaffeoylquinic acid, *N-trans*-feruloyl 4'-*O*-methyldopamine, resin glycosides, pheophorbide A, diterpenes, flavonoids and capsaicin) and synthetic EPIs (e.g. piperine analogs, fluoroquinolone analogues, indole-based inhibitors, berberine-INF55 hybrids, substituted dihydronaphthalene and mesolonic compounds); of which hybrid molecules were suggested for further investigation. An EPIs must be nontoxic and highly selective in order to be a potential candidate for clinical use. In this context, reserpine cannot enter further developments due to its neurotoxicity at concentrations required to inhibit NorA (Markham & Neyfakh, 1996; Schindler, Jacinto, & Kaatz, 2013; Zhang & Ma, 2010).

For Gram-negative bacteria, promethazine, a phenothiazine, combines with penicillin G have been used to inhibit RND pumps in *E. coli* (Lehtinen & Lilius, 2007), as well as inhibit ABC pumps in yeast (Kolaczkowski, Michalak, & Motohashi, 2003). Phenothiazines are able to reverse MDR phenotypes of pathogenic bacteria like *P. aeruginosa* or *S. typhimurium* (Michalak, Wesolowska, Motohashi, Molnar, & Hendrich, 2006; Molnar et al., 1996). Paroxetine can inhibit AcrAB-TolC pump of *E. coli* (German, Kaatz, & Kerns, 2008; Kaatz, Moudgal, Seo, Hansen, & Kristiansen, 2003; Munoz-Bellido, Munoz-Criado, & Garcìa-Rodrìguez, 2000). It is pointed out that arylpiperazines reverse MDR in bacteria overexpressing AcrAB and AcrEF pumps. Moreover, NMP (1-naphthylmethylpiperazine) is the most effective inhibitor that enhances the intracellular concentration of drugs like chloramphenicol, tetracycline, linezolid, macrolides and fluoroquinolones (Kern et al., 2006). The structures with dihalogens among arylpiperidines have been shown to restore the antimicrobial activity of linezolid in *E. coli* (Thorarensen et al., 2001).

Quinolines have been shown the ability to re-establish various antibiotic activities like quinolones, cyclines and chloramphenicol. They are now applied as broad spectrum inhibitors for resistant *E. aerogenes* and *K. pneumoniae* to make them susceptible for the antimicrobials (Chevalier et al., 2004). The analogs of aminoglycoside paromomycin have been applied as inhibitors of the efflux pumps using the bacterium *H. influenzae* (Alekshun & Nelson, 2004). AcrAB efflux pump was inhibited by using antibodies in *E. coli* and this strategy has been patented (Oethinger & Levy, 2002). A recent report has introduced the use of antisense phosphorothioate oligonucleotide encapsulated in a novel anion liposome to restore the activity of fluoroquinolones in *E. coli* (Meng et al., 2011). This method could be utilized for a wide variety of pumps with known gene sequences. Using antibody or parts thereof in order to inhibit MexAB-OprM pumps in *P. aeruginosa* has been patented (Inoko & Yoshihara, 2011).

In addition, a list of about 200,000 synthetic and natural compounds was tested with the aim of finding potential compounds preventing the activity of levofloxacin against *P. aeruginosa* (Chamberland et al., 2002; Coban, Ekinci, & Durupinar, 2004; Lomovskaya et al., 2001; Lomovskaya & Watkins, 2001; Renau et al., 1999). MC-207, 110 (Phenylalanine Arginyl β - Naphthylamide/PAβN) was identified as an inhibitor of Mex pumps. The crystal structure of *E. coli* AcrB has been solved in the presence of MC-207 and its binding to the pump has been proved (Edward, Aires, McDermott, & Nikaido, 2005). This compound has been shown to decrease the frequency of the emergence of highly levofloxacin resistant *P. aeruginosa* strains and also to reduce the intrinsic resistance of the bug to levofloxacin 8-folds (Coban et al., 2004; Lomovskaya et al., 2001; Renau et al., 1999). It is a competitive inhibitor of the efflux pumps and operates by binding to the same pocket or at a site closer to the antibiotic substrate binding site (Mahamoud, Chevalier, Alibert-Franco, Kern, & Pagès, 2007; Pagès, Masi, & Barbe, 2005). The compound has not only restored the activity of levofloxacin but has also been found to potentiate the activity of other antibiotics such as oxazolidinones, chloramphenicol, rifampicin, macrolides/ ketolides

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

(Zechini & Versace, 2009). Furthermore, it has these effects not only *for P. aeruginosa*, but also for *K. pneumoniae*, *C. jejuni*, *E. coli*, *S. typhimurium* and *E. aerogenes* (Malléa, Chevalier, Eyraud, & Pagès, 2002; Mazzariol, Tokue, Kanegawa, Cornaglia, & Nikaido, 2000).

Drug Design Targets Bacterial Efflux Pumps

Structure-based drug design plays an important part of the success story in the discovery of new drug leads. It is known that a thorough understanding of MDR transporter structure and function, as well as mechanism, would considerably facilitate the drug discovery. There have been, however, the scarcity of atomic structures of these membrane proteins due to difficulties related to the process of protein expression and crystallization (Chang, Ray, & Swaan, 2005; Rosenbusch, 2001). Additionally, it was suggested that there are some limitations associated with protein structures solved by crystallography that should be taken into consideration (DePristo, de Bakker, & Blundell, 2004). To date, the number of available bacterial efflux pump structures is still small compared to the number of identified bacterial transporters, which were described in previous reviews (Delmar, Su, & Yu, 2014; S. Kumar & Varela, 2012; Li & Nikaido, 2009; Van Bambeke & Lee, 2006; Zechini & Versace, 2009). This has hindered the computer-aided discovery of efflux pump chemosensitizers. The Table 1 enumerates MDR transporters with determined structures, of which recently structure-found transporters have mostly belonged to *Escherichia coli* and *Pseudomonas aeruginosa*.

Regarding MDR Gram-negative bacteria, RND transporter AcrAB-TolC and its homologues (including MexAB-OprM and MexXY-OprM) are main contributors to bacterial survival during infection. Certain studies on *Pseudomonas aeruginosa* MexAB-OprM pump, using both ligand-based and structure-based pharmacophore approaches in combination with docking method, recommended several important structural modification favoring inhibitory potentiation of known inhibitors: the incorporation of a hydrophobic group at the 2-position of the pyridopyrimidine scaffold or the inclusion of an olefin spacer between the tetrazole and pyridopyrimidine scaffold can render a boost in potency of this derivative, hydrophilic substitution was feasible on a piperidine moiety at the 2-position without adversely affecting activity, paving the way for the increase of aqueous solubility (Nakayama et al., 2004); in another study, the compound ASN05108137 exhibited maximum similarity to the pharmacophore hypothesis of MC207110, the first inhibitor against MexAB-OprM efflux system of *P.aeruginosa*, and also showed the druglikeness property satisfying the Lipinski's rule of five (Aparna, Mohanalakshmi, Dineshkumar, & Hopper, 2014).

In a recent study, the crystal structure of AcrB and MexB bound to the pyridopyrimidine derivative ABI-PP was determined. This result provides detailed insight into the mechanism by which the inhibitor ABI-PP acts on RND transporters thereby generating a structural basis for designing a universal inhibitor of multidrug efflux transporters (Nakashima et al., 2013). A pharmacophore study was aimed to circumvent the drug resistance in *P.aeruginosa* and *E.coli* by identifying natural compounds from plants having effect on MexB and its counterpart AcrB. Lanatoside C and daidzein were found to have a high possibility to counteract the MDR pumps in the resistance bacteria (Aparna, Dineshkumar, Mohanalakshmi, Velmurugan, & Hopper, 2014).

Another pharmacophore hypothesis was generated by the HipHop method to analyze the structure-activity relationships of active sites of protein-ligand interactions thereby increasing the knowledge of structure and mechanism of RND-type AdeABC EPIs in *Acinetobacter baumannii*. The achieved 3D common feature pharmacophore model revealed that two hydrogen bond acceptors (HBA) and three

(From Protein Data Bank).

hydrophobic aromatic (HpAr) were found to be significant for binding to the active site of the target protein. Three HpAr features displayed the required substitution of bulky aromatic moieties, while two HBA atoms or groups were necessary in the molecule to bind to the target protein (Yilmaz et al., 2014).

More recently, structures of interest for rational design include the advent of the pseudo-atomic structure of complete AcrAB-TolC in complex with AcrZ, a modulatory protein partner from *E.coli*. It was found that the studied structure is likely to be similar to homologous assemblies in pathogenic species that infect humans such as *Vibrio cholerae, P.aeruginosa, Neisseria gonorrhoeae* and *Salmonella enterica* (Du et al., 2014).

QSAR APPROACHES IN SEARCH FOR EFFLUX PUMP INHIBITORS

QSAR Approaches in Search for EPIs in Gram Positive Bacteria

The methicillin-resistant *Staphylococcus aureus* (MRSA) is one of the most frequent nosocomial pathogens in developed countries. Among the Gram positive bacteria, *S.aureus* is responsible for a large number of deaths worldwide. MRSA is resistant to a variety of antibiotics including tetracyclines, aminoglycosides and fluoroquinolones. Studies found that NorA is a predominant protein efflux pump responsible for efflux mechanisms in *S.aureus* (Sabatini et al., 2012). For these reasons, NorA has been one of the most studied Gram-positive bacterial efflux pumps in the search for efflux pump inhibitors. Although other protein targets have been investigated and there are some newly found derivatives proved to have inhibitory activities towards those proteins, there is still a lack of QSAR studies focused on such inhibitors. With respect to NorA in *S.aureus*, while there have been a number of natural and synthetic product known to be inhibitors of NorA efflux pump, there is still a need to discover new and potent NorA inhibitors. However, the slow emergence of high-resolution structure of this pump has hampered the intelligent design of its modulators, necessitating a ligand-based approach. With currently available structural data regarding known NorA inhibitors, robust QSAR models were generated, paving the way for preliminary identification of compounds with NorA inhibitory activities, whereby more thorough research can be conducted in order to identify the inhibitors with high potentiality to become future "adjuvants" of antibiotics.

QSAR of Piperine Analogs for Bacterial NorA Efflux Inhibitors

Piperine, a major component of Piper nigrum, is a putative bacterial EPI (Khan, Mirza, Kumar, Verma, & Qazi, 2006). In addition, piperine has been found to be associated with several activities (Amit Nargotra et al., 2009): inhibiting several cytochrome P450-mediated pathways and phase II reactions in animal models (Atal, Zutshi, & Rao, 1981; Singh, Dubey, & Atal, 1986); inhibiting human P-glycoprotein (Bhardwaj et al., 2002) and potentially inhibiting rat hepatic microsomal constitutive and inducible cytochrome P450 activities (Koul et al., 2000).

After screening a chemical library consisting of 200 structurally diverse compounds for inhibition of the NorA efflux pump, three piperine analogues, namely SK-20, SK-56 and SK-29, were found to be the most potent inhibitors of the NorA efflux pump. The structural adjustments of piperine that can lead to bacterial efflux pump inhibitors with significantly higher activities include: (i) the introduction of an alkyl group at the C-4 position mainly contributes to potentiation, and ethyl and n-propyl show highest effect; (ii) substitution of a piperidinyl moiety by an aromatic amine such as anisidine or toluidine renders greatest potentiation, whereas other substituents such as aniline, amino esters, pyrollidine, azepine and alkylamines (except isobutyl amine) appear to be less effective; (iii) unsaturation is a critical feature for potentiation, as di- and tetra-hydro piperine show much less activity than corresponding unsaturated analogues; (iv) the omission of amide carbonyl group leads to a decrease in potentiation; and (v) the presence of a 3,4-methylenedioxyphenyl or 4-methoxyphenyl group in structure of piperine derivatives can enhance potentiation (A. Kumar et al., 2008).

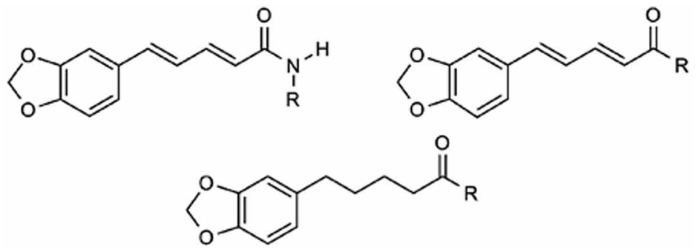
In the QSAR study of piperine analogs for bacterial NorA efflux pump inhibitors (Amit Nargotra et al., 2009), researchers at Indian Institute of Integrative Medicine, India employed the Cerius2 4.10 software package (from Accelrys Inc.) to calculate 2D descriptors differentiating the molecules in terms

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

of their size, degree of branching, flexibility, and overall shape. A total set of 25 compounds was divided into 20 molecules in training set and 5 molecules in test set. The general structures of the compounds are given in Figure 1.

All the molecules were energy minimized using the Cerius2 OFF module with default parameters of Smart Minimizer. The QSAR model was generated using the genetic function approximation (GFA) method and its statistical significance was validated using randomization procedure. As a result, the final QSAR equation after removal of outliers was as follows:

$$\log (PF) = 0.84 - 0.002 \times Hf + 0.01 \times Jurs_PNSA\text{-}1 - 0.01 \times Shadow_XZ$$



($N = 17$; LOF = 0.015; $r^2 = 0.962$; $r^2_{adj} = 0.953$; F-test = 110.08; LSE = 0.006; $r = 0.981$; $q^2 = 0.917$)

where PF (potentiation factor) of the compounds (efflux pump inhibitors – EPI) express the reduction in the MIC values of ciprofloxacin, hence represent the potentiation of activity of ciprofloxacin in the presence of piperine analogs based efflux pump inhibitors; N is number of compounds in training set, LOF is lack of fit score, r^2 is squared correlation coefficient, r^2_{adj} is square of adjusted correlation coefficient, F-test is a variance-related static which compares two models differing by one or more variables to see if the more complex model is more reliable than the less complex one, the model is supposed to be good if the F-test is above a threshold value, LSE is least-square error, r is correlation coefficient, q^2 is the square of the correlation coefficient of the cross-validation.

The QSAR model was proved robust by using the method proposed by Golbraikh *et al*., and Roy. The achieved QSAR model had the values of $R^2_{pred} = 0.78$ and $r^2_m = 0.72$, indicating the good external predictability of the QSAR model.

Jurs_PNSA-1, Shadow_XZ and Hf are important descriptors responsible for the relationship between piperine analogs' structure and activity as *S. aureus* NorA efflux pump inhibitors. Jurs_PNSA-1 is the partial negative surface area, calculated by using the sum of the solvent accessible surface area of all negatively charged atoms in the compound. Shadow_XZ is the area of the molecular shadow in the XZ plane. Hf is the heat of formation descriptor. These parameters were proved to be important contributors to the potentiating activity and must be taken into consideration while designing the efflux pump inhibitors.

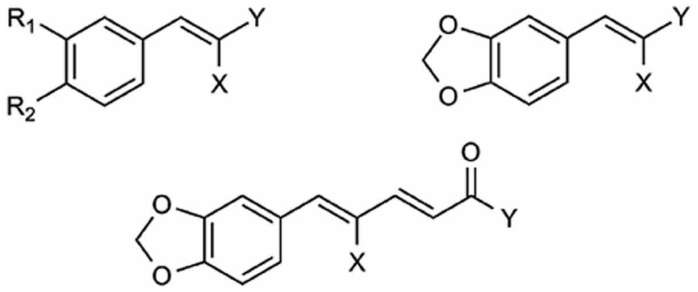
QSAR of Aryl Alkenyl Amides/Imines

Another QSAR study on activity of aryl alkenyl amides/imines having structural similarity to piperine (structures shown in Figure 2) in inhibiting bacterial efflux pump was also conducted by Nargotra *et al* (A Nargotra et al., 2009).

The total set of 42 compounds was divided into 34 molecules in training set and 8 molecules in test set by arranging the molecules in ascending order of their PF and selecting every fifth molecule to be included in the training set. About 200 descriptors were calculated using the Cerius2 4.10 software package. After the removal of the descriptors with zero values for all the compounds, remaining descriptors were filtered using genetic function approximation (GFA) method. The study showed that the ideal number of descriptors should be five. After analyzing the equation with five descriptors and removing outliers, the following equation was achieved:

$$\log (PF) = -0.2028 - 0.000936*Hf + 0.342484*S_dssC$$



$$+ 0.441556*RadOfGyr - 0.2087*Atype\text{-}C\text{-}16$$

$$- 0.00104*Jurs\text{-}WNSA2$$

($N = 30$; LOF = 0.051; $r^2 = 0.866$; $r^2_{adj} = 0.833$; F-test = 28.875; LSE = 0.022; $r = 0.929$; $q^2 = 0.757$)

The final QSAR model had the values of $R^2_{pred} = 0.825$ and $r^2_m = 0.634$, indicating the good external predictability of the QSAR model. The QSAR study also gives us the revelation that E-state indices and A log P atom type are important descriptors responsible for describing the activity of aryl alkenyl amide/imine based efflux pump inhibitors. In addition, solvent accessible surface area, partial charged surface area of a molecule, radius of gyration and heat of formation of the molecule are also important parameters to be taken into account while designing new inhibitors belonging to the class of compounds mentioned above.

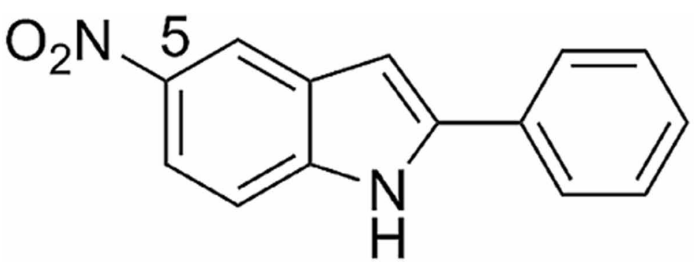
QSAR of 2-Aryl-5-Nitro-1H-Indole Derivatives

It has been found that the combinatorial administration of lead structure 5-nitro-2-phenylindole (INF55) and the antibiotic significantly increases *S. aureus* susceptibility to ciprofloxacin (Ambrus et al., 2008). Structure-activity relationship studies mostly aimed at disclosing the importance of the C5 position of INF55 (Figure 3) for inhibitory activity against the NorA pump:

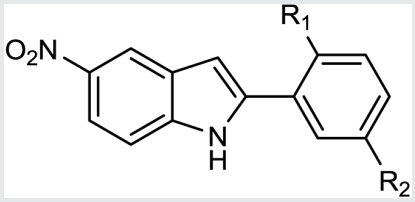
1. Reduction of C5 substituent will adversely affect the activity.
2. Carbonyl based electron-withdrawing groups at C5 eliminate all activity.
3. C5 substituents such as sulfonic acids/esters/amides have no effect on potentiation.
4. INF55 derivatives bearing a nitrile group show similar potentiation activity to INF55 (compound 14) (Ambrus et al., 2008).



All compounds lacking 5-NO_2 groups were significantly less potent than INF55. The 3′-CO_2Me INF55 derivative showed slightly higher potency than INF55 against all three *S.aureus* strains. INF55 analogue containing a 4′-CH_2OH group was nearly equipotent with INF55 against the wild type and NorA overexpressing strain, representing a promising candidate for incorporation into dual action mutual prodrugs targeting the NorA pump (Ambrus et al., 2008).

Berberine is the active constituent of the medicinal plants echinacea and golden seal. The extrusion of berberine by bacterial efflux pumps can make this antimicrobial agent ineffective. Nevertheless, it was found that the use of berberine along with an effective MDR pump inhibitor could restore its activity. In another related study, an inhibitor of Major Facilitator MDRs, namely SS14, was made on the basis of covalent link between berberine and INF55. Compared to berberine, SS14 was 100-fold more active against *S.aureus* and 200-400 fold more active against *S.aureus* mutants overexpressing the NorA MDR (Ball et al., 2006).

In a QSAR study on MDR inhibitory activities of indole derivatives, the 3D structures of ten 2-aryl-5-nitro-1-*H*-indole derivatives (structures shown in Table 2) were optimized with the semi-empirical PM3 method and density functional theory (DFT) at b3lyp/6-31 g* level successively (Dai, Zhang, Zhang, Wang, & Lu, 2008).



Some structural and electric parameters were subsequently obtained from single point energy and natural bond orbital analysis. These parameters included the lowest unoccupied molecular orbital energy (E_{LUMO}), the highest occupied molecular orbital energy (E_{HOMO}), the polarizability (α), the nuclear-nuclear repulsion energy (E_{rep}), the molecular total energy (E_{tot}), the dipole (μ), the molecular volume (V_{mol}), and the Mulliken atomic charges of the six carbons of the 2-aryl (Q_{C1}-Q_{C6}). A genetic algorithm-

based multi-linear regression analysis (GA-MRA) was carried out to reduce the number of the structural and electric parameters originally from 13 parameters obtained from the quantum chemistry calculations, thus rendering the optimized set of descriptors for constructing the QSAR model. With each data set containing m variables, a QSAR model was built. Then the optimum combinations containing the same numbers of descriptors were screened out with GA method. For each m of 2-7, two combinations of the descriptors with the top square correlation coefficient R^2 are analyzed based on the trends of their R^2, R^2_{CV}, and F (a=0.05) values in accordance with changes of *m* values. The QSAR model was built based on partial least square (PLS) analysis.

The outcomes of genetic algorithm analysis indicated that the model containing five descriptors of μ, V_{mol}, Q_{C2}, Q_{C3} and Q_{C4} with the highest R^2_{CV} of 0.9941 and a good R^2 of 0.9982 could be considered as an ideal model for QSAR of 2-aryl-5-nitro-1-*H*-indole. These five descriptors were re-analyzed with partial least square (PLS) and the LOO cross validation. The QSAR model achieved with 5 independent variables is shown as follows:

$$-\lg \mathrm{MIC} = -0.397 \times \mu + 0.019 \times V_{mol} + 1.231 \times Q_{C2} + 9.976 \times Q_{C3} - 6.177 \times Q_{C4} - 0.198 \quad (*)$$

$$N = 10,\ R^2 = 0.998,\ R^2_{CV} = 0.996$$

The equation showed that increasing Q_{C3} and decreasing Q_{C4} could improve the activity of 2-aryl-5-nitro-1-*H*-indole derivatives as efflux pump inhibitor. With the model achieved, the electric and structural descriptors of a new compound, 2-(2-azidomethyl-5-phenoxy-phenyl)-5-nitro-1*H*-indole (8d, R_1

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

= -CH_2N_3, R_2 = -OCH_2Ph) were calculated with the same quantum chemistry calculation method and they were predicted from the equation (*) to lower the MIC of berberine to 0.091 μg/ml for inhibiting K2361 of *S.aureus* with NorA efflux pump protein overexpression.

Case Study of Using QSAR Model for Virtual Screening of NorA Efflux Pump Inhibitors

In a QSAR study conducted by Thai *et al.* (Thai et al., 2015), a total of 47 compounds belonging to different structural classes in company with the efflux pump inhibitory (EPI) activity against NorA mediated ethidium bromide efflux (IC_{50}) were compiled from the literature (German et al., 2008; Kaatz, Moudgal, Seo, Hansen, et al., 2003; Kaatz, Moudgal, Seo, & Kristiansen, 2003; Michalet et al., 2007; Pieroni et al., 2010; Sabatini et al., 2012; Sabatini, Kaatz, Rossolini, Brandini, & Fravolini, 2008; Smith, Williamson, Wareham, Kaatz, & Gibbons, 2007; Stavri, Piddock, & Gibbons, 2007). In MOE, all chemical structures of the data sets were built and energy minimized before computing 184 2D molecular descriptors. Subsequently, the variables were selected using RapidMiner (RapidMiner), Weka (WEKA) and MOE (MOE) software packages respectively. This attribute selection resulted in five descriptors which were analyzed in correlation matrix with experimental pIC_{50} values. Subsequently, linear regression models ($y=a_0+a_ix_i$) were generated by using the QuaSAR-Model tool in MOE (MOE) with the method Partial Least Square (PLS) and the activity field pIC_{50}. Based on the training set, different models generated from different descriptors were internally validated by the cross-validation technique and externally validated by the test set. The descriptors used for the best one were continuously used for modeling the whole data set to get the final model which was internally validated by the cross-validation technique and externally validated by the external test set. As a result, the finally achieved model with statistical values $Q^2 = 0.8$, $\overline{r_m^2} = 0.71$ and $\Delta r_m^2 = 0.18$ met validation criteria for the data set following Roy *et al.* (Ojha, Mitra, Das, & Roy, 2011; Pratim Roy, Paul, Mitra, & Roy, 2009; Roy et al., 2011).

The yielded model was applied on drug-likeness compounds from the mixture library of 182 flavonoids (Belsare, Pal, Kazi, Kankate, & Vanjari, 2010; Farkas, Jakus, & Héberger, 2004; Park et al., 2006; Phosrithong, Samee, Nunthanavanit, & Ungwitayatorn, 2012; Seyoum, Asres, & El-Fiky, 2006; Tran, Park, Kim, Ecker, & Thai, 2009; Yokozawa et al., 1998) and the traditional Chinese medicine (C. Y. Chen, 2011) (TCM) database that met the rules of five/three to identify novel Nor-A inhibitors with $pIC_{50} \geq 4.5$. Among 182 flavonoids having the rings values ≥ 2, 27 of 169 compounds that matched the criteria of the rule of five and none of 8 compounds that matched the criteria of the rule of three were predicted as potential NorA inhibitors. Among 52957 TCM compounds with the descriptor rings ≥ 2, 2866 of 15250 compounds that matched the criteria of the rule of five and 9 of 1679 compounds that matched the criteria of the rule of three were determined as hit compounds for NorA inhibitory activity as well. Ultimately, 27 flavonoids and 2863 TCM compounds had fully satisfied at least the Lipinski's rule of five and had good predicted pIC_{50} values and thus were considered as potential drugs to reverse the efflux-mediated multidrug resistance of *Staphylococcus aureus*.

Additional Discussion

From QSAR studies on piperine, aryl alkenyl amides/imines and 2-aryl-5-nitro-1*H*-indole derivatives as ligands of NorA efflux pump, it was observed that certain portion of any kind of ligands do involve themselves in hydrophobic interaction or electronic or in both with the receptor. The crucial binding in most of the cases is, nonetheless, hydrogen bonds. NorA is, therefore, assumed to have certain critical features capable of interacting with all kinds of structurally different ligands. These features may comprise some hydrogen-bond donor and acceptor sites, some lipophilic areas, and a few polar sites.

This view was justified by two docking studies using NorA homology models: Thai *et al*. developed homology model of NorA based on the transporter (PDB ID: 2gfp) while Kalia *et al*. used GlpT (PDB ID: 1PW4) as the protein template to create homology model. Thai *et al*. docked 6 traditional Chinese medicine (TCM) and 27 flavonoids into the central channel and the Walker B. Most molecules had better affinities to the Walker B than the central channel due to the hydrophilic property of the latter. Compared with TCM, flavonoids have higher affinities towards NorA binding site because of tight interactions (hydrogen bonding and π-π stacking) with NorA homology model made by substituents in flavonoid structures (Thai et al., 2014). Kalia *et al*. conducted docking studies of two ligands namely reserpine and capsaicin, which are two known NorA inhibitors, in the binding site of NorA. The most important finding was that a hydrophobic cleft of NorA provided stability as well as affected the orientation of the ligand within the binding pocket. Hydrogen bondings between substituents of ligands and amino acid residues of the binding site attributed to the stability of the ligand-protein complex (Kalia et al., 2012). These results consolidated the outcomes of above-presented QSAR studies that most of parameters selected for final models are associated with surface charge, polarity and molecular weight.

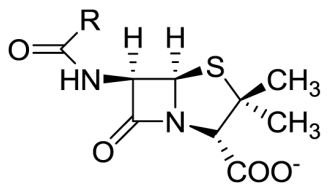
Compared with QSAR studies of specific derivatives, the QSAR analysis of natural products for NorA EPIs was performed with a larger and more diversified database including the compounds from different structural classes. However, this strong point became an obstacle that made the validation results of obtained models be at a disadvantage compared with those of the model generated by Koul *et al.* (A. Nargotra et al., 2009). Among three descriptors used for the model of these authors (A. Nargotra et al., 2009), this study revealed that the descriptor "partial negative surface area" might be relevant to the descriptor "total negative vdw surface area" (PEOE_VSA_NEG) that was determined as a less important variable and removed from final models.

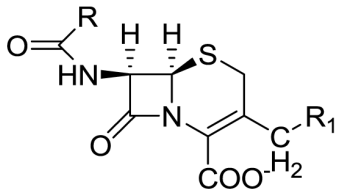
QSAR Approaches in Search for EPIs in Gram Negative Bacteria

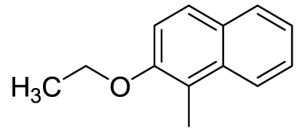
Gram-negative bacteria seem to be more dangerous than Gram-positive bacteria in some cases. Some can be named such as *P. aeruginosa, K. pneumoniae*, *C. jejuni*, *E. coli*, *S. typhimurium* and *E. aerogenes, etc.* Moreover, their levels of MDR have increased alarmingly. Nonetheless, no efflux pump inhibitor has been licensed for use in the treatment of bacterial infections in human or veterinary medicine. It must stimulate research that leads to the development of new EPI molecules.

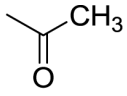
With the recent advent of high-resolution 3D-structure of drug transporters, the co-crystallization of AcrB and MexB with some substrates, and the analyses of the biological effects of several mutations in the pump, it is now possible to rationally design functional targets located inside the bacterial pumps. Consequently, the synthesis of efficient molecules with strong EPI capacity will be more readily achieved. In this context, there should be more QSAR models that help to save time and money on searching "new drugs" for mediation of efflux pumps in Gram-negative bacteria. However, it is noticed with deep con-

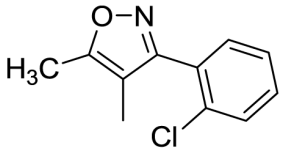
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

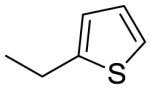


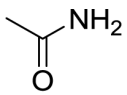


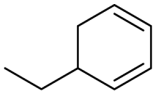


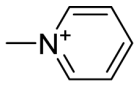












cern that scientists have not paid enough attention on this kind of QSAR studies. In comparison with a large number of other efflux pumps in Gram-negative bacteria, studies on the two kinds of efflux pumps (MATE efflux pump VmrA from *V.parahaemolyticus*, and AcrAB–TolC from *Escherichia coli*) are likely insufficient to deal with Gram-negative bacterial resistance. Therefore, it is hoped that new and solid QSAR models for MDR efflux proteins would be yielded in order to provide a more complete picture of the molecular requirements.

QSAR Study of β-Lactam Antibiotic Efflux by the Bacterial MDR Pump AcrB

A QSAR study related to Gram-negative bacterial efflux pumps was conducted by researchers Marcia Ferreira and R.Kiralj in 2004 (Ferreira & Kiralj, 2004). The target of the study was AcrAB-TolC – an efflux pump identified in several Gram-negative bacteria including *Salmonella typhymurium*. AcrAB-TolC is a tripartite efflux pump, which consists of the inner-membrane transporter AcrB (Edward, McDermott, Zgurskaya, Nikaido, & Koshland, 2003; Elkins & Nikaido, 2003; Murakami, Nakashima, Yamashita, & Yamaguchi, 2002; Pos & Diederichs, 2002), the outer-membrane channeltunnel protein (Koronakis et al., 2000) of the TolC family (Elkins & Nikaido, 2003), and the periplasmic linker lipoprotein AcrA from the membrane fusion family (Thanabalu, Koronakis, Hughes, & Koronakis, 1998).

The study was aimed at establishing multivariate quantitative lipophilicity–MIC and β-lactam structure–MIC relationships for *S. typhimurium* strains (Nikaido, Basina, Nguyen, & Rosenberg, 1998). Mass concentration MICs for 16 penicillines and cephalosporins (structures shown in Table 3) with respect to bacterial strains *S. typhimurium* SH5014 (parent strain) and its mutants low resistant SH7616 and AcrAB

overproducer HN891, were collected from the literature (Nikaido et al., 1998). Around 50 molecular properties of 16 β-lactam antibiotics were calculated using different methods based on their modeled molecular structures. These computed properties included lipophilicity parameters and other molecular properties which were prepared based on two-dimensional chemical formulae of studied penicillins and cephalosporins. HCA (hierarchical cluster analysis) and PCA (principal component analysis) studies indicated that the presence of charged groups and hydrophobic moieties determined the antibiotic behavior with respect to AcrAB-TolC pumps. Highly charged β-lactams with small hydrophobic fraction w_C or S_f might be poor AcrB substrates due to energetically unfavorable pump–drug interaction in molecular recognition. Nonetheless, the HCA-PCA approaches could not give answers to the question of which lipophilicity parameters were most reliable for these antibiotics, so the QSAR studies were carried out.

QSAR studies, which were performed by means of the partical least squares (PLS) and based on lipophilicity and electronic and hydrogen bonding molecular descriptors, demonstrated that

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

1. Biological activities (pMICs) strongly depend both on properties of bacterial strains and drug molecules. β-lactams were classified as good, moderately good and poor AcrAB-TolC substrates;
2. Among the most important β-lactam molecular properties quantitatively related to pMICs are lipophilicity and electronic and hydrogen bonding properties; and
3. Lipophilicity parameters calculated in different ways do not necessarily present the same information about drugs, and cannot produce parsimonious and accurate regression models for MICs originated by active AcrAB-TolC pumps.

Two strains HN981 and SH5014 were found to act similarly, and the third one – SH7616 is significantly different from each of them (Table 4). This was manifested by the similarity, even with the same molecular descriptors, of the PLS models related to strains HN891 and SH5014.

Additionally, penicillins and cephalosporins which can be characterized as hydrophilic, with good hydrogen bonding properties and able to establish polar-polar interactions with bacterial pump receptors, are bad pump substrates, and so potentially good drugs. This finding has been supported by recent studies of AcrB in which most pharmacophore models generated by 49 AcrB substrates contain hydrophobic centers and hydrogen bond acceptors or donors. Molecular interactions of phytochemicals with the active site residues in the binding site of AcrB also consist of hydrogen bondings and hydrophobic contacts (Aparna, Dineshkumar, et al., 2014). Vargiu and Nikaido confirmed the similar features of AcrB binding sites. Distal pocket and proximal pocket were shown to be two main active regions of AcrB. 15 hydrophobic residues and 11 polar or charged amino acid residues in the distal binding pocket were found to contribute to the binding of all ligands examined (Vargiu & Nikaido, 2012). In another study publicized on *Nature* magazine in 2013, scientists found that AcrAB-MexAB specific inhibitor of pyridopyrimidine derivative (ABI-PP) is deeply inserted into a hydrophobic trap rich in phenylalanine residues. Based on the results of site-directed mutagenesis and molecular dynamics simulations, the trap has been considered to indirectly affect drug-binding site. Phe178 located at the edge of this trap in AcrB contributes to the tight binding of the inhibitor molecule through a π-π interaction with the pyridopyrimidine ring (Nakashima et al., 2013).

QSAR/SAR Study of Structurally Unrelated Substrates of a MATE Efflux Pump VmrA from V.Parahaemolyticus

Multidrug transporters of MATE family have been known to expel dissimilar lipophilic and cationic drugs across cell membranes by dissipating a preexisting Na+ or H+ gradient (Lu et al., 2013). Brown *et al*. classified the MATE family into three subfamilies. Subfamily 1 includes NorM, subfamily 2 includes ERC1, and subfamily 3 includes DinF. VmrA has been considered to be a member of subfamily 3 (DinF branch). The *vmrA* gene consisted of 1,341 nucleotides, with a deduced popypeptide (VmrA) consisting of 447 amino acids residues with a calculated molecular mass of 49 kDa. VmrA was very rich in hydrophobic residues, indicating that the protein was an integral membrane protein (J. Chen et al., 2002). This characterization of MATE pump favoring hydrophobic substrates were illustrated in a QSAR study of VmrA substrates done by Rudolf Kiralj and Marcia M.C. Ferreira in 2008 (Kiralj & Ferreira, 2008).

Kiralj and Ferreira aimed at correlating the efflux activity of *V. parahaemolyticus* VmrA with molecular properties of 12 diverse agents at QSAR and SAR levels. The training set in this work consists of 12 agents (organic molecules/ions including 4',6-diamino-2-2phenylindole, tetraphenylphosphonium chloride, acriflavine chloride, ethidium bromide, chloramphenicol, norfloxacin, rhodamine 6G chloride, tetracycline, erythromycin, streptomycin, sodium deoxycholate and sodium dodecyl sulfate). The corresponding activities pMIC = -log(MIC/mol/dm^3) are pMIC(KAM) and pMIC(pVCJ6), which are efflux activity pMIC of the *E.coli* strains KAM32 and KAM32/pVCJ6, respectively. The prediction of the MDR character of VmrA with respect to 19 diverse substrates was performed at both QSAR and SAR levels.

Analysis of descriptors in correlation with the biological activities pMIC indicates that MDR of VmrA was directed against agents with shorter bonds, a few polar atoms, elevated contents of rings, planar structures, and aromatic carbon atoms. This is generally a rigid aromatic structure with exo- and/or endocyclic heteroatoms. Satisfactory prediction power statistics Q^2>0.5 and R^2>0.6 for QSAR models can be observed for all the models. The low R^2 and Q^2 values indicated that the good results in the original models were not due to a chance correlation or structural dependency of the training set.

There were also common structural features related to efflux from KAM32 and KAM32/pVCJ6 strains. In general, agent efflux was not determined by specific functional groups due to the strictly nonbonding nature of pump-mediated MDR. Exploratory analysis related to the two strains points out that good substrates of efflux systems in *E.coli* strains KAM32 and KAM32/pVCJ6 are neither linear nor extended, preferably were ring structures with some branching, rather hydrophobic, weak dipoles, difficult to polarize, possess some polar groups, and could establish hydrogen bonds with receptors. The strains differed in their preferences for good substrates: KAM32 binds rather hydrophobic species, while KAM32/pVCJ6 attracts heteroaromatics. Therefore, aromatic-aromatic and hydrophobic-hydrophobic VmrA-substrate interactions seemed to be crucial. Agent-receptor interaction statistics show that agent-receptor interaction descriptors depend on agent molecular properties, receptor molecular properties, agent position and binding mode relative to the receptor, and the presence of other molecular/ionic species. Supposing that agent properties might substantially affect agent-receptor interactions, variations in receptors and agent binding modes/positions were expected to have a secondary importance. In addition, good substrates of VmrA efflux pump from *V. parahaemolyticus* strain AQ3334 must also be rather rigid and condensed heteroaromatic systems, with very few or no flexible side-chains, with exo- or endocyclic heteroatoms, and establish aromatic-aromatic contacts with VmrA.

This QSAR study proved that chemometric methods are very useful in practice and the agent-receptor interaction descriptors, based on PDB data, correlate reasonably with biological activities, further rationalizing the VmrA-agent interactions.

DESCRIPTORS AND METHODS

It has been recognized that most descriptors employed to build QSAR models for prediction of interactions between chemical agents and Gram-negative bacterial efflux pumps were mostly parameters of molecular field (steric, electrostatic and hydrophobic). In the study of AcrAB-TolC, critical β-lactam molecular descriptors related to pMICs were associated with lipophilicity. For the examination of VmrA substrates, VmrA in strain KAM32 extrudes agents characterized by three lipophilicity descriptors (Nh, sighyd and wh2) and two electronic descriptors (E4 and HOMO) while the regression vectors for KAM32/pVCJ6 have contributions of three electronic descriptors (FF, Np2 and Mrefn2), a steric (wr) and a hydrophobic (sighyd) descriptors accounting for agent efflux by VmrA. In studies of MDR efflux pumps of Gram-positive bacteria, in addition to molecular field descriptors as main contributors to QSAR models, other relevant descriptors relate to quantum chemical (heat of formation), constitutional (number of rings), topological and geometrical (molecular volume and radius of gyration) properties. These observations were consistent with the fact that even though the mechanisms of drug transport in bacterial efflux pumps have remained unknown and controversial, empiric observations on properties of known pump substrates and inhibitors have indicated several regular features, of which amphiphilic nature of compounds play a key role. Further discussion regarding this character of MDR pump inhibitors can be found in the review and the commentary done by Van Bambeke *et al*. in which the presence of well-defined lipophilic and hydrophilic regions of antibiotics was mentioned (Van Bambeke, Balzi, & Tulkens, 2000; Van Bambeke & Lee, 2006).

All QSAR studies concerning NorA inhibitors included in this chapter principally relied on two-dimensional (2D) descriptors to generate the models. Among the used methods, the most common was PLS, others included PCR and HCA. However, 2D descriptors could not give relevant information regarding the ligand – efflux pump protein interaction. Besides, there was only a limited number of studied transport proteins, as the researchers focused on several efflux pumps, namely NorA, AcrAB-TolC, and VmrA, out of a large number of identified antibiotic-resistant efflux pumps mentioned in previous sections of this chapter. Therefore, the need of broadening the scale of QSAR research and studies based on bacterial efflux pumps is evident.

FUTURE RESEARCH AND OUTLOOK

As far as we are concerned, since the parameters used for presented 2D-QSAR models are mostly molecular field descriptors, the COMFA/COMSIA-based 3D-QSAR might be an appropriate alternative for the exploration of relationships between certain structural properties and the binding mode in which the ligand interacts with the efflux pump at the active domains. However, this method also has several limitations. The alignment protocols used in 3D-QSAR assumes that the ligands observed in the model bind to the efflux pump at the same binding site in the same manner. As a result, researchers may have difficulties achieving 3D-QSAR models in the circumstances where the efflux pumps have either one

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

large binding site or multiple binding sites which can accommodate simultaneous ligands in various ways. In such cases, VolSurf/GRIND-based descriptors should be employed to obtain 3D-QSAR models with acceptable predictive capability. These are alignment free and thus allow the analysis of structurally diverse compound sets. Although QSAR approaches do not enable one to decipher the underlying mechanism of ligand-protein interaction, they might represent versatile tools for *in silico* filtering large combinatorial libraries for compounds with bacterial efflux pump inhibitory activity.

Moreover, the studies mentioned in the chapter mainly relied on the PLS analysis to yield predictive models. This approach was limited to sets of compounds whose biological activity and molecular descriptors are in linear correlations. Thus, there should be QSAR studies using machine learning and neuron network methods which can deal with non-linear structure-activity relationships. These approaches may pave the way for the establishment of rapid *in silico* screening that are routinely applied in the early drug discovery phase. Additionally, pharmacophore modeling should also be considered in such the cases where the database includes a large number of compounds that have diverse structural properties. This method may be used alongside 3D-QSAR in order to assess the drug – transporter interactions, and also to give certain suggestions on the direction of synthesizing new chemical compounds to inhibit the studied efflux pumps. The pharmacophore models can be derived from either the binding site of the protein or a group of active compounds (Guner, 2000; Mannhold, Kubinyi, Folkers, Langer, & Hoffmann, 2006).

Recently, many researchers are working on the efflux pump namely NorA of *S. aureus*. However, no X-ray crystal structures have been found until now. Hence, physiological, pharmacological and medicinal chemistry studies on NorA pump have contributed to our understanding of the structure and mechanism of drug resistance. Further *in silico* as well as *in vitro* studies and X-ray crystal structures of certain efflux pumps like NorA have remained attractive targets to scientist working in intelligent designs of new novel NorA inhibitors as well as other EPIs.

CONCLUDING REMARKS

This review provides a summary of current knowledge about efflux-pump-mediated multidrug resistance and QSAR studies on bacterial EPIs. QSAR modeling results provide useful information for structural modifications of existing compounds in order to gain more potent compounds in use. The major benefits derived from developing efficient EPIs will be the ability to reuse various antibiotics affected by the efflux pumps as well as the control of the emergence and the dissemination of MDR efflux strains. Until now, the majority of the known inhibitors have been obtained from screening libraries of synthetic compounds, from purification of natural compounds or chemical modification of existing molecules.

As far as Gram-positive bacteria are concerned, most of the QSAR studies on bacterial MDR are dedicated to NorA in *S.aureus*. Obtained QSAR analyses, coupled with molecular docking studies, proved that hydrophobicity and hydrogen bondings are essential for NorA inhibitory activity. For Gram-negative bacterial EPIs, there has been a modest number of QSAR studies conducted. With the advent of high-resolution crystal structures of efflux pumps of *Escherichia coli* and *Pseudomonas aeruginosa*, it is hoped that consequent increase in the population of identified molecules with high EPI capacity would foster ligand-based approaches in this area. For general QSAR studies on bacterial EPIs, 2D-QSAR using partial least squares method and molecular field parameters were largely employed. Therefore, it is suggested that 3D-QSAR and machine learning methods should be taken into consideration when generating future

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

QSAR models. Also, additional X-ray structures of proteins will definitely aid in the understanding of the molecular principles underlying the ligand-protein binding mode of bacterial efflux pumps.

To date, none of bacterial EPIs have entered clinical trials yet, the active compounds found with EPI-potency should still be subjects of deeper examination, including their pharmacokinetic properties and toxicity, as they give a hope for their future therapeutic usage. Moreover, the development of combination therapy poses additional complexity due to the necessity of precision tailoring of the pharmacokinetics of both agents to achieve the desired pharmacodynamic effect.

KEY TERMS AND DEFINITIONS

Bacterial Efflux Pumps: Proteinaceous transporters located in the cytoplasmic membrane of bacteria. These transporters are responsible for moving a wide range of compounds including antibiotics out of bacterial cells, which can contribute to bacterial antibiotic resistance.

Docking Study: The method used for the simulation of optimal binding orientations of one molecule to its target protein thereby predicting the affinity and biological activity of small organic molecules. Docking may be applied in hit identification and lead optimization in the field of drug design.

Efflux Pump Inhibitors (EPIs): Compounds that can inhibit the efflux-mediated extrusion of antibiotics. The co-administrations of these compounds and antibiotics to restore antibiotic activity have been investigated, but none of the efflux inhibitors tested has been in clinical use until now.

Homology Modeling (Also Known as Comparative Modeling): The method used for construction of an atomic-resolution model of the target protein based on its amino acid sequence and an empirically determined 3D-structure of a template – the protein having the highest sequence identity with the target sequence. A homology model can be used for various purposes including molecular docking, protein-protein interaction prediction, homology model based ligand design, etc.

MultiDrug Resistance (MDR): A condition enabling pathogenic micro-organisms (including bacteria) to oppose the action of certain antibiotics, rendering the antibiotics ineffective.

Pharmacophore Hypothesis: A geometrical description of molecular features represents a binding mode of a ligand to a receptor site. Typical pharmacophore features include hydrophobic centers, aromatic rings, ionizable points, hydrogen bond donors and acceptors.

Protein Data Bank: A freely accessible source for 3D-structures of biological macromolecules such as proteins and nucleic acids. Most of these structures are determined by NMR spectroscopy and X-ray diffraction.

Protein X-Ray Crystallography: The method of characterizing the molecular structure and function of various biological molecules including proteins. In principle, when X-rays strikes a protein crystal, they are scattered into many specific directions. The patterns and relative intensities of these diffracted X-ray beams can be processed to provide information about protein structure.

ABSTRACT

In this chapter, the methodology of building up quantitative structure—property/activity relationships (QSPRs/QSARs)—by means of the CORAL software is described. The Monte Carlo method is the basis of this approach. Simplified Molecular Input-Line Entry System (SMILES) is used as the representation of the molecular structure. The conversion of SMILES into the molecular graph is available for QSPR/QSAR analysis using the CORAL software. The model for an endpoint is a mathematical function of

the correlation weights for various features of the molecular structure. Hybrid models that are based on features extracted from both SMILES and a graph also can be built up by the CORAL software. The conceptually new ideas collected and revealed through the CORAL software are: (1) any QSPR/QSAR model is a random event; and (2) optimal descriptor can be a translator of eclectic information into an endpoint prediction.

INTRODUCTION

Almost seventy years ago one of the areas of theoretical chemistry named the quantitative structure – property / activity relationships (QSPRs/QSARs) was established (Wiener, 1947, pp. 17-20; Wiener, 1948, pp. 425-430). However, if one considers the publication of Hammett's Free-energy relationship (Hammett, 1935, pp. 125–136) as the first exercise in the QSPR/QSAR analyses, then the introduction of this area of theoretical chemistry should be moved back by eighty years. This is obviously an evidence of the long lasting importance of the QSAR approaches. Such significance is due to their wide applications. The main target of QSPR/QSAR analyses is the prediction of the numerical data related to various endpoints (physicochemical in the case of QSPR; and biochemical, ecological, medicinal, etc., in the case of QSAR).

One can consider three periods of evolution in this field.

1. The first period can be defined as the construction of molecular descriptors and establishing of their correlation with various endpoints (Bonchev & Trinajstic, 1977; Balaban, 1982, pp. 399-404; Bonchev, 1995, pp. 137- 156; Diudea & Gutman, 1998; Ivanciuc, Ivanciuc, & Balaban, 1998; Randic, DeAlba, & Harris, 1998; Castro, Tueros, & Toropov, 2000; Randic & Basak, 2001; Nicolic, Kovacevic, Milicevic, & Trinajstic, 2003; Ren, 2003, pp. 29-39; González, Terán, Teijeira, & González-Moa, 2005; Melagraki, Afantitis, Sarimveis, Igglessi-Markopouloua, & Supuran, 2006).
2. The second period can be defined as the construction of molecular descriptors, establishing of their correlation with an endpoint for the compounds of "visible" training set with the further testing of the predictive potential of this correlation with "invisible" compounds (i.e. compounds which are not involved in building up of the model) involved in the test set (Cronin et al., 2002; Golbraikh & Tropsha, 2002; Taskinen & Yliruusi, 2003; Hemmateenejad, 2004, pp. 475–485; Duchowicz, Castro, Fernandez, & Gonzalez, 2005; Oberg, 2005, pp. 2189–2200; Afantitis et al., 2006; Coi et al., 2006; Leonard & Roy, 2006; Pan, Jiang, & Wang, 2007; Roy & Roy, 2008; Porto, Souza, Junkes, Yunes, & Heinzen, 2008; Toropova, Toropov, Benfenati, Leszczynska, & Leszczynski, 2010; Toropov et al., 2012a; Toropov, Toropova, Raska Jr, Benfenati, & Gini, 2012b; Nesmerak, Toropov, Toropova, & Kohoutova, 2013; Papa, van derWal, Arnot, & Gramatica, 2014).
3. The third period can be defined as building up of the QSPR/QSAR models according to OECD principles (Kruhlak, Contrera, Daniel Benz, & Matthews, 2007; Kar & Roy, 2010, 2012; Putz, Ionascu, Putz, & Ostafe, 2011; de Melo, 2012, pp. 213–222; Sahigara et al., 2012; Toropova & Toropov, 2014).

According to the OECD principles, the QSPR/QSAR model should be characterized by:

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

1. A defined endpoint;
2. An unambiguous algorithm;
3. A defined domain of applicability;
4. Clear measures of predictive potential; and
5. A mechanistic interpretation, if possible (OECD, 2007).

It was during the second period of the methodology development, when optimal descriptors calculated with the molecular graph were suggested as a tool to solve the QSPR/QSAR tasks (Randic & Basak, 1999, 2001; Randic & Pompe, 2001; Toropov & Toropova, 2002; da Silva Junkes, Arruda, Yunes, Porto, & Heinzen, 2005). In fact, majority of molecular descriptors are not expected to correlate with a certain endpoint, but they can be involved in building up model for arbitrary endpoint. However, the optimal descriptor is aimed to correlate with a certain endpoint via a one-variable correlation.

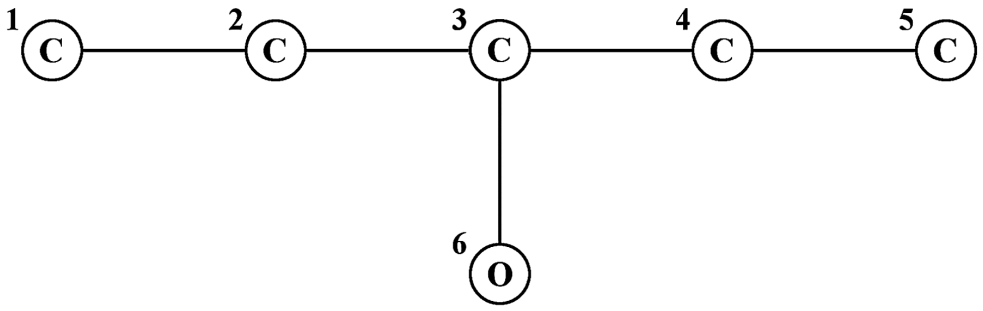
Interestingly, simplified molecular input-line entry system (SMILES) is an attractive alternative for representation of the molecular structure by graph (Weininger, 1988, pp. 31-36; Weininger, 1990, pp. 237-243; Weininger,Weininger, & Weininger, 1989). There are databases available on the Internet where the molecular structure is represented by SMILES (Toropov, Toropova, Raska Jr, Leszczynska, & Leszczynski, 2014). Under such circumstances, the development of QSPR/QSAR approaches, where SMILES is the representation of the molecular structure becomes an attractive direction of research work in the field of the QSPR/QSAR theory and applications. The CORAL software is a tool of the QSPR/QSAR analyses with representation of the molecular structure by SMILES (Toropova, Toropov, Benfenati, Leszczynska, & Leszczynski, 2010d; Toropova et al., 2011a,b). It is to be noted that the CORAL software is able to extract from the SMILES various graph theoretical invariants such as vertex degree and extended connectivity of higher orders (Toropov & Toropova, 2002), as well as invariants for the graph of atomic orbitals (Toropov & Toropova, 2001).

The description of:

1. The organization of the CORAL software,
2. Results obtained using this software,
3. Advantages and disadvantages of the approach, as well as
4. Discussion of possible modifications of this software are the main aims of the chapter.

Background

The basic paradigm of the QSPR/QSAR prediction can be expressed as the following:



Endpoint = F(Molecular Structure).

The classic mathematical representation of the molecular structure can be done by means of the adjacency matrix A(G) (Gutman, 1988, pp. 93-94; Gutman, 1997, pp. 281-287). The hydrogen-suppressed graph (HSG) for 3-pentanol (CAS 584-02-1) can be represented as seen in Figure 1.

The hydrogen-suppressed graph is characterized by the following adjacency matrix A(HSG):

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 1. The hydrogen-suppressed graph for 3-pentanol (CAS 584-02-1)

A(HSG)

	1	2	3	4	5	6	δ_k
1	0	1	0	0	0	0	1
2	1	0	1	0	0	0	2
3	0	1	0	1	0	1	3
4	0	0	1	0	1	0	2
5	0	0	0	1	0	0	1
6	0	0	1	0	0	0	1

A*(HSG)

	1	2	3	4	5	6	δ_k^*
1	x	1	0	0	0	0	$1+x$
2	1	x	1	0	0	0	$2+x$
3	0	1	x	1	0	1	$3+x$
4	0	0	1	x	1	0	$2+x$
5	0	0	0	1	x	0	$1+x$
6	0	0	1	0	0	y	$1+y$

Majority of the molecular descriptors are a mathematical function of the A(HSG), in particular the Randic index (Randic, 1975) is calculated as

$$^1X = \sum_{(i,j)edge}(\delta_i\delta_j)^{-0.5}. \tag{1}$$

The pioneer version of the optimal descriptor (Randic & Basak, 1999; Randic, 2001) is represented by the calculation of classic descriptors using the modified adjacency matrix A*(HSG):

$$^1X^* = \sum_{(i,j)edge}(\delta_i^*\delta_j^*)^{-0.5}. \tag{2}$$

The next step in the evolution of the optimal descriptors is the application instead of numerical contributions of vertex degrees (δ_k) the so-called correlation weight of the presence of a certain vertex degree, together with the correlation weight of a certain chemical element (A_k):

$$^0X_{CW} = \sum_k CW(A_k) + \sum_k CW(\delta_k). \tag{3}$$

The correlation weights are calculated by the Monte Carlo method. The numerical data on the correlation weights being used for calculation of the $^0X_{CW}$ should provide maximum of correlation coefficient

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

between the descriptor and a certain endpoint for the training set of compounds. Having the numerical data one can calculate the ${}^{0}X_{CW}$ for compounds of the training set and define the model:

$$Endpoint = C_0 + C_1 \times {}^{0}X_{CW} \tag{4}$$

However, the predictive potential of the model calculated with Equation 4 should be checked up with external test set.

The representation of the molecular structure in databases by adjacency matrix is not convenient and non economical, in comparison to the representation by SMILES string. Consequently, one can define the descriptor similar to the above-mentioned ${}^{0}X_{CW}$ which can be calculated with SMILES:

$$DCW = F(SMILES) \tag{5}$$

The simplest way is to define the descriptor as a mathematical function of SMILES atoms, i.e. as a mathematical function of each character of SMILES, except situations where two symbols cannot be examined separately (e.g. 'Cl', 'Br', etc.). In the case of 3-pentanol with SMILES= "CCC(O)CC", the scheme can be illustrated as the following:

$$\begin{aligned} DCW = {} & CW('C') + CW('C') + CW('C') + CW('(') \\ & + CW('O') + CW(')') + CW('C') + CW('C') = \Sigma CW(SA_k) \end{aligned} \tag{6}$$

The scheme expressed by Equation 6, can be useful for relatively simple physicochemical properties, such as the normal boiling point of a certain class of organic compounds (alkanes, alkylbenzenes, ethers, etc.). However, in the case of mixture of various classes of organic compounds, or in the case of more complex endpoints (toxicity, carcinogenicity, etc.), the scheme gives poor statistics for both the "visible" training set and for the "invisible" test set. Fortunately, the approach can be improved if in addition to correlation weights of SMILES atoms, combinations of two and / or three SMILES-atoms would be involved in the model.

However, in the cases of two or three SMILES atoms some paradoxical situations occur. For example, SMILES fragment "CN" and "NC" (similarly, "CCN" and "NCC") will be examined as different molecular features. Fortunately, one can avoid these cases if usees normalized combines of SMILES atoms. A simple way is to select order which obey principle: the first and last characters are placed according to their ASCII codes (Toropov, Toropova, & Benfenati, 2010b). In addition, SMILES attributes which are fragments of molecular structure, the global invariants of the molecular structure are involved to build up a model. These global attributes are a mathematical function of presence (absence) of various molecular features which are represented in Table 1.

The above-mentioned Monte Carlo optimization in the case of the unlimited number of epochs will provide maximum of correlation coefficient for the training set. However (Figure 2), a maximum of correlation coefficient between optimal descriptor and endpoint for a certain number of the epochs exists for the external test set. This amount of epochs is preferable in calculations, because when the number of epochs reaches such a value the obtained model is characterized by a good predictive potential.

Vice versa, the increase of threshold is accompanied by decrease of the correlation coefficient for the training set, but again, the threshold which provide maximum correlation coefficient for the test set

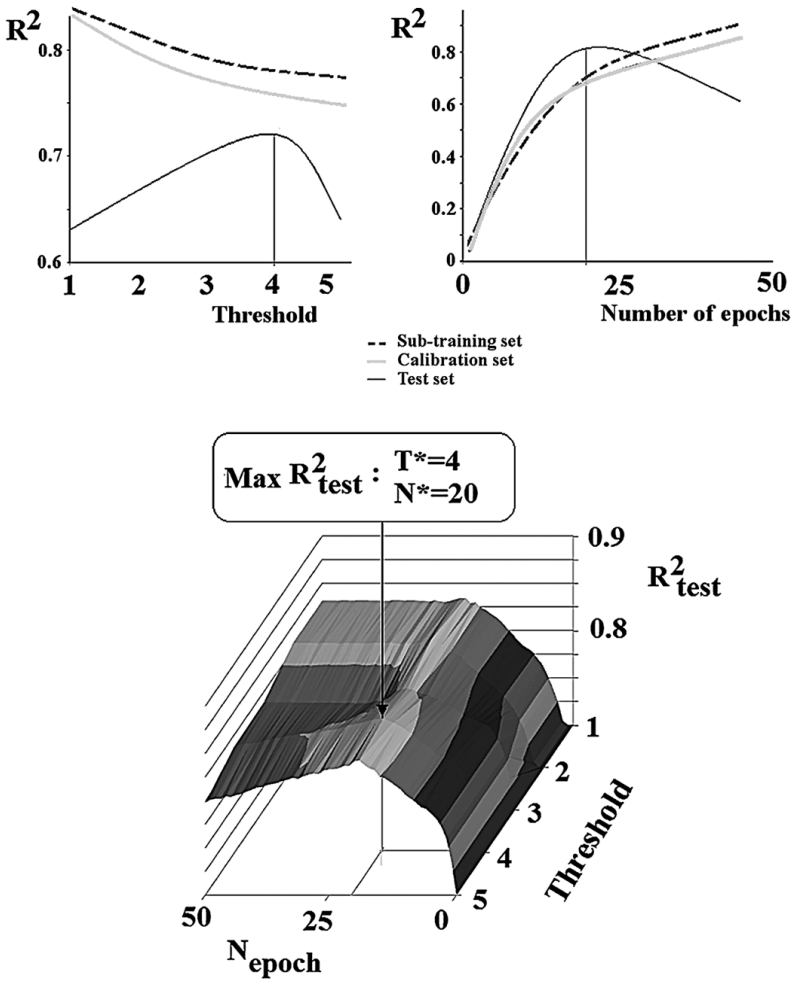
Table 1. The scheme of extraction of SMILES atoms and other SMILES attributes in order to build up a model

SMILES Attribute	Example of the Representation for the CORAL Software
S_k	SMILES-atoms, i.e. one symbol or two symbols which cannot be examined separately, e.g. 'C' and 'Cl': this information is represented by sequences of twelve symbols: C.......... Cl.........
SS_k	A combination of two SMILES-atoms 'CC' and 'CN': this information is represented by sequences of twelve symbols: C...C..... C...N.....
SSS_k	A combination of three SMILES-atoms 'CNC' and 'C#N': this information is represented by sequences of twelve symbols: C...N...C... C...#...N...
BOND	The presence / absence of double ('='), triple ('#'), and stereo chemical ('@') bonds, e.g. if SMILES = "CCC(O)CC" = # @ / 0 0 0 ⇨ BOND00000000
NOSP	Presence (absence) of nitrogen, oxygen, sulphur, and phosphorus, e.g. if SMILES="CCC(O)CC" N O S P / 0 1 0 0 ⇨ NOSP01000000
HALO	Presence (absence) of fluorine, chlorine, bromine, and iodine atoms, e.g. if SMILES='ClCC(=O)CCl F Cl Br / 0 1 0 ⇨ HALO01000000



continued on following page

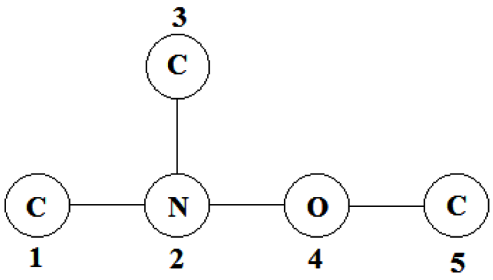
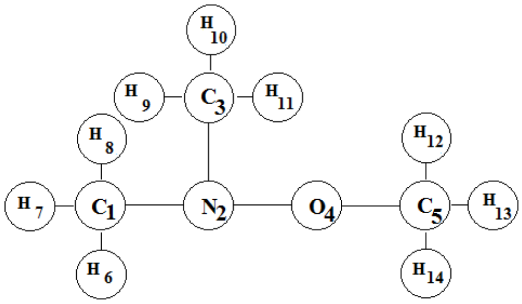
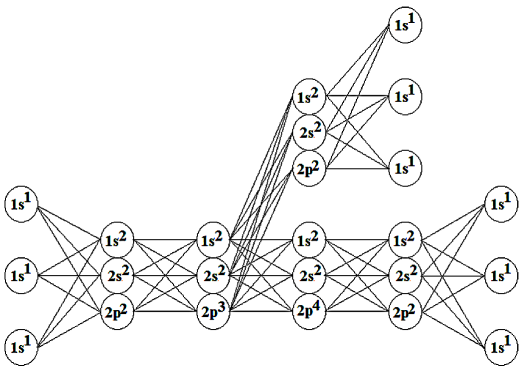
Table 1. Continued

SMILES Attribute	Example of the Representation for the CORAL Software
PAIR	Simultaneous presence of two SMILES-atoms from the list: F, Cl, Br, I, N, O, S, P, #, =, and @; e.g. if SMILES="ClCC(=O)CCl" the following pairs will be extracted: `++++Cl..O...` i.e. 'Cl' and 'O' `++++Cl..B2..` i.e. 'Cl' and '=' `++++O...B2..` i.e. 'O' and '='

Figure 2. The generalized scheme of selection of preferable threshold and the number of epochs of the Monte Carlo optimization







EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

exists. This threshold is preferable from practical point of view. Consequently, in order to prepare a good model by means of the CORAL software, one should define preferable values of the threshold and the number of epochs of the Monte Carlo optimization (T* and N*) (Toropova et al., 2011a).

Table 2 contains the list of possible representations of the molecular structure which can be used to build up a model. Thus, the CORAL software is able to provide the following types of QSPR/QSAR models:

Table 2. The representations of the molecular structure which can be used to build up a model by means of the CORAL software

The Representation of the Molecular Structure	Graphical Interpretation
SMILES	CN(C)OC
Hydrogen-Suppressed Graph, HSG	
Hydrogen-Filled Graph, HFG	
Graph of Atomic Orbitals, GAO	

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

1. **SMILES Based Models:**

$$^{SMILES}DCW(Threshold, N_{epoch}) = \alpha\sum CW(S_k) + \beta\sum CW(SS_k) \\ +\gamma\sum CW(SSS_k) + x \cdot CW(NOSP) + y \cdot CW(HALO) + z \cdot CW(BOND) + t \cdot CW(PAIR) \quad (7)$$

2. **Models Based on the Representation by Molecular Graphs:** These are HSG, or HFG, or GAO (Table 2).

$$^{Graph}DCW(Threshold, N_{epoch}) = \sum CW(A_k) \\ +\alpha\sum CW(^0EC_k) + \beta\sum CW(^1EC_k) + \gamma\sum CW(^2EC_k) + \delta\sum CW(^3EC_k) \quad (8)$$

In Equations 7 and 8, coefficients α, β, γ, δ, t, x,y, and z can be 1 (yes) or 0 (no). Various combines of their values give possibility to define certain version of the optimal descriptor;

3. **The Hybrid Models which Involves Molecular Feature Extracted from Both Smiles and Graph:**

$$^{Hybrid}DCW(Threshold, N_{epoch}) = {}^{SMILES}DCW(Threshold, N_{epoch}) + {}^{Graph}DCW(Threshold, N_{epoch}) \quad (9)$$

4. Last but not least: the CORAL software is able to provide models for phenomena where eclectic information is the only basis for prediction, e.g. property and activity of proteins (Toropov, Toropova, Raska Jr, Benfenati, & Gini, 2012b) as well as endpoint related to nanomaterials (Toropova & Toropov, 2013). The generalized form of the optimal descriptor which can be used for the above-mentioned situations is the following:

$$DCW(Threshold, N_{Epoch}) = \Sigma CW(CI_k) \quad (10)$$

where CI_k represent codes of available eclectic data (e.g. concentration, size, condition of synthesis, technological details, etc.).

Selected Technical Details Related to the CORAL Software

There are some limitations of the SMILES in CORAL software. The maximal length for SMILES is 500 symbols; the maximal number of atoms (or atomic orbitals in the case of the graph of atomic orbitals) is equal to 300; the maximal number of compounds (which are involved in building up model) is equal to 50,000.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Development of a Model by Means of the CORAL Software Is Based on the Following Principles

1. Molecular structure of each compound can be represented by molecular features which are extracted from SMILES and/or from molecular graph;
2. There are local and global molecular features which can be extracted from SMILES. The local features represent some fragments (or individual atoms). The global features are some indexes which characterized molecules as whole.
3. Building up of QSPR/QSAR model for an arbitrary split into the training and validation sets can be examined as a random event.
4. The statistical quality of each QSPR/QSAR model is a mathematical function that represents split of the data into the "visible" training set and "invisible" test set.
5. The average statistical quality of QSPR/QSAR models that is obtained for several splits into training and test sets is more robust criterion for the estimation of an approach than the statistical quality for solely one split.
6. The average statistical quality of a model for external "invisible" validation sets is more significant information related to the quality of the model than the average statistical quality for "visible" (i.e. substances involved in building up model) sub-training and calibration sets.

Every model that includes geometry-dependent molecular descriptors usually involves a relatively expensive calculation of the optimum molecular geometry, involving high computational costs and long CPU time. In this context, the conformation-independent 0D, 1D and 2D-QSPR methods emerge as an alternative approach for developing models based on constitutional and topological molecular features of compounds (Duchowich, Comelli, Ortiz, & Castro, 2012; Talevi et al., 2012). The exclusion of 3D-structural aspects also avoids problems associated with ambiguities, resulting from an incorrect geometry optimization output due to the existence of compounds in various conformational states. Such kind of problems may also lead to the vanishing of predictive capability of the QSPR/QSAR when applied for the prediction of an external test set of compounds. In the realms of the CORAL approach, the calculated flexible descriptor is a molecular descriptor which depends both on the molecular structure and the property under analysis, but does not explicitly depend on details from the 3D-molecular geometry. In previous QSPR/QSAR studies the importance of this methodology has been shown. Such approach is able to provide models having a comparable or sometimes better quality than the ones found by searching the best descriptors in a pool containing thousands of 0D-3D descriptors (Mullen, Duchowicz, & Castro, 2011; Garcia et al., 2011; Ibezim, Duchowicz, Ortiz, & Castro, 2012).

THE COLLECTION OF QSPR/QSAR MODELS

Over the years the CORAL software has been used for QSPR/QSAR analyses of a group of various endpoints. The results are listed in the following sections.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Water Solubility of Organic Compounds

Data on water solubility of 1311 substances, i.e. their CAS number, SMILES, and the values of negative logarithm of water solubility –log S (mol / L) were taken from the web site of Virtual Computational Chemistry Laboratory (http://www.vcclab.org/lab/alogps/). These substances were distributed by means of five random splits into the sub-training set (≈55%), calibration set (≈25%), and test set (≈20%). The statistical quality of the CORAL models (Table 3) is better than the statistical quality of the models suggested earlier in the literature for the same large database (Huuskonen, 2000, pp. 773-777; Tetko, Tanchuk, Kasheva, & Villa, 2001; Yan & Gasteiger, 2003). The best prediction is characterized by n_{test}=21, r^2_{test}=0.91, s_{test}=0.63 (Huuskonen, 2000, pp. 773-777).

Solubility of [C60] and [C70] Fullerene Derivatives

The numerical data on the solubility of [C60] and [C70] fullerene derivatives in chlorobenzene in mg/mL were taken from the literature (Troshin et al., 2009). Unfortunately, since at present, the QSPR analysis of these data by other methods is not available we are not able to compare the obtained results with various approaches.

Octanol/Water Partition Coefficient of Antineoplastic Drugs

The numerical data on octanol/water partition coefficient (logP) for 55 organic compounds have been taken from the literature (Wishart at al., 2008). The CORAL model (Table 3) is better than the model described in the literature (Fouchécourt, Béliveau, & Krishnan, 2001) for the same data (n=55, r^2=0.8180).

Half-Wave Potential

The half-wave oxidation/reduction potential is very useful characteristic of electronic properties of the chemical compounds. The first SMILES-based QSPR analysis of half-wave potentials was performed for 40 benzoxazines (Toropov, Nesmerak, Raska Jr., Waisser, & Palat, 2006). The statistical quality this approach (r^2 = 0.882) is fully comparable with classical approach based on Hammett constants (r^2 = 0.897; Nesmerak, Nemec, Sticha, Waisser, & Palat, 2005). Other example of SMILES-based QSPR of half-wave potential using CORAL software is analysis of experimental data for 23 derivatives of *N*-benzylsalicylthioamides. From the statistical point of view, the model is comparable with data obtained in the experiment (Nesmerak, Toropov, Toropova, Kohoutova, & Waisser, 2013).

Rate Constants of Reactions between Organic Aromatic Pollutants and Hydroxyl Radical

The degradability of 78 compounds expressed in terms of second-order degradation rate constants, K_{OH}, between $OH^{\cdot}$- and each targeted aromatic compound have been taken from the literature (Kušić, Rasulev, Leszczynska, Leszczynski, & Koprivanac, 2009). Decimal logarithm of the K_{OH} was evaluated as the endpoint for the QSPR models. The model from the above-mentioned work (Kušić, Rasulev, Leszczynska,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Leszczynski, & Koprivanac, 2009) is characterized by r^2_{test}=0.760. Hence the statistics of the CORAL model (Table 3) are better, because for four random splits into the training and test sets for the CORAL models (Toropov et al., 2012a) the average r^2_{test}=0.8253.

Chromatographic Retention Data

The retention factors of 41 derivatives of 1-phenyl-5-benzylsulfanyltetrazole in reverse-phase HPLC were measured for various compositions of mobile-phase. The retention characteristics of the linear solvent strength model were calculated using the linear relationship between logarithm of retention factor and volume fraction of organic modifier in mobile phase. The logarithms of the solute retention factor extrapolated to a mobile phase composition with 0% organic modifier, and constants for a given solute in a given chromatographic system (i.e. the slopes of the linear regressions) were used as endpoints. The one-variable QSPRs developed show that the CORAL software is a tool for building up a robust quantitative structure-retention relationships (QSRR) model for retention characteristics (Nesmerak, Toropov, & Toropova, 2014).

Toxicity towards *Daphnia magna*

The descriptions of toxicity of organic chemicals related to 48 h *Daphnia magna* toxicity expressed in negative decimal logarithm of the dose that kills 50% of organisms i.e. pLC50 were taken from the literature (Kar & Roy, 2010). The data set covers range of octanol/water partition coefficient from −2 to 8. According the values, it could be more possibly logarithms of octanol/water partition coefficient. The range of toxicity (daphnia) is from 0.46 to 10.09. In regard to the chemical domain, the data set includes hydrocarbons, aliphatic alcohols, phenols, ethers, and esters; anilines, amines, nitriles, nitroaromatics, amides, and carbamates; urea and thiourea derivatives; iso-thiocyanates; thiols; phosphorothionate and phosphate esters; and halogenated derivatives. The statistical quality of the model described in the original article is the following: n=222, r^2=0.695 (training set), and n=75, r^2_{pred}=0.741, R_m^2 =0.707 (test set). Thus, the statistical quality of the Coral model (Table 3) is at least comparable with the model suggested in the above-mentioned work (Kar & Roy, 2010).

Toxicity in Rats

Rat toxicity data (LD50, in mg/kg, oral exposure, n=689) was taken from the U.S. Library of Medicine (http://toxnet.nlm.nih.gov/). The $\log_{10}$[1/LD50] has been used as endpoint. Unfortunately, information on QSAR analysis of these data by other approaches is not available. However, comparison of optimal descriptors and Multiple Linear Regression (MLR) has shown (Toropov, Rasulev, & Leszczynski, 2008) that the models for rat toxicity based on optimal descriptors calculated with SMILES have better statistical characteristics than one-, two-, three-, and four-variable MLR models based on the topological and quantum mechanical descriptors.

Toxicity of Binary Mixtures

The numerical data on the toxicity of binary mixtures was taken from the literature (Zhang, Zhou, Yang, & Wang, 2007). The toxicity is expressed as pEC50 (i.e. negative decimal logarithm log[1/EC50]),

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

logarithm of the inverse of the effective concentration required to bring about a 50% decrease in light emission, for *Photobacterium phosphoreum* (T3 mutation). The statistical quality of four-variables model (calculated with involvement of the quantum mechanical descriptors) suggested in the literature (Zhang, Zhou, Yang, & Wang, 2007) for the toxicity of the same 50 binary mixtures is the following: n=50, r^2=0.85, s=0.270. Consequently, the CORAL model for this endpoint provides better results (Table 3).

Carcinogenicity

Experimental values for carcinogenicity were taken from the web site of United States Environmental Protection Agency (http://www.epa.gov/ncct/dsstox/sdf_cpdbas.html). Carcinogenicity is expressed as the potency dose that induces cancer in rats (TD50, in mg/kg body weight). These values have been converted into mmol/kg body weight. The log(TD50) was selected as endpoint for modeling. The correlation coefficient of the QSAR for carcinogenicity of 45 benzene derivatives amounts to about r^2 = 0.7 (Vracko, 1997, pp.1037–1043). Another QSAR model for rodent carcinogenicity nitroso compounds obtained by multiple linear regression analysis (Helguera, Cordeiro, Pérez, Combes, & González, 2008) has the following statistical characteristics: n=48, r^2 = 0.859, s=0.361, F=42 (training set) and n=6, Q^2 = 0.71, s=0.488 (test set). The CORAL model for carcinogencity (Table 3) should be consider as comparable with the above-mentioned models, since the number of examined compounds for the CORAL model is considerable larger.

Carcinogenicity of Drugs

Numerical data on carcinogenic potentials of the selected 1464 organic compounds (chemical domain which includes hydrocarbons, aliphatic alcohols, phenols, ethers, and esters; anilines, amines, nitriles, nitroaromatics, amides, and carbamates; urea and thiourea derivatives, isothiocyanates, thiols, phosphate esters, and halogenated derivatives) are expressed by DF (Discriminate Function). The range of DF is from -9.91 to 9.86. Positive value of DF is an indicator of carcinogenic compound, negative value of DF is an indicator of non-carcinogenic compound. The predictive potentials of QSAR models for the same series of compounds suggested in the literature are characterized by n_{test}= 732, r^2_{test}=0.713 (Kar & Roy, 2011); and n_{test}= 732, r^2_{test}=0.77 (Duchowicz, Comelli, Ortiz, & Castro, 2012). Thus the statistical quality of the CORAL model is better than those available in the literature (Table 3).

Anticancer Agents (Murine P388 Leukemia)

The decimal logarithm log(1/IC50), where IC50 represents the concentration of the agent necessary to reduce cell viability by 50% against Murine P388 Leukemia (in vitro cytotoxic activity) is considered as the endpoint. Numerical data on this endpoint was taken from the literature (Atanasova, Ilieva, & Galabov, 2007). The QSAR model suggested in the published work (Atanasova et al., 2007) is characterized by n_{test} = 25; r^2_{test}=0.700. Thus, predictive potential of the CORAL model for the anticancer activity is better that the previously published results.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Anticancer Agents (SK-MEL-5 Cell Line and UACC-62 Cell Line)

The observed cell anti-proliferative activities of the triphenylmethyl containing compounds inducing death in the human melanoma cell lines SK-MEL-5 and UACC-62 are extracted from the literature (Palchaudhuri, Nesterenko, & Hergenrother, 2008; Palchaudhuri & Hergenrother, 2008). The models calculated with MLR approch (Mullen, Duchowicz, & Castro, 2011) are characterized by n_{train}=17, r^2_{train}=0.781, s_{train}=0.16, n_{test}=6, r^2_{test}=0.243, s_{test}=0.44 (SK-MEL-5); and n_{train}=19, r^2_{train}=0.859, s_{train}=0.17, n_{test}=4, r^2_{test}=0.722, s_{test}=0.30 (UACC-62). It can be compared to the results obtained using CORAL approach, included in the Table 3.

Anti-Malaria Agents (Aryl-Piperazine Derivatives)

The experimental inhibitory concentrations (IC50) in micromolar units of aryl-piperazine derivatives against the chloquine resistant strains W2 and FCR3 and against the chloroquine-sensitive strains D10 and NF54 are extracted from the literature (Molyneaux, Krugliak, Ginsburg, & Chibale, 2005). The QSAR calculated with optimal descriptors gave possibility to suggest some perspective molecular structures of anti-malaria agents.

Anti-Malaria Agents (4(1-H)-Quinolone Derivatives)

A series of 53 endochin analogs (4(1-H)-quinolone derivatives) with anti-malarial activity against the clinically relevant multidrug resistant malarial strain TM-90-C2B has been taken from the literature (Ojha & Roy, 2011). The statistical characteristics of the model suggested in the published work (Ojha & Roy, 2011) are the following: n_{train} = 39, r^2_{train}= 0.797, s_{train} = 0.517; n_{test} = 14, r^2_{test}= 0.808. Thus, the statistical quality of the CORAL model is comparable with the above-mentioned model (Ojha & Roy, 2011).

Anti-HIV-1

The binding affinity values of fullerene derivatives pEC50 were taken from the literature (Durdagi, Mavromoustakos, & Papadopoulos, 2008). The QSAR analysis of these data has shown that even for the case of small set of data, the Monte Carlo technique gives reproducible results. In spite of relative lower statistical quality of the CORAL model for the endpoint, this model provides satisfactory prediction for a several splits of the data into the training and test sets. Thus, the optimal descriptors should be considered as reasonable alternative for the 3D QSAR analysis.

High-Affinity 5-HT1A Receptors

A dataset of 88 arylpiperazines considered as high affinity 5-HT1A receptor ligands, to which the in vitro affinity values (as measured by inhibition constants, Ki) were collected from the literature (Martinez-Esparza et al., 2001a,b) was analyzed. The CORAL software is able to be an efficient tool to build up a robust model for affinity of 5-HT1A receptor ligands of arylpiperazines. The suggested modeling process for affinity of 5-HT1A receptor ligands is based on the representation of the molecular structure by SMILES and on the application of experimental data. The predictive potential of the applied approach

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

was tested with four random splits of the data into the training and test sets. In addition, the SMILES attributes, which are promoters of increase/decrease ligand binding affinity to 5- HT1A receptor, were identified. The mechanistic interpretation of these models from probabilistic point of view was suggested.

Calcium Channel-Antagonistic Effect

A dataset of 72 1,4-dihydropyridine derivatives with values for pIC50 was taken from the literature (Gecen, Saripinar, Yanmaz, & Şahin, 2012). Almost identical statistical quality of the QSAR models has been obtained for four different random splits of data. The mechanistic interpretation of these models in terms of promoter increase / decrease of the endpoint was suggested.

Anticonvulsant Agents

The experimental information on the antiepileptic activities ED50 of the molecular structures was obtained from the literature (Eddington et al., 2002, 2003; Edafiogho, Ananthalakshmi, & Kombian, 2006; Cox, Gao, Raje, Scott, & Eddington, 2001a; Cox, Scott, Gao, Raje, & Eddington, 2001b; Vamecq, Lambert, Poupaert, Masereel, & Stables, 1998). The MLR analysis gives preferable accuracy of the two ED50 models (Garro Martinez, Duchowicz, Estrada, Zamarbide, & Castro, 2011) r^2_{test}=0.856 and r^2_{test}=0.948. For this case the CORAL model provides worse results (Table 3).

Anesthetic Activity of Alkaloids

The duration of anesthesia (related to protein binding of a drug) and the onset time (determined by the pK_a) are important characteristics in assessment of local anesthetic agents. In the study (Turabekova et al., 2014) we utilized toxicity, duration, and onset of action as endpoints to construct QSAR models for the series of 34 diterpenoid alkaloids characterized by local anesthetic activity using GA-MLRA/PLS and SMILES-based optimal descriptors approach (CORAL). SMILES-based optimal descriptor approach application resulted in models of relatively improved both statistical fit of toxicity and duration of anesthesia models (r^2≈85% and r^2≈95%, respectively) and predicting ability (≈72%) for all three endpoints. This approach appeared to be more sensitive to structural peculiarities of molecules than regression methods that have to be taken into account in potential data splitting.

Membrane Damage TiO_2 Nanoparticles

Large databases related to physicochemical and biological activity of nanomaterials remain scarce. Under such circumstances, the possible way to build up a predictive model is an analysis of eclectic available data on various phenomena related to nanomaterials. As a result of exchange of classic paradigm Endpoint = F (molecular structure) by paradigm Endpoint = F(eclectic information), an analogy of classic QSPR/QSAR approach applied to nanomaterials can be obtained (Toropova & Toropov, 2013). The data obtained using this approach are provided in the Table 3.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

SOLUTIONS AND RECOMMENDATIONS

The variety of QSPR/QSAR models developed with the CORAL software indicates that this approach can be an efficient tool of the QSPR/QSAR analyses. However, it is to be noted, there are problems related to utilization of the CORAL software.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Problem 1: The involvement of combinations of two and three SMILES atoms in building up a model can lead to appearance of SMILES attributes (Table 1) with unclear physical meaning, e.g.:
\...1.....
=...2.....
=...1...(...
[.../.....
[...=.....

Problem 2: The approach is able to detect three-atom fragments as basis for the mechanistic interpretation. In reality, an active fragment can involve larger number of atoms.

Problem 3: If all SMILES contain certain, an indeed active fragment, this fragment cannot be recognized by the CORAL software as an active one.

Problem 4: If an active fragment is rare, the fragment cannot be recognized by CORAL software as an active one.

However, a preliminary analysis and classification (filtration) of dataset can help to solve these problems, at least partially.

FUTURE RESEARCH DIRECTIONS

The recently published works have shown, that the CORAL software can be a tool of QSPR/QSAR analyses for other endpoints in addition to results listed in Table 3 (Singh and Gupta, 2014; Achary, 2014, pp. 73-90; Worachartcheewan, Nantasenamat, Isarankura-Na-Ayudhya, &Prachayasittikul, 2014).

QSAR Prediction Reporting Format (QPRF) (version 1.1, May 2008) available on the Internet http://ihcp.jrc.ec.europa.eu/our_labs/predictive_toxicology/qsar_tools/qrf/QPRF_version_1%201_DEREK_SS.pdf is multi-component system. Most likely, the system can be useful and attractive for the case of standardized situations. However, in order to be widely applied as a research tool, it is preferable to use OECD principles together with the following probabilistic rules:

1. A QSPR/QSAR model should be represented for a group of splits of data into the "visible" training set (compounds involved in the modeling process) and the "invisible" test set (compounds which are not involved in the modeling process);
2. The splits should be random and different (they should be far from identity). The Monte Carlo technique in general, and the CORAL software in particular, can be basis for the QSAR Prediction Reporting Format, at least for the first steps of the QSPR/QSAR analyses of ecologic, pharmacologic and other systems of endpoints which are characterized by high complexity and wide prevalence.

CONCLUSION

The CORAL software can be considered as an universal tool for the QSPR/QSAR analysis. As all software packages the CORAL has certain advantages and disadvantages. The software provides the following options:

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

1. QSPR/QSAR analysis for data represented in format described at http://www.insilico.eu/coral;
2. The analyses should be carried out using a number of various data splits;
3. The software can be involved in build up models for phenomena characterized by eclectic information. Thus, the most important advantages of the approach are:
   a. The possibility of analysis of a QSPR/QSAR as a random event (not unique action); and
   b. The possibility of the translation of eclectic information into endpoint prediction.

KEY TERMS AND DEFINITIONS

Correlation Weight: A coefficient which should be added to optimal descriptor if a given SMILES attribute or graph invariant takes place in the given SMILES or in the given molecular graph.

Global SMILES Attribute: A characteristic of molecules in whole, e.g. the presence of nitrogen together with oxygen, presence of double bonds and cycles, the presence of nitrogen and sulphur and absence of oxygen, and others (Table 1).

Graph of Atomic Orbitals (GAO): Molecular graph where vertexes are the representation of atomic orbitals (e.g. 1s2, 2p3, 3d7, etc.).

Hydrogen-Filled Graph (HFG): Molecular graph where presence of hydrogen atoms is taken into account.

Hydrogen-Suppressed Graph (HSG): Molecular graph where presence of hydrogen atoms is ignored.

Local SMILES Attribute: Fragment of SMILES line which contains one ('C', 'N', '=', etc.) or two symbols ('Cl', 'Br', '@@', etc.) which cannot be examined separately.

Monte Carlo Optimization: The calculation of the numerical data on the correlation weights which give maximal value of the correlationn coefficient between an endpoint and the optimal descriptor.

Optimal Descriptor: A descriptor which is calculated for a substances with simplified molecular input-line entry system (SMILES) or with molecular graph using correlation weights for SMILES attributes or for graph invariant (vertex degree, valence shells, etc.).

ABSTRACT

Chagas disease is one of the most important neglected tropical diseases. Endemic in Latin America, the disease is a global public health problem, affecting several countries in North America, Europe, Asia and Oceania. The disease affects around 8-10 million people worldwide and the limited treatments available present low efficacy and severe side effects, highlighting the urgent need for new therapeutic options. In this work, the authors developed QSAR models for a series of fenarimol derivatives exhibiting anti-T. cruzi activity. The models were constructed using the Hologram QSAR (HQSAR), Comparative Molecular Field Analysis (CoMFA) and Comparative Molecular Similarity Indices Analysis (CoMSIA) methods. The QSAR models presented substantial predictive ability for a series of test set compounds (HQSAR, r2pred = 0.66; CoMFA, r2pred = 0.82; and CoMSIA, r2pred = 0.76), and were valuable to identify key structural features related to the observed trypanocidal activity. The results reported herein are useful for the design of novel derivatives having improved antichagasic properties.

INTRODUCTION

Neglected tropical diseases (NTDs) represent a group of 18 serious conditions prevalent in low-income countries with tropical and subtropical climate (Feasey, Wansbrough-Jones, Mabey, & Solomon, 2010), according to the World Health Organization (WHO). Chagas disease, one of the most important NTDs, is

a chronic infection caused by the protozoan parasite *Trypanosoma cruzi* and affects around 8-10 million people, predominantly in Latin American countries such as Brazil, Argentina and Mexico (Viotti et al., 2014). As a result of the international population migration, the disease has reached new boundaries, primarily in North America, Europe, Asia and Oceania, thus becoming an increasing worldwide concern (Hotez et al., 2012). Chagas disease is transmitted to humans while the parasites are eliminated with the feces of triatomine hematophagous bugs during their blood meal (Rassi Jr, Rassi, & de Rezende, 2012).

The limited therapy for the disease is based only on two old drugs – benznidazole (Rochagan®, Roche) and nifurtimox (Lampit®, Bayer) (Figure 1) – which possess low efficacy and severe side effects (Castro, Montalto deMecca, & Bartel, 2006). This exceptionally unfavorable scenario supports the urgent need for the development of novel, safe and effective drugs for Chagas disease (Clayton, 2010).

The repositioning of drugs targeted to different conditions has been one of the most important strategies in NTDs, including Chagas disease (Chatelain & Ioset, 2011). Compounds possessing well-established pharmacodynamics, pharmacokinetics and toxicity profile are attractive alternatives, especially in a field that is not a priority in pharmaceutical research and development (R&D). Eflornithine, for instance, which was initially developed as an anticancer therapy, is used in human African trypanosomiasis (Brun, Blum, Chappuis, & Burri, 2010). Another example is the use of antimycotic agents, such as ketoconazole and fluconazole, in the treatment of leishmaniasis (Sundar & Chakravarty, 2013). Drug repositioning provides an excellent trade-off between risk and reward over traditional R&D strategies, and various studies on the subject have been carried out in Chagas disease drug discovery (Planer et al., 2014).

Antifungals have been investigated as trypanocidal agents since the 1980s, when the *in vitro* inhibitory activity of miconazole and econazole against *T. cruzi* was first determined (Maertens, 2004; Docampo et al., 1981). The strong interest in this class of compounds resulted in the recent approval of the fungicides posaconazole and the prodrug of ravuconazole (E1224) to undergo clinical trials for Chagas disease (de Figueiredo Diniz et al., 2013). These results have stimulated valuable repositioning studies approaching the trypanocidal activity of antifungal agents used as agrochemicals (Nosten et al., 2006). Since the approval of a given compound for use as an agrochemical requires evaluation of its toxicity profile, such molecules are a useful source for repositioning studies in the field of NTDs (Witschel, Rottmann, Kaiser, & Brun, 2012). Among these investigations, the fungicide fenarimol, broadly used as an agrochemical, was identified as a pyrimidine derivative with potent *in vitro* activity against *T. cruzi* (IC_{50} = 350 nM) (Figure 2) (Keenan et al., 2012). Recent studies have demonstrated that fenarimol analogs act by inhibiting the *T. cruzi* 14-α-sterol demethylase (CYP51), a key enzyme in the sterol biosynthesis pathway of the parasite (Keenan et al., 2013).

Fenarimol

In this work, we have developed two- and three-dimensional quantitative structure-activity relationships (2D- and 3D-QSAR) for a series of highly potent fenarimol analogs, using the Hologram QSAR (HQSAR) (Seel, Turner, & Willett, 1999), Comparative Molecular Field Analysis (CoMFA) (Cramer, Patterson, & Bunce, 1988), and Comparative Molecular Similarity Indices Analysis (CoMSIA) (Klebe, Abraham, & Mietzner, 1994) methods. These chemometric tools collect and interpret complex data from series of bioactive molecules to construct computational models that correlate chemical properties with biological activity (Vaidya, Sourabh Jain, Shweta Jain, A. Jain, & Agrawal, 2014). Through this approach, molecular features responsible for the antitrypanosomal activity of the investigated compounds were identified using the HQSAR contribution maps, and the CoMFA and CoMSIA contour plots. Furthermore, the statistical consistency of the developed models was evaluated on the basis of their correlation ability for the training set, as well as their predictive power for an external test set.

METHODOLOGY

Several QSAR methods, such as neural networks, are available for the analysis of nonlinear data (Devillers, Doucet, Doucet-Panaye, Decourtye, & Aupinel, 2012). These techniques are very useful to analyze heterogeneous compound series, and compensate for discontinuities and anomalies in the modelled data; however, such methodologies generally require large data sets to produce stable and reliable models (Eriksson et al., 2003). Given the limited number of compounds and the high degree of similarity and homogeinity of the investigated compounds, generation and analysis of linear QSAR models were carried out as previously described, using the molecular modeling platform SYBYL-X 2.0 (Tripos, St. Louis, EUA) (Ferreira & Andricopulo, 2013; Moda & Andricopulo, 2012; Guido et al., 2008). The three-dimensional structures of the data set compounds were generated by applying the default geometric and atomic parameters of SYBYL-X 2.0. Tripos force field and Powell conjugate gradient algorithm were applied to minimize (in vacuum) the 3D conformation of each compound (minimum energy change of 0.005 kcal/molÅ) (Powell, 1977; Clark, Cramer, & Van Opdenbosch, 1989). A distance-dependent dielectric function and a dielectric constant of 80 were applied to generate the Gasteiger-Hückel charges (Tsai et al. 2010). A number of methods for generating conformers have been reported in the literature

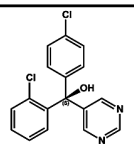
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

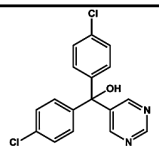
and it is a well-known fact this is a critical aspect in the computation of molecular descriptors, which can lead to large divergences in QSAR results (Hechinger, Leonhard, & Marquardt, 2012). Given the low conformational flexibility of the investigated data set, which consists of compounds composed mainly by three aromatic rings, only the minimum energy conformers generated by the molecular mechanics-based Tripos force field were used to derive the reported QSAR models.

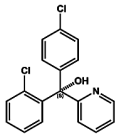
Data Set

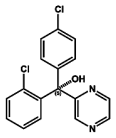
The data set used to develop the QSAR models was retrieved from the literature and consists of 77 compounds inspired in the structure of the fungicide fenarimol (Table 1) (Keenan et al., 2012). The biological activity of this series was measured under the same experimental conditions and expressed as the concentration of compound required to inhibit 50% of the *in vitro* reproduction of *T. cruzi* (IC_{50}). The IC_{50} values, which vary between 1 nM and 27 μM, were transformed into - log IC_{50} (pIC_{50}), an appropriate scale for QSAR modeling purposes. This data set was select because it encloses a suitable structural diversity, along with accurate and well-distributed biological data. Besides their highly potent trypanocidal activity, these fenarimol derivatives have additionally demonstrated favorable safety profile. A recent study published by Keenan et al. (2013) confirmed that this class of compounds exhibits *in vivo* efficacy profile similar to posaconazole, and superior to that of benznidazole, in experimental models of Chagas disease. As a result, the fenarimol analogs studied in this work consist of a highly attractive chemical diversity to be explored in the development of novel drug candidates for Chagas disease.

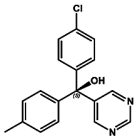
Principal Component Analysis and Selection of Training and Test Sets

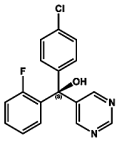


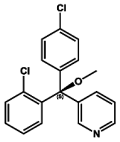


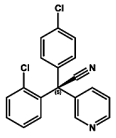


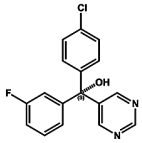


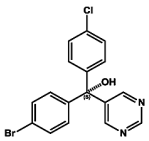


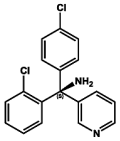


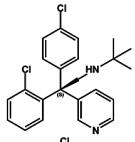


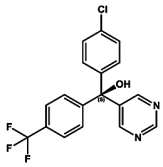


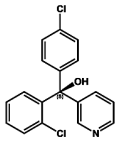


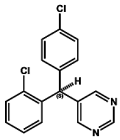


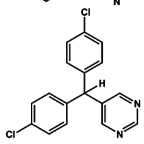


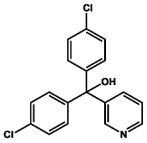


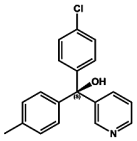


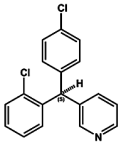


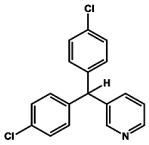


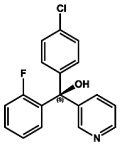


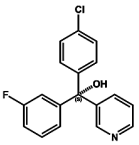


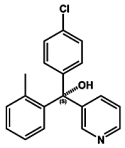


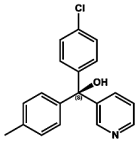


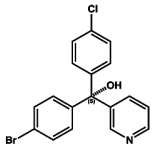


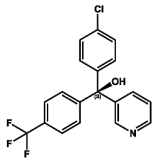


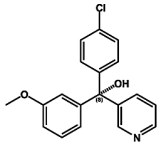


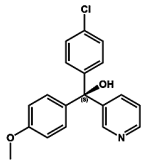


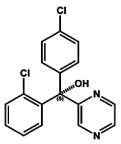


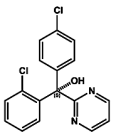


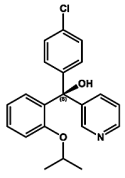


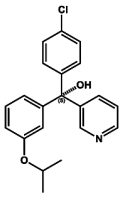












The selection of training and test sets is a critical procedure to generate reliable QSAR models (Leonard & Roy, 2006). Both sets should extend over a broad chemical and biological space across the entire data set. In this context, a principal component analysis (PCA) was performed to evaluate the structural similarity between the compounds and their distribution with respect to the biological data (Abdi & Williams, 2010). Digital fingerprints were generated for each compound using the UNITY module of SYBYL-X 2.0 and employed as molecular descriptors in the PCA (Hert et al., 2004). The output of the PCA was graphically represented as a structural similarity map, in which the distance between the points is inversely proportional to structural similarity. These points were plotted using Tanimoto similarity distances between the molecular fingerprints (Flower, 1998). In addition to the similarity analysis, a color code was employed to divide the biological data into five activity ranges. Figure 3 depicts the structural similarity map for the whole data set. Through a visual analysis of this diagram, the data set was divided into 60 training set molecules, which were employed to build the QSAR models, and 17 test set compounds used to evaluate the external predictive power of the models. The selection was carried out in such a manner as to include in both sets structurally distinct molecules covering the entire activity interval.

Structural Alignment

The structural alignment of the data set compounds in the Cartesian space is a key procedure to generate useful 3D QSAR models. Among the diverse approaches available for this purpose, the procedure adopted in this study was based on the maximum common substructure (MCS) method, as it is implemented in

the Distill Rigid module of SYBYL-X 2.0 (Patel & Ghate, 2015). First, the MCS between all compounds was identified using the default value of 5 as the minimum number of atoms enclosed in the MCS fragment. Then, the minimum energy conformation of each compound was flexibly overlaid upon the MCS. The dihedral angles of the most potent compound (molecule 61) were used as the template upon which the MCS of all the remaining compounds were superimposed. Figure 4 illustrates the complete data set aligned using the MCS approach. The searching method (i.e. the run mode) was restricted to single MCS

HQSAR Approach

The HQSAR method converts the two-dimensional structure of the data set molecules into a non-binary bit string called molecular hologram. Each structure is divided into all possible fragments, which are then allocated across the molecular hologram. A particular position in the bit string encodes information regarding the identity and occurrence of a given fragment (See, Turner, & Willett, 1999). The HQSAR models were generated employing the 12 default molecular hologram lengths: 53, 59, 61, 71, 83, 97, 151, 199, 257, 307, 353, and 401. The fragmentation procedure was carried out by applying several combinations of the available fragment distinction parameters: atoms (A); bonds (B); connections (C); hydrogen atoms (H); and hydrogen bond donor/acceptor (DA). Using the best fragment distinction combination, several models were further developed by varying the fragment size: 3-7, 3-9, 4-7, 4-8, 4-9 and 4-10 atoms.

CoMFA Approach

CoMFA is a 3D QSAR method based on the assumption that intermolecular interactions determine important properties, such as biological activity (Cramer, Patterson, & Bunce, 1988). The molecular descriptors employed to explain the variance in the target property consist of electrostatic and steric interaction energies calculated between an aligned set of molecules and a probe atom. According to this rationale, electrostatic and steric molecular interactions are calculated using Coulomb and Lennard-Jones potentials, respectively. This approach was used to explore the relationships between these 3D molecular descriptors and the trypanocidal activity of the investigated data set. The compounds aligned as illustrated in Figure 4 were used in the CoMFA analyses. A 3D cubic lattice with a grid spacing of 2.0 Å was created to fully enclose all molecules with an extension of 4 Å in the *x*, *y* and *z* axis. Steric and electrostatic potentials were estimated at every grid intersection with the default Tripos force field and a sp^3 carbon positively charged (+1 net charge) as the probe atom. The CoMFA standard value of 30 kcal/mol was used as the cut-off for both electrostatic and steric interaction energy. Coulombic electrostatic energy was set to vary according to a distance-dependent dielectric function (*i.e*. the energy falls as $1/r^2$). Steric and electrostatic energy values were properly scaled employing the default CoMFA scaling method. The models were refined and the resolution of the CoMFA contour maps was improved using the region focusing approach. The focusing procedure and the generation of the contour maps were carried out by weighting the product between the standard deviations (StDev) and the partial least squares (PLS) coefficients (Coeff) of each lattice point (Bush & Nachbar Jr., 1993).

CoMSIA Approach

Besides considering electrostatic and steric potentials, CoMSIA additionally estimates hydrophobic interactions and hydrogen bonds. Also, the molecular descriptors used in CoMSIA are similarity indices computed on the lattice points. These descriptors are calculated by taking into account the distance between the probe atom and the aligned compounds. The dependence of the similarity indices on the distance between the probe and the molecules is described by a Gaussian function (Klebe, Abraham, & Mietzner, 1994). The compounds aligned as illustrated in Figure 4 were used in the CoMSIA analyses. A 3D cubic lattice was built using the same methodology employed in the CoMFA proceeding. The similarity indices were calculated using hydrophobic, hydrogen bond donor and acceptor molecular in-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

teraction fields. Similar to the CoMFA modeling, the region focusing procedure was applied to improve the resolution of the CoMSIA contour maps, using the StDev*Coeff weighting method. The steepness of the Gaussian function was defined by applying the default value of the attenuation factor (0.3).

Model Validation Procedures

The statistical robustness of the generated models was assessed by calculating the non-cross-validated (r^2) and full cross-validated (q^2) correlation coefficients (Hawkins, Basak, & Mills, 2003). First, each model was subjected to a leave-one-out cross-validation analysis (LOO) to determine the optimum number of components and the q^2 value. Next, a full partial least squares (PLS) regression was performed using the optimum number of components to determine the r^2 value. Then, the stability of the best models against more significant removals of data was estimated by the leave-many-out (LMO) cross-validation procedure (Tropsha, Gramatica, & Gombar, 2003). The liability of these PLS analyses to chance correlations was determined by the progressive scrambling Y-randomization test (Clark & Fox, 2004). All of these validation strategies were executed for the training set. Finally, as an external validation protocol, the trypanocidal activity of the test set compounds was predicted. This proceeding was able to demonstrate, through the calculation of predictive r^2 values (r^2_{pred}), the power of the constructed QSAR models to estimate the activity of novel structurally related compounds.

RESULTS

HQSAR Results

HQSAR models were developed using the default hologram lengths. Initially, four models were generated employing the following combinations of fragment distinction parameters: A/B/C, A/C/DA, A/B/C/H e A/B/C/H/DA; and the default fragment size of 4-7 atoms (Table 2). The LOO validation procedure was used to determine the q^2 value and the number of components of each model. The models with the best number of components were subjected to a full PLS analysis to produce the r^2 values.

As can be observed, the best model was produced using A/B/C/H as the fragment distinction combination (q^2 = 0.60; r^2 = 0.81; and SEE = 0.37). Since fragment size interferes with the hologram

Table 2. HQSAR statistical results generated with LOO cross-validation and full non-cross-validated PLS analysis (fragment size 4-7 atoms)

Model	Fragment Distinction		Statistical Parameters				
		q^2	r^2	SEE	SEP	HL	N

generation, and therefore with the results, variation of this parameter was performed using the A/B/C/H fragment distinction. Table 3 shows the statistical indicators for the fragment sizes: 3–7, 3–9, 4–7, 4–8, 4–9 and 4–10.

The data shown in Table 3 demonstrate that the variation of fragment size was able to promote a subtle increase in r^2 and a decrease in SEE. With respect to the remaining indicators, similar results were obtained compared to the default value (fragment size of 4–7 atoms).

It is a well-known fact that internal validation procedures provide a satisfactory measure of the correlation ability of QSAR models. However, their predictive power can be assessed only by estimating the activity of compounds that were not employed in the generation of the models (Tropsha, 2010). This procedure, called external validation, employs the predictive correlation coefficient (r^2_{pred}) as the statistical indicator. Thus, the test set selected on the basis of the structural similarity map (Figure 3) was employed in the external validation process. Accordingly, the predictive strength of the models listed in Table 3 was estimated by the calculation of r^2_{pred} values. As observed, the model with fragment size of 4–10 (model 10) was the most robust in terms of predictive power for the test set compounds (r^2_{pred} = 0.66). The correlation between the experimental and predicted pIC_{50} values for this model is exhibited in Table 4 for the test set compounds, and graphically illustrated in Figure 5a for the entire data set.

Model 10 was additionally evaluated with respect to its stability against rigorous removals of data. With this purpose, the training set was randomly divided into five groups and the LMO cross-validation was applied. This process resulted in a LMO q^2 of 0.50, demonstrating the stability of model 10 when a larger number of compounds were removed for the activity prediction. This model was also evaluated for its vulnerability to produce chance correlations. The procedure was carried out using the progressive scrambling randomization method, which introduced small, random perturbations on the dependent property (pIC_{50}). After the scrambling procedure, a Q^2 of 0.36 and an effective slope (dq^2/dr^2_{yy}) of 1.01 were obtained, indicating the robustness of the original model in regard to inconsistent correlations.

HQSAR converts the chemometric analysis performed by the PLS routine into a graphical output that illustrates the contribution of each atom of a molecule to its biological activity. The method uses a color code, called contribution map, in which atoms that contribute positively are colored in yellow, green-blue and green, while those that contribute negatively are colored in red, red-orange and orange. Neutral contributions are represented as white fragments. Figure 6 depicts the contribution maps for compounds 28, 41, 45, and 53. Compound 28 is a potent chlorophenyl-pyridine (pIC_{50} = 7.77) for which the HQSAR

[a]Difference between experimental and predicted values.

contribution map highlights the three aromatic rings as favorable to the activity of the compound (Figure 6a). As can be observed, the 4-chlorophenyl and the pyridine rings are regarded as the most important fragments compared to the *p*-tolyl moiety, since they have a higher number of atoms colored in green and yellow. Compound 41 is a highly active trifluoromethyl derivative ($pIC_{50} = 8.10$) and likewise 28 has its 4-chlorophenyl and pyridine rings labelled as key fragments (Figure 6b). Otherwise, compound 45 ($pIC_{50} = 8.70$) holds a 3-fluorobenzonitrile rather than a 4-chlorophenyl moiety, a structural modification that led to a significant increase in the trypanocidal activity of this compound compared to the derivatives 28 and 41. This aspect is graphically represented through the HQSAR map in which the 3-fluorobenzonitrile is stressed as highly favorable (Figure 6c). Finally, compound 53 differs from 45 by lacking the fluorine and carrying an isopropyl as the substituent of one of the aromatic rings. Although this strategy was not able to improve the biological activity (since both compounds are equipotent), the isopropyl-benzene fragment contributes significantly to the activity of molecule 53 (Figure 6d).

CoMFA Results

Several CoMFA models were developed aimed to investigate the 3D properties determining the activity of the studied series of fenarimol derivatives. The internal consistency of the models was primarily evaluated using LOO cross-validation to provide the q^2 values and the best number of components. Next, the best models (*i.e.* those with the highest q^2) were subjected to complete PLS analyses to produce the r^2 values. Region focusing weighted by StDev*Coeff values of 0.3; 0.6; and 0.9 was applied to improve the resolution of the CoMFA contour maps.

The same test set used in the HQSAR analysis was employed in the external validation of the CoMFA models, which had their predictive power assessed by the calculation of r^2_{pred} values. Table 5 shows the statistical indicators of the CoMFA models generated by applying the region focusing technique. As can be observed, the model weighted by a StDev*Coeff value of 0.3 (model 11) demonstrated the best external predictive ability ($r^2_{pred} = 0.82$). The correlation between the experimental and predicted pIC_{50} values for model 11 is shown in Table 6 for the test set compounds, and graphically illustrated in Figure 5b for the entire data set.

LMO cross-validation was applied to model 11, resulting in a q^2 of 0.62 for five groups. The randomization test yielded a Q^2 of 0.50 and an effective slope of 0.96, indicating the stability of the model with respect to chance correlations.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

The structure-activity relationships identified in model 11 were translated into steric and electrostatic 3D contour maps. These graphs indicate regions encompassing the van der Waals surface where variations in steric and electrostatic properties are strongly correlated with changes in biological activity. Green spots indicate areas where the presence of bulky groups is favorable to activity, whereas yellow graphs identify regions where such groups correlate with decrease in biological activity. Blue and red contours define areas where increased positive charge and electron density, respectively, contributes to improve the target property.

Figure 7 depicts StDev*Coeff steric and electrostatic contour maps for the highly active derivatives 45, 52 and 53. Compound 45 is a potent trifluoromethyl derivative ($pIC_{50} = 8.70$), for which the steric map indicates that bulky groups such as the 3-fluorobenzonitrile and the trifluoromethyl-benzene are strongly correlated with its trypanocidal activity (Figure 7a). For molecule 52 ($pIC_{50} = 8.22$), the steric map correlates the biological activity with the *p*-trifluoromethyl substituent attached to one of the benzene rings, as well as the presence of the *N,N*-dimethylaniline moiety (Figure 7b). Figure 7c shows green spots surrounding the trifluoromethyl-benzene and the isopropyl-benzene fragments of compound 53 ($pIC_{50} = 8.70$), indicating the relevance of these substituted aromatic systems for its remarkably potent activity.

Figure 7 also shows the CoMFA electrostatic contour maps generated by the region focusing procedure. As indicated by the red contours, the electron density concentrated at the pyridine nitrogen and the hydroxyl oxygen is a major contribution to the activity of the highlighted derivatives. The partial negative charge at the trifluoromethyl fluorine atoms of compounds 45 and 53 is also labelled as a favorable property (Figures 7d and 7f). Similarly, the electron density centered at the *N,N*-dimethylaniline nitrogen of compound 52 is a key element to determine the high trypanocidal activity of this analog. Although the CoMFA electrostatic maps are affected mainly by electron-withdrawing groups (which is consistent with the structural pattern of the data set), a blue spot near the hydroxyl hydrogen stresses the value of a positive dipole in this region of the compounds.

*Figure 7. CoMFA StDev*Coeff steric (a, b, and c) and electrostatic (d, e, and f) contour maps for compounds 45, 52, and 53*

CoMSIA Results

CoMSIA models were developed based on the structural alignment illustrated in Figure 4 to investigate the relationships between the trypanocidal activity of the data set compounds and their hydrophobic and hydrogen bonding properties. The attenuation factor of the Gaussian function was maintained with the default value of 0.3 in all CoMSIA analyses. First, the q^2 values and the optimum number of components were determined by applying LOO cross-validation. Next, full PLS analyses were performed employing the best number of components. StDev*Coeff region focusing was applied to eliminate redundant descriptors, increase the weight of lattice points consistently correlated with the variation in the biological data, and refine the CoMSIA contour maps. The statistical indicators for these analyses are listed in Table 7.

The same test set used in the HQSAR and CoMFA analyses was employed in the external validation of the CoMSIA models. As observed in Table 7, the models weighted by a StDev*Coeff value of 0.6 and 0.9 exhibited the same external predictive power ($r^2_{pred} = 0.76$). Therefore the q^2 value was used as the criterion to select model 15 as the best CoMSIA model. The experimental and predicted pIC_{50} values for model 15 are shown in Table 8 for the test set, and plotted in Figure 5c for the whole data set.

As an additional validation procedure, model 15 was subjected to LMO cross-validation, which produced a q^2 of 0.62 for five randomly selected groups. The model was also evaluated using the randomization analysis, resulting in a Q^2 of 0.42 and an effective slope of 1.02.

The CoMSIA-PLS analyses were graphically interpreted through the examination of hydrophobic and hydrogen bond donor and acceptor contour maps. Figure 8 shows hydrophobic contour maps for two potent compounds. The fluorobenzonitrile derivative 46 ($pIC_{50} = 8.00$) has the chlorine atom of the chlorobenzene ring enclosed by a yellow spot, indicating the favorable character of a hydrophobic group at this position (Figure 8a). This finding also applies for the chlorofluorobenzene derivative 66 ($pIC_{50} = 8.30$). A yellow contour surrounds the thiophene ring of this compound (Figure 8b), illustrating that its trypanocidal activity is highly correlated with the presence of this hydrophobic group.

CoMSIA donor and acceptor contour maps are pictured in Figure 8 for the trifluoromethyl derivative 45. Spots colored in cyan and magenta indicate that hydrogen bond donors and acceptors, respectively, are favorable to biological activity. As displayed in Figure 8c, the cyan contour near the hydroxyl hydrogen highlights the favorable character of a hydrogen bond donor attached to the tetrahedral carbon that links the three aromatic rings. Figure 8d shows magenta spots surrounding the trifluoromethyl group, as well as the nitrile and pyridine nitrogen. In the case of the nitrile group, this finding corroborates the key role played by hydrogen bond acceptors as *para*-substituents of the phenyl ring. The CoMSIA acceptor maps also demonstrate the essential contribution of the pyridine ring for the biological activity of the investigated data set.

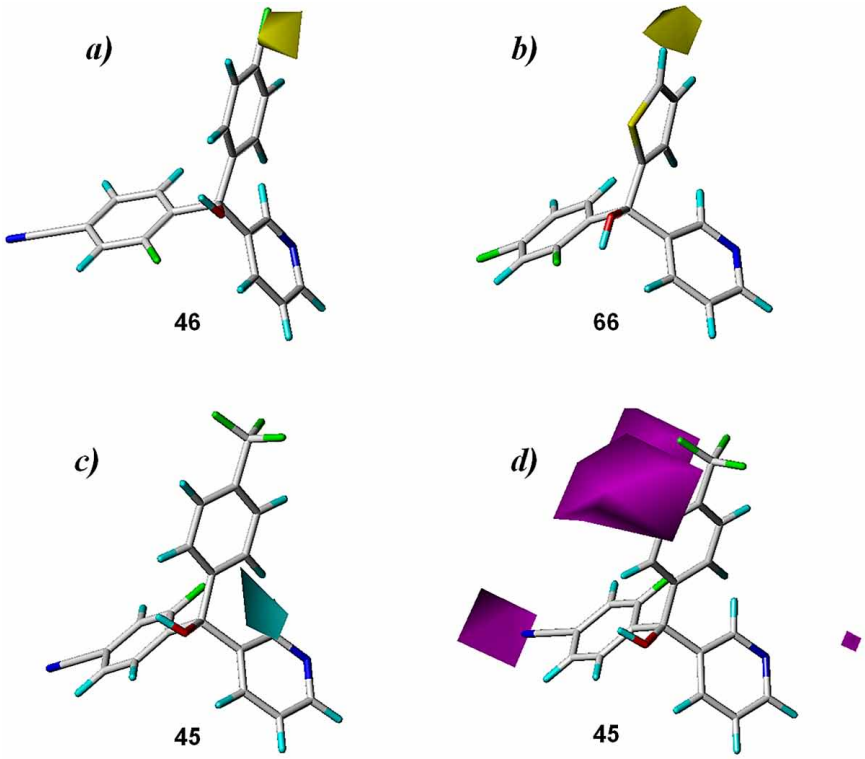
[a]Difference between experimental and predicted values.

Comparison between 2D and 3D Results and Design of Novel Fenarimol Derivatives

Aiming to provide a comparison amongst the final HQSAR, CoMFA and CoMSIA models, Table 9 lists the main statistical indicators for the best 2D and 3D models.

As observed, both 2D and 3D methodologies were able to produce statistically solid QSAR models. Good correlation ability was observed for the training set used to construct the models and high predictive power was achieved for the test set compounds. From the LMO and the randomization results it is possible to verify the stability of the models against rigorous removal of data and chance correlations.



From a chemical perspective a comparison of the models can be carried out by analyzing the HQSAR contribution maps and the 3D CoMFA and CoMSIA plots. As can be seen in Figure 6 the HQSAR maps highlighted the aromatic rings as the main positive contributions for the biological activity of the

Table 9. Statistical indices for the final HQSAR, CoMFA and CoMSIA models

Model	q^2 (LOO)	r^2	r^2_{pred}	q^2 (LMO)	Q^2	dq^2/dr^2_{yy}
HQSAR (model 10)	0.57	0.90	0.66	0.50	0.36	1.01
CoMFA (model 11)	0.71	0.99	0.82	0.62	0.50	0.96

fenarimol derivatives. The 4-chlorophenyl, the 3-fluorobenzonitrile and the pyridine rings were stressed as critical molecular fragments for conservation of the trypanocidal activity. Otherwise, the 3D maps identified important physical-chemical properties, which were analyzed in terms of the functional groups enclosed by such plots. As in the HQSAR analysis, the 3-fluorobenzonitrile, the 4-chlorophenyl and the pyridine rings were highlighted as important for activity; however, the 3D methods were able to detect a broader range of chemical functionalities, such as the mutual hydroxyl group linked to the tetrahedral carbon atom. As illustrated in Figures 7 and 8, the CoMFA and CoMSIA plots, differently from the HQSAR maps, concentrated mainly in the substituent groups rather than the aromatic rings. This could be explained by the structural pattern of the data set molecules, which is characterized by a conserved core of three aromatic rings substituted by a variety of functional groups.

All these findings may be used to design improved compounds. For example, the final 2D model showed that the three aromatic rings are essential for activity, therefore, this structural scaffold must be conserved in newly designed derivatives; however, replacement of the pyrimidine or pyridine with a similar system, such as an imidazole ring, could be explored as a molecular optimization strategy. As observed in the CoMFA and CoMSIA maps, introduction of steric bulk and electron-withdrawing moieties are recommended as substituents of the phenyl rings; this could be investigated by linking to these rings, bulky hydrogen-bond acceptor groups such as pyridine, pyrimidine, benzothiazole, 2-oxazolidinone and thiazole.

CONCLUSION

Predictive QSAR models were developed for a series of highly active compounds against the parasite *Trypanosoma cruzi*, the causative agent of Chagas disease. The HQSAR, CoMFA and CoMSIA models exhibited high internal and external consistency as demonstrated by the several validation methods employed to assess their statistical quality. The external validation using a test set demonstrated the ability of the models to estimate with proper accuracy the trypanocidal activity of novel compounds structurally related to fenarimol. Moreover, the final 2D and 3D models provided a detailed description of the molecular aspects underlying the biological activity of the targeted compounds. The HQSAR contribution maps along with the CoMFA and CoMSIA contour plots were able to identify molecular fragments, functional groups and physicochemical properties strongly correlated with the biological activity of this series. The highlighted features are valuable information to delimitate the chemical space to be explored in the design of novel compounds within the investigated structural diversity.

Chapter 38
The "ETA" Indices in QSAR/QSPR/QSTR Research

Kunal Roy
Jadavpur University, India

Rudra Narayan Das
Jadavpur University, India

ABSTRACT

Descriptors are one of the most essential components of predictive Quantitative Structure-Activity/Property/Toxicity Relationship (QSAR/QSPR/QSTR) modeling analysis, as they encode chemical information of molecules in the form of quantitative numbers, which are used to develop mathematical correlation models. The quality of a predictive model not only depends on good modeling statistics, but also on the extraction of chemical features. A significant amount of research since the beginning of QSAR analysis paradigm has led to the introduction of a large number of predictor variables or descriptors. The Extended Topochemical Atom (ETA) indices, developed by the authors' group, successfully address the aspects of molecular topology, electronic information, and different types of bonded interactions, and have been extensively employed for the modeling of different types of activity/property and toxicity endpoints. This chapter provides explicit information regarding the basis, algorithm, and applicability of the ETA indices for a predictive modeling paradigm.

INTRODUCTION

Chemicals are the inseparable components of human life, and thus they can affect a wide variety of industrial, agricultural as well as household processes if not monitored properly. Elucidation of the chemistry of compounds is an essential task of the designer so as to enable easy tuning of their properties. The diverse manifestation of chemicals can be systematically explored when the study of their chemistry is suitably attended with the related biology (including toxicology), mathematics and accompanying statistics. Since the past, mathematics has been considered as an effective media of natural science (Wigner, 1960) and has been employed in different branches of science to derive logical relationship employing abstract ideas. Chemistry has a very good coherence with mathematics that leads to the quantification

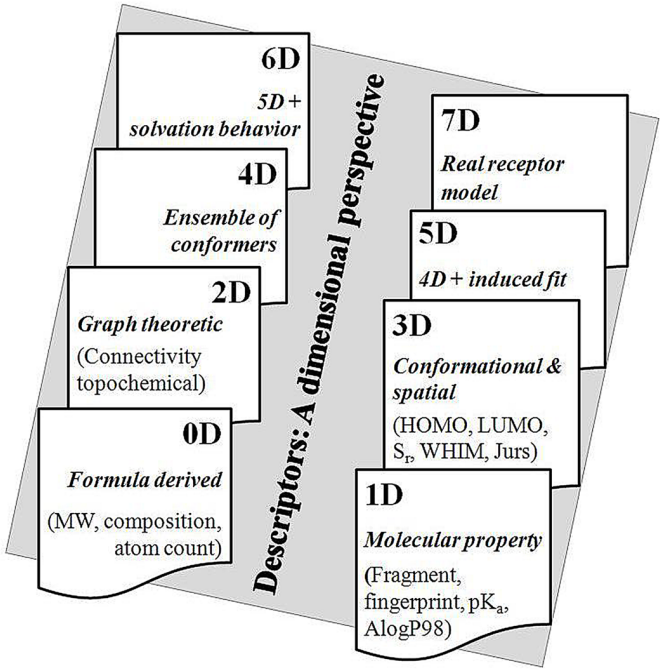
of chemical information by providing suitable platform for the generation of various algorithms. How different chemicals act differently and even the same chemical elicits different responses give the hint to nurture the 'chemistry' of compounds and explore the possible quantitative phenomena involved. The attempt to quantify the chemistry of compounds has lead to the development of several independent parameters termed as predictor variables or descriptors. These descriptors are further utilized to bring under a quantitative relationship with the responses of the chemicals commonly termed as the quantitative structure-activity/property/toxicity relationship (QSAR/QSPR/QSTR) studies. Mathematics plays a great role in deriving such predictor variables as well as in the development of correlations.

Through the journey of QSAR analysis, several predictor variables have evolved by exploring the concepts of chemistry, mathematics and physics. However, the 'graph theory' has contributed much to the development of initial ideas about descriptors. The graph theory, one of the branches in mathematics, can be traced back to Euler's Königsberg bridges problem (Euler, 1736) which led to the idea of solving problems in different fields of science namely the study of electrical circuit by Kirchhoff (Kirchhoff, 1847), chemical isomer enumeration by Cayley (Cayley, 1875) etc. In a true mathematical sense, the term 'graph' also denotes cartesian plot of data, although it was Sylvester (Sylvester, 1878) who coined the term from a contemporary chemical perspective. Application of the graph theory in chemistry leads to the concept of 'chemical graph' which was supposed to have its origin in the late eighteen century holding the hand of the Scottish chemist Cullen (Crosland, 1959). William Cullen introduced the application of 'affinity diagrams', although it remains controversial with similar type of contributions by Black (Crosland, 1959). Later Higgins (Higgins, 1789) employed the use of graphical diagrams to denote the forces between atoms in a molecule. It was Dalton (Dalton, 1808) in the nineteenth century who started the concept of ball-and-stick representation of chemical models. The idea of diagrammatic presentation of chemical compounds was very primitive during that age and through various notable discoveries the chemistry got explored gradually. The famous scientist Kekulé brought the idea of three-dimensional orientation (Fischer, 1974) and later idea of chemical valence came likewise. Considering the scope of this chapter, we would like to limit this discussion at this point.

It was in the twentieth century when the chemical graphs were explored properly, and utilizing the concepts of topological distance measures the scientific fraternity started developing theoretical variables to correlate activity of chemicals with their chemistry. Although the history of QSAR starts back in the past when Cross (Cross, 1863) reported his idea of possible correlation between chemical composition and toxicity of alcohols, the concept of theoretical descriptor did not come in action properly until the year 1947 when the Wiener index (Wiener, 1947) and the Platt number (Platt, 1947) were introduced as the first two graph theoretical descriptors for modeling boiling point of hydrocarbons. Following these milestone achievements in the realm of quantification of chemistry paradigm, a new wave was hit towards the exploration of graph theoretic parameters, and in the 1960s and 1970s the pathway was systematically imputed by the following pioneering contributions namely Simon's minimal topological difference (MTD) concept (Simon, 1974), Balaban J (Balaban, 1982), Gordon and Scantlebury index (Gordon & Scantlebury, 1964), Schultz molecular topological index (MTI) (Schultz, 1989), Hosoya Z (Hosoya, 1971), Randić's branching parameter (Randić, 1975), Kier and Hall's molecular connectivity, Kappa shape, sub-graph count, flexibility and electrotopological state (E-state) atom indices (Kier & Hall, 1986), Zagreb index by Trinajstić and co-workers (Gutman & Trinajstić, 1972), Harary index (Plavšić et al., 1993), Verloop's STERIMOL parameter (Verloop, 1987), etc. Graph theoretic descriptors are purely based on a two dimensional basis, whereas concepts of three dimension was also under parallel research and various predictor variables were also derived employing three dimensional basis.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

A torrential amount of research on the descriptors has led to the development of a wide variety of predictor variables till today. The present chapter gives an account of such a group of two-dimensional novel descriptors named extended topochemical atom (ETA) indices which have been developed in the twenty first century from the modification of another set of topologically arrived unique (TAU) scheme descriptors of the late eighties. The ETA indices are now available under two generations and have been used in various modeling studies to predict property, activity as well as toxicity endpoints.



Descriptors in QSAR Studies: The Impact and Required Quality

Scientific deductions are based on logical components that aids in deriving conclusion from an observation. The chemoinformatics study also bears such inevitable components that ultimately help in developing predictive mathematical models and also leave a plausible explanation for the reasons involved. The molecular descriptors in QSAR studies can be viewed as the quantitative presentation of chemical structures obtained by processing the molecule using a specified mathematical algorithm. Todeschini and Consonni (Todeschini & Consonni, 2000) have ascribed descriptors as the useful numbers or the standardized experimental results obtained as the final result of a logic and mathematical procedure that leads to the transformation of chemical information which is encoded within symbolic representation of molecules. So, the mathematics is here utilized to unwrap the chemical information of compounds in the form of numerical entities. Descriptors are the algorithmic mathematical entities that strongly adhere to the chemistry of compounds and thereby form a core to the QSAR analysis. Since, the attributes of chemical compounds are depicted using different levels and dimensions of theory of chemistry and physics, descriptors are also defined on the basis of such theory coupled with a definite algorithm of mathematics. A good number of descriptors are available now-a-days corresponding to different algorithms which can be conveniently categorized from the dimensional perspective. Figure 1 shows a representative dimensional classification of various descriptors for QSAR analysis.

Descriptors can be defined for a whole molecule or they may also refer to specific fragments of the molecule. Again from the basis of computation, descriptors can be theoretical or experimental. Experimental descriptors correspond to various derived physicochemical properties namely partition coefficient, molar refractivity, optical rotation, pK_a values, reaction rate, parachor etc. and they usually depict characteristics of the entire molecule while theoretical descriptors are usually computationally derived mathematical entities and can define specific molecular fragment as well as the whole molecule. An interesting fact about descriptors is that they evolved from lower to higher dimensions as the practice of QSAR made its progress and so the theory. Looking back at the history of QSAR, it can be observed that Cross (Cross, 1863) was the first who observed the toxicity of primary aliphatic alcohols to be possibly correlated with their water solubility. Crum-Brown and Fraser (Crum-Brown & Fraser, 1868) are inexorably believed to be first to report the physiological action as the mathematical function of chemical constituents during an investigation of muscle paralysis activity of strychnine derivatives. Richardson (Richardson, 1869) observed a proportional relationship of narcotic effect of primary alcohols with their molecular weight and almost after two decades Richet (Richet, 1893) found the cytotoxicity of ethers, alcohols and ketones to be inversely related with their aqueous solubility measure. Then Meyer (Meyer, 1899) and Overton (Overton, 1901) came with their decisive work by correlating narcotic potency with lipid/water partition coefficient. After that, at the beginning of the twentieth century Trabe (Trabe, 1904) and Seidell (Seidell, 1912) came with their correlation analysis employing surface tension and solubility and partition coefficient respectively. Then came the pioneering discovery by Ham-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 1. Dimensional perspective of descriptors used in predictive modeling (QSAR) analysis

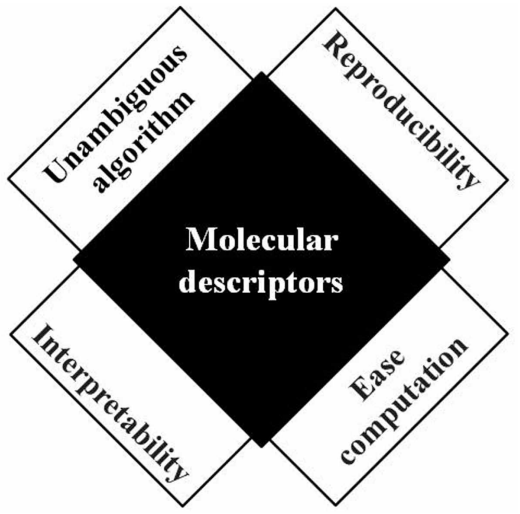
mett (Hammett, 1935) who initially showed relationship between reaction rates with acid dissociation constant values (pK_a) and the parameter σ (sigma) which afterwards led to a "sigma-rho" culture in the field of predictive modeling analysis. Some more notable research activities were performed during this time namely correlation of narcotic activity with partition coefficient and exploring thermodynamics of chemicals by Ferguson (Ferguson, 1939), study on the involvement of ionization and shape factors towards the bacteriostatic action of aminoacridines by Albert (Albert et al., 1941) and correlation studies on antibacterial action (*E. coli*) of sulfonamides with their ionization and shape parameters by Bell and Roblin (Bell & Roblin, 1942). In this journey, it may be observed that QSAR started with the concept of correlating toxicity of chemicals with aqueous solubility by Cross whereas the term 'chemical constituents' in Crum-Brown and Fraser's hypothesis can be connected to the elemental composition of the compounds. Richardson and Richet found toxicity to be expressible in terms of molecular weight and aqueous solubility respectively. Hence, we can see that at the dawn of QSAR, scientists used different physicochemical properties, *i.e.*, experimental descriptors as variables and at the same time the concept of zero dimensional parameter like elemental composition, molecular weight were also used. The practice of using physicochemical properties like partition coefficient, solubility etc. as descriptors was also done by other scientists namely Trabe and Seidell. The concept of extracting chemical information was getting boosted during this time and Hammett led to the discovery of a theoretical parameter σ (sigma) in connection with modeling reaction kinetics. The contributions by Albert et al. and Bell & Roblin are also notable since they were the first to focus on the ionization factor and shape factors as independent parameters to derive correlation. It was in 1947, Wiener (Wiener, 1947) and Platt (Platt, 1947) came up with some more light to the path with their first topologically derived graph theoretic descriptors namely Wiener index and Platt index respectively by developing QSPR models for the boiling points of

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

paraffin hydrocarbons. The inception of graph theoretic parameters as chemical descriptors opened a big doorway in the field of theoretical descriptors, and since then a significant amount of research has taken place towards the development of more informative parameters. The discovery of Hammett (Hammett, 1935) was forwarded by Taft who introduced a steric parameter E_s (Taft, 1952) that distinguishes polar, steric and resonating effect exerted by chemicals and reported the first multiple regression method based linear free energy relationship (LFER) equation. In the early 1960s, several newer developments were made in the field of 2D-descriptors. In 1962 Hansch (Hansch et al., 1962) introduced a substituent hydrophobicity parameter π and later in 1964 Hansch and Fujita (Hansch & Fujita, 1964) extended the analysis by combining parameters of Hammett and Taft and developed LFER models comprising of σ, E_s and π. The analysis by Fujita and Hansch has undergone further parabolic extension and later it was also modified by Kubinyi (Kubinyi, 1976). Another concept of presenting molecular descriptors as the contribution of the parent moiety and substituents was depicted by Free-Wilson (Free & Wilson, 1964) which gave rise to 'indicator variables'. The Free-Wilson analysis was later modified by Fujita-Ban (Fujita & Ban, 1971) by incorporating logarithmic terminology.

It is to be noted that from the bases of the two-dimensional chemistry, concepts of three- dimensional (3D) molecular structure representation, electronic information and the descriptors thereof were also in the developing stage starting in 1930s. Some of the notable contributions can be cited namely the chemical bonding theory by Pauling (Pauling, 1939) and Coulson (Coulson, 1939), Sanderson's (Sanderson, 1952) electronegativity parameters, electronic distribution theory by Fukui et al. (Fukui et al., 1954) and Mulliken (Mulliken, 1955), charged partial surface area measures of Jurs & Stanton (Stanton & Jurs, 1990), shadow indices (Rohrbaugh & Jurs, 1987), WHIM (Todeschini & Lasagni, 1994) & GETAWAY descriptors by Todeschini and co-workers (Consonni et al., 2002), 3D-MoRSE descriptors (Schuur et al., 1996), EEVA descriptors, CoMFA and CoMSIA analysis by Cramer et al. (Cramer et al., 1988) and the ligand-receptor based analyses including multidimensional (4D, 5D, 6D and so on) features in the modern century (Lill, 2007). However, considering the scope of this article we would like to focus our topic on two-dimensional topological structure representation only.

Hence it is observed that the molecular descriptors of chemical compounds are pivotal as they play a very crucial role in predictive modeling analysis. Through the journey of QSAR paradigm, the attempt to generate quantitative numbers using the chemistry of compounds has yielded various mathematical descriptors. Now, the obvious question arises regarding the required quality of such essential component of QSAR analysis. It is apparently true that quantitative predictor variables were introduced to establish mathematical relationships so that predictions can be made when changes (*e.g.*, new substituents) are incorporated into structures. Since a good amount of mathematics is involved in this aspect, care should be taken such that the descriptors do not become just random numbers for developing correlation equations, rather they should encode proper chemical information. The experimental properties which are used as descriptors usually do not suffer from such problem, since they are the true reflection of the physicochemical behavior of the chemicals. However, there is possibility of incomplete information in theoretically derived parameters if they are not judged properly. Proper care is required while dealing with the mathematics since it only acts as a tool to define the final index employing several algebraic and arithmetic operations while the diagnosis of chemical information entirely belongs to the part of chemistry. Hence, two required criteria of molecular descriptors can be identified namely predictive ability and interpretability. From practical examples, in many cases it has been observed that descriptors giving high correlation against an endpoint of interest suffer from the lack of chemical diagnosis potential and vice-versa. A proper balance between this two makes a descriptor important for the QSAR



EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

analysis. This feature has also been indicated in the definition of descriptors prescribed by Todeschini and Consonni (Todeschini & Consonni, 2000) mentioned earlier as the 'useful numbers' which states the descriptors having the insight of the molecular attributes as well as ability to take part in predictive modeling analysis.

Four of the basic features of chemical descriptors are shown in Figure 2. Here, the term 'easy computation' refers to simplicity and explicitness of the descriptor algorithm since many of the higher dimensional variants require complex pretreatment operations. The descriptor should also be easily reproducible irrespective of the computational environment employed. The predictive ability refers to the skill of the descriptor in giving good correlation with an endpoint under investigation while the interpretability focuses on the chemical attributes of the analyzed molecular structures. Once a proper basis of chemical or biological activity of the molecule is established, the tuning of its features becomes easier and technically more specific. Two- dimensional descriptors are usually simple, derived using hydrogen suppressed molecular graphs with a high degree of precision and consume less computational time than the higher order indices. In the beginning of the development of graph theoretic descriptors, much more emphasis was given on the establishment of quantitative correlation than the search for mechanistic basis. As a matter of fact, many of the formerly defined descriptors were found to be flawed when chemometric modeling studies started in a much larger scale.

This article presents a group of two-dimensional descriptors, extended topochemical atom (ETA) indices, which were developed addressing several flaws of the previously described parameters. The ETA indices comprise a few graph theoretic parameters as well as some electronic indices to describe the bonding pattern, unsaturation, electronegativity and hydrogen-bonding related information. Till date, the ETA indices have been used to model several endpoints employing different categories of chemical compounds ranging from simple alkanes to complex drug molecules and agrochemicals. An account of the definition of various ETA indices with an overview of their modeling status is presented in the next sections.

Figure 2. The required features of theoretically derived descriptors

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

THE ETA INDICES

Brief Background

The ETA indices use information from hydrogen suppressed graphical presentation of molecules where atoms are denoted by vertices while edges represent covalent bonds. The ETA formalism was derived as an extension of another group of graph theoretic descriptors called topochemically arrived unique (TAU) scheme indices. Before getting into details of the ETA indices, we would like to provide the readers with some basic information and the motivation of developing TAU scheme parameters.

The branching parameter by Milan Randić (Randić, 1975) gave the measure of ramification of branching in a graph theoretical topological problem. This idea was extended by Kier and Hall (Kier & Hall, 1986), who gave a more comprehensive description on the type of branching by incorporating the concepts of path, cluster and chain. The molecular connectivity index of Kier and Hall's was observed to produce good correlational results with some physico-chemical and biological endpoints. However, in the late eighties Pal et al. (1988, 1989, 1990) observed several limitations in Kier and Hall's parameters and argued that predictive feature of this group of descriptors is biased, especially when higher order indices are used. The following drawbacks of Kier and Hall molecular connectivity or chi (χ) indices were identified by Pal and co-workers.

1. Kier and Hall's molecular connectivity indices chiefly portray additive information with no consideration of constitutive aspects.
2. It bears a good correlation with some quantum mechanical indices and mass spectroscopic fragmentation pattern and thereby possesses a similar pattern like logPo/w.
3. The molecular connectivity index formalism does not include information for steric interaction, stereoisomerism, resonance and aromaticity.
4. The vertex valency term δ^v often shows redundancy and becomes inconsistent when atoms of different quantum levels are considered.
5. Unlike vertex valency, the relative weight of the edges is not properly distinguished which leads to the fact that only ${}^1\chi$ and ${}^1\chi^v$ have graph theoretical meaning. Furthermore, higher order indices, i.e., ${}^m\chi^v$ (m>1), were found to possess good correlation when ${}^1\chi^v$ showed similar result and reflect that ${}^m\chi^v$ is strongly correlated with ${}^1\chi^v$.
6. The sigma and pi bonds in a system are equally weighted in this scheme.
7. Suitable adjustment in the molecular structure of several compounds of varied structures which do not possess optimum biological response in the dataset can yield the ideal value of ${}^m\chi^v$ obtained from the regression equation.

With the aim of circumventing such undesirable shortcomings of molecular connectivity indices, Pal et al. (1988, 1989, 1990) proposed a new set of topological descriptors namely TAU indices emphasizing the nuclear and electronic features of the atoms. In the TAU formalism, the vertex in a connected molecular graph has been considered to be composed of a core and a valence electronic environment. The valence electronic environment has been further partitioned into a localized and a mobile electron measure. Table 1 shows the formal definitions of various TAU parameters. It should be noted that other than characterizing the core and the valence electronic environment (both local and mobile), parameters defining the branching and contribution of functional groups were also defined in the TAU scheme.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Several modeling studies were performed using TAU indices and reliable results were obtained. Later the same group of authors also attempted to develop models employing other descriptors along with TAU parameters so as to judge the relative contribution of TAU scheme indices in predictive modeling studies. Table 2 summarizes the various endpoints modeled employing TAU scheme parameters. It was shown by Pal et al. (1988, 1989, 1990) that isosteric groups or isovertices have similar θ or θ' values.

The Motivation for Developing ETA Indices

Nearly a decade after the development of TAU indices, Roy and Ghosh (2003) observed that even the TAU scheme has some drawbacks and there are opportunities of their further development into more appropriate descriptors. The present authors' group observed the following aspects of the TAU scheme to be inconsistent:

1. The core count 'λ' was observed to have a disproportionate incremental relationship with the atomic number of different vertices.
2. The VEM vertex count was not suitably distributed and a vertex forming sigma bond with another vertex of similar electronegativity and different electronegativity were given the same value.
3. Although it provides a weighting scheme for sigma and pi bonds, the TAU scheme does not differentiate the double bonds of different types *i.e.*, ordinary alkenes, ordinary alkynes, conjugated system, aromatic system, etc.
4. Furthermore, the TAU scheme considers the contribution of functional groups at the molecular level, which should rather be considered at the atomic level or fragmental basis.

These were the chief motivations to the present authors' group towards the development of a new group of predictor variables in order to achieve better diagnostic potential. In 2003, Roy and Ghosh presented a new formalism named ETA indices (Roy & Ghosh, 2003) comprising several molecular level as well as atomic level parameters. Then these indices were subjected to a thorough chemometric modeling employing different endpoints. Later in 2011, the present authors' group realized the need for some more parameters to encode the issues related to hydrogen bonding propensity of molecules, measure of polar surface area, unsaturation and electronegativity, and they came up with a second generation indices (Roy & Das, 2011). Figure 3 presents the basic features of the ETA indices from a perspective of their developmental stages.

The ETA Indices: Formalism

Presently the ETA indices comprise a set of two generation descriptors defining chemical features at the atomic as well as molecular level. Table 3 gives a generation-wise listing of the derived ETA indices. In the present article, we would present all the ETA parameters from the viewpoint of atomic and molecular basis.

Table 1. Definition of the descriptors under the topochemically arrived unique (TAU) scheme formalism

Sl. No.	Type	Mathematical Definition		Note (If Any)
Parameter for the Vertex Core				
1	Core count	$\text{Core count} = \lambda = \frac{Z - Z^v}{Z^v}$ where Z=atomic number, Z^v=number of valence electron, *i.e.*, number of positive charges not neutralized by core electrons.		λ shows a regular change with Pauling's electronegativity (ε^0) across the period and along the group in an opposite manner. $1/\lambda$ gives a rough measure of the strength of the positive field of the atomic core.
Parameters for the Localized and Mobile Valence Electron Environment				
		Valence Electron Local (VEL)	**Valence Electron Mobile (VEM)**	
2	Valence electron count	$\theta' = 2h + 1.5\nu + 2l$ h is the number of bonded H-atoms, ν is the number of sigma bonds other than with hydrogen and l is the lone pairs of electrons.	$\theta = \left(8 - \theta'\right) = 8 - (2h + 1.5\nu + 2l)$	θ' gives a count of the relatively localized valence electron that the positive field of the atomic core enjoys while θ represents the count of relatively mobile electrons enjoyed by the field of the core. The number '8' in the definition of VEM denotes the number of electrons in the valence octet of a bonded atom. It was assumed that an atom sigma bonded to another non-hydrogen atom shares 50% of the other electron through the sigma bond apart from its own electrons. For a covalently linked organic atom, $h + l + \pi + \nu = 4$, π being the number of pi-bonds. So, $\theta' = 8 - \left(0.5\nu + 2\pi\right)$ and $\theta = 0.5\nu + 2\pi$. Isosteric group or isovertices are characterized by similar θ or θ' values.
3	Vertex valency	$V_i' = \frac{\lambda_i}{\theta_i'}$	$V_i = \frac{\lambda_i}{\theta_i}$	
4	Edge weight	$E_{ij}' = E_{ji}' = \left(V_i' \times V_j'\right)^{\frac{1}{2}}$ when $i \neq j$ and i, j connected $= 0$ otherwise	$E_{ij} = E_{ji} = \left(V_i \times V_j\right)^{\frac{1}{2}}$ when $i \neq j$ and i, j connected $= 0$ otherwise	
5	Molecular index (1st order)	$T' = 0.5\sum E_{ij}'$	$T = 0.5\Sigma E_{ij}$	
6	Molecular index (Zero order)	${}^0T' = 0.5\sum V_i'$	${}^0T = 0.5\Sigma V_i$	
7	The composite index	$T = \sum_{i<j} E_{ij} = \sum_{i<j}\left(V_i \times V_j\right)^{0.5}$		
Parameter for Branching and Functional Group				
8	Functionality parameter	$F = T_R - T$ T_R being the first order VEM molecular index of the corresponding reference alkane.		A reference alkane of a molecule corresponds to a structure where all heteroatoms are replaced with carbon atom and multiple bond (covalent) with single bond. The branching parameter and the functionality parameter can be correlated as: $T = T_R - F = T_N - B - F$
9	Branching parameter	$B = T_N - T_R$ T_N being the first order VEM molecular index of the normal alkane.

Definition of the Atomic Level ETA Indices

The Core Count (α)

The ETA core count is formally defined as:

$$\alpha = \frac{Z - Z^v}{Z^v} \cdot \frac{1}{PN - 1}. \quad (1)$$

Here *PN* stands for period number, while Z and Z^v represent atomic number and valence electron number respectively. Hydrogen atom being considered as the reference, α for hydrogen is taken to be zero. It was observed that α values of different atoms in common organic compounds show a high correlation (R=0.946) (Roy & Ghosh, 2003) with uncorrected van der Waals volume (Moriguchi et al., 1976).

Hence, a summed value of the parameter, i.e., $\Sigma\alpha$ for all non-hydrogen atoms in a molecule gives a measure of molecular bulk. In order to incorporate relativeness to this parameter with respect to the number of vertices, another term $\Sigma\alpha/N_v$ is commonly used where N_v is the number of non-hydrogen atoms, *i.e.*, vertices in the molecule.

The Electronegativity Count (ε)

The ETA electronegativity count can be defined as follows:

$$\varepsilon = -\alpha + 0.3 \times Z^V \quad (2)$$

The term ε is characterized by a significant correlation (R=0.937) with Pauling's electronegativity scale (EN) (Roy & Ghosh, 2003).

The Hydrogen-Bonding Propensity (ψ)

The ETA hydrogen bonding propensity measure can be defines as follows:

$$\psi = \frac{\alpha}{\varepsilon} \quad (3)$$

Based on the values of α and ε, this parameter (ψ) was defined which performs a discrimination among the atoms involved and not involved in hydrogen bonding. Table 4 gives the α, ε, and ψ values of some atoms commonly found in organic molecules.

The VEM Count (β)

In the ETA scheme, a new formalism has been incorporated to describe the VEM vertex measure. The VEM count β for a non-hydrogen vertex can be defined as:

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Table 4. α, ε, and ψ values of the commonly occurring atoms

Sl. No.	Atoms	α	ε	ψ
1	H	0.000	0.300	0.000
2	C	0.500	0.700	0.714
3	N	0.400	1.100	0.364
4	O	0.333	1.467	0.227
5	F	0.286	1.814	0.158
6	P	1.000	0.500	2.000
7	S	0.833	0.967	0.861
8	Cl	0.714	1.386	0.515
9	Br	1.333	0.767	1.738
10	I	1.643	0.457	3.595

$$\beta = \Sigma x\sigma + \Sigma y\pi + \delta \tag{4}$$

where the parameters σ and π correspond to the number of sigma and pi bonds, respectively, in the connected hydrogen suppressed molecular graph and δ represents a correction factor having a value of 0.5 per atom with loan pair of electrons capable of making resonance with an aromatic ring (e.g. nitrogen of aniline, oxygen of phenol etc.). Here x and y are the respective contributions of sigma (σ) and pi (π) bonds. We have assigned different contribution values for the sigma as well as pi bonds in the VEM count (β) of the ETA scheme. For the computation of β, contribution of a sigma bond (x) between two atoms of similar electronegativity ($\Delta\varepsilon \leq 0.3$) is considered to be 0.5, and for a sigma bond between two atoms of different electronegativity ($\Delta\varepsilon > 0.3$), it is considered to be 0.75. Again, the contributions for π bonds (y) are assigned depending on the type of double bonds as depicted below.

1. For a π bond between two atoms of similar electronegativity ($\Delta\varepsilon \leq 0.3$), the value of y is 1.
2. For a π bond between two atoms of different electronegativity ($\Delta\varepsilon > 0.3$) or for conjugated (non-aromatic) π system, y is considered to be 1.5.
3. For an aromatic π system, the value of the contribution factor is 2.

Hence, it is observable that the TAU scheme considered a value of 2.0 for all kinds of π bonds which is not in the case of ETA formalism. Furthermore, the VEM sigma contribution for a non-hydrogen vertex can be designated as β_s and defined as:

$$\beta_s = \Sigma x\sigma \tag{4a}$$

Similarly, the VEM non-sigma contribution of a non-hydrogen vertex can be designated as β_{ns} and defined as:

$$\beta_{ns} = \Sigma y\pi + \delta \tag{4b}$$

It should be noted that,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$\beta = \beta_s = \beta_{ns}. \tag{4c}$$

The VEM Vertex Count (γ)

The VEM vertex count γ_i of the i^{th} vertex in a connected molecular graph can be defined as:

$$\gamma_i = \frac{\alpha_i}{\beta_i} \tag{5}$$

where α_i stands for the alpha value for the i^{th} vertex and β_i being the VEM count considering all bonds connected to the atom and lone pair of electrons (if any).

The Atom Level Composite Index ($[\eta]_i$)

The contribution of a particular vertex or position (within the common substructure in a congeneric series) to the composite index η can be determined in the following manner:

$$[\eta]_i = \sum_{j \neq i} \left[\frac{\gamma_i \gamma_j}{r_{ij}^2} \right]^{0.5} \tag{6}$$

Here, $[\eta]_i$ denotes the contribution of the i^{th} vertex to η. The term in the denominator r_{ij} corresponds to the topological distance between the i^{th} and j^{th} atoms.

Definition of the Molecular Level ETA Indices

The molecular level indices indicate computation of those descriptors which involve the entire molecular structure. There are some ETA indices which can be computed at the atomic level as well as at the whole molecular level, while there are some indices for whole molecule only. Table 5 presents a comprehensive assembly of ETA indices for the whole molecule/ molecular fragment/ substructure with their notation, mathematical definition and significance. We would just like to clarify that throughout the Table 5, N indicates total number of atoms including hydrogens while N_v corresponds to the number of vertices, *i.e.*, only non-hydrogen atoms. Again few terms are associated with a subscript 'R', e.g., N_R, $[\Sigma\alpha]_R$, η_R etc. corresponding to a reference alkane which refers to a molecular graph of the original structure where all the heteroatoms are replaced with carbon and multiple (double and triple) bonds with single bonds. Furthermore, four terms in Table 5 namely $\Delta\alpha_A$, $\Delta\alpha_B$, $\Delta\psi_A$ and $\Delta\psi_B$ are spline terms (denoted by angle bracket or chevrons, $< >$) meaning that any negative value will be considered zero. Regarding the computation of VEM β count, one more subtle point to be noted is that the index β is computed for edges taking the value of vertices. Since an edge is comprised of two vertices, the following relationships exist:

$\sum\beta_s$ = Sum of β_s values of all non-hydrogen vertices / 2

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Table 5. Definition of the ETA indices at the whole molecule/fragment/substructure level

Sl. No.	Mathematical Definition	Significance
1	$\sum\alpha$	Summed α values of all non-hydrogen vertices of a molecule (or fragment/ substructure). Gives a measure of molecular bulk (or for the fragment/substructure).
2	$\Sigma\alpha/N_v$	A relative measure of molecular bulk with respect to the number of vertices.
3	$(\Sigma\alpha)_p/\Sigma\alpha$	$(\sum\alpha)_p$ stands for summation of α values of the vertices that are joined to one other non-hydrogen vertex in the connected molecular graph. Gives a measure of molecular shape.
4	$(\Sigma\alpha)_Y/\Sigma\alpha$	$(\sum\alpha)_Y$ stands for summation of α values of the vertices that are joined to three other non-hydrogen vertices in the connected molecular graph. Gives a measure of molecular shape.
5	$(\Sigma\alpha)_X/\Sigma\alpha$	$(\sum\alpha)_X$ stands for summation of α values of the vertices that are joined to four other non-hydrogen vertices in the connected molecular graph. Gives a measure of molecular shape.
6	$\Delta\alpha_A = \left\langle \frac{\sum\alpha - \left[\sum\alpha\right]_R}{N_v} \right\rangle$	A measure of count of heteroatoms.
7	$\Delta\alpha_B = \left\langle \frac{\left[\sum\alpha\right]_R - \sum\alpha}{N_v} \right\rangle$	A measure of count of hydrogen bond acceptor atoms and/or polar surface area.
8	$\varepsilon_1 = \frac{\sum\varepsilon}{N}$	Summed epsilon (ε) value in a molecule relative to the total number of atoms including hydrogen. Gives a measure of electronegative atom count.
9	$\varepsilon_2 = \frac{\sum\varepsilon_{EH}}{N_v}$	$\Sigma\varepsilon_{EH}$ stands for summed epsilon count of a molecule excluding hydrogen atoms. Gives a measure of electronegative atom count.
10	$\varepsilon_3 = \frac{\left[\sum\varepsilon\right]_R}{N_R}$	Summation of epsilon (ε) value relative to the total number of atoms including hydrogen in the connected molecular graph of the reference alkane.
11	$\varepsilon_4 = \frac{\left[\sum\varepsilon\right]_{SS}}{N_{SS}}$	Summation of epsilon (ε) value relative to the total number of atoms including hydrogen for a saturated carbon skeleton moiety of the normal molecule *i.e.*, carbon-carbon multiple bonds considered as single bond.
12	$\varepsilon_5 = \frac{\sum\varepsilon_{EH} + \sum\varepsilon_{XH}}{N_v + N_{XH}}$	Here, $\Sigma\varepsilon_{XH}$ stands for summed epsilon value for those hydrogen atoms which are connected to a heteroatom (e.g., $-$OH, $-NH_2$, $-$SH etc.) and N_{XH} gives a count of such hydrogens.
13	$\Delta\varepsilon_A = \varepsilon_1 - \varepsilon_3$	A measure of contribution of unsaturation and electronegative atom count.
14	$\Delta\varepsilon_B = \varepsilon_1 - \varepsilon_4$	A measure of contribution of unsaturation.
15	$\Delta\varepsilon_C = \varepsilon_3 - \varepsilon_4$	A measure of contribution of electronegativity.
16	$\Delta\varepsilon_D = \varepsilon_2 - \varepsilon_5$	A measure of contribution of hydrogen bond donor atoms.
17	$\sum\beta'_s$	$\Sigma\beta'_s = \Sigma\beta_s / N_v$. Summed β values for all the sigma bonds (VEM sigma contribution) relative to the number of vertices. Gives a measure of electronegative atom count of the molecule relative to the molecular size.

Table 5. Continued

Sl. No.	Mathematical Definition	Significance
18	$\sum\beta'_{ns}$	$\Sigma\beta'_{ns} = \Sigma\beta_{ns}/N_v$. Summed β values for all the non-sigma bonds including lone electron pairs capable of resonance if any (VEM non-sigma contribution) relative to the number of vertices. Gives a measure of electron-richness of the molecule relative to the molecular size.
19	$\sum\beta$	$\Sigma\beta = \Sigma\beta_s + \Sigma\beta_{ns}$. Summation of β values of all non-hydrogen vertices in a molecule.
20	$\sum\beta'$	$\Sigma\beta' = \Sigma\beta/N_v$. Summed β values relative to the number of vertices. Gives a measure of electronic features of the molecule relative to the molecular size.
21	$\sum\beta_{ns(\delta)}$	A measure of lone electrons entering into resonance with an aromatic system.
22	$\sum\beta'_{ns(\delta)} = \sum\beta_{ns(\delta)}/N_v$	A measure of lone electrons entering into resonance relative to the molecular size.
23	$\Delta\beta = \Sigma\beta_{ns} - \Sigma\beta_s$	A measure of relative unsaturation content.
24	$\Delta\beta' = \frac{\Delta\beta}{N_v}$	A measure of relative unsaturation content with respect to the molecular size.
25	$\psi_1 = \frac{\sum\alpha}{\left[\sum\varepsilon\right]_{EH}} = \frac{\sum\alpha/N_v}{\varepsilon_2}$	A measure of hydrogen bonding propensity of the molecules and/or polar surface area.
26	$\Delta\psi_A = \left\langle 0.714 - \psi_1 \right\rangle$	A measure of hydrogen bonding propensity.
27	$\Delta\psi_B = \left\langle \psi_1 - 0.714 \right\rangle$	A measure of hydrogen bonding propensity.
28	$\eta = \sum_{i<j}\left[\frac{\gamma_i\gamma_j}{r_{ij}^2}\right]^{0.5}$	The composite index (η). Here r_{ij} stands for the topological distance between i^{th} atom and j^{th} atom. Accounts for the global topology of the molecule/fragment/substructure under investigation.
29	η'	$\eta' = \eta/N_v$. The composite index relative to molecular size.
30	$\eta_R = \left\{\sum_{i<j}\left[\frac{\gamma_i\gamma_j}{r_{ij}^2}\right]^{0.5}\right\}_R$	The composite index for reference alkane (η_R).
31	$\eta_F = \eta_R - \eta$	The functionality index (η_F). Gives a measure of the heteroatoms and multiple bonds.
32	η'_F	$\eta'_F = \eta_F/N_v$ Functionality index relative to the molecular size.
33	$\eta^{local} = \sum_{i<j, r_{ij}=1}(\gamma_i\gamma_j)^{0.5}$	The local composite index (η^{local}). Reflects the local topology of the analyzed structure since only bonded interactions are considered (r_{ij}=1).
34	$\eta_R^{local} = \left\{\sum_{i<j, r_{ij}=1}(\gamma_i\gamma_j)^{0.5}\right\}_R$	The local composite index for the corresponding reference alkane.

continued on following page

Table 5. Continued

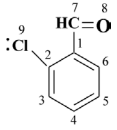
Sl. No.	Mathematical Definition	Significance
	$\eta_F^{local} = \eta_R^{local} - \eta^{local}$	Local functionality contribution.
35	$\eta_F'^{local}$	$\eta_F'^{local} = \eta_F^{local} / N_v$ Local functionality contribution relative to molecular size.
36	$\eta_B = \eta_N^{local} - \eta_R^{local} + 0.086 \times N_R$	ETA branching index (η_B), where N_R stands for the number of rings in the connected molecular graph of the reference alkane structure and η_N^{local} can be defined as: $\eta_N^{local} = 1.414 + (N_v - 3) \times 0.5$ when N_v>3, otherwise 0.
37	η'_B	$\eta'_B = \eta_B / N_v$. It is a measure of branching relative to molecular size.

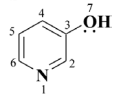
$\sum\beta_{ns}$ = (Sum of β_{ns} values of all non-hydrogen vertices – Sum of all $\beta_{ns(\delta)}$ values of all vertices) / 2 + Sum of all $\beta_{ns(\delta)}$ values of all vertices

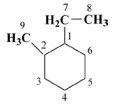
$\sum\beta_{ns(\delta)}$ = Sum of all $\beta_{ns(\delta)}$ values of all vertices

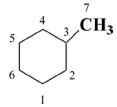
SAMPLE CALCULATION

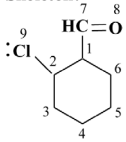
The ETA indices are easily computed from the information of molecular composition and two dimensional representations. The topological aspects of the ETA formalism is enlightened using the hydrogen suppressed molecular graph based distance matrix, while parameters like shape, size, electronegativity, electron-richness, heteroatom content, unsaturation, hydrogen bonding propensity etc. involve chemical attributes of atoms and bonds. Since, such calculation does not require any spatial information or energy minimization operation, these indices for a large number of compounds can readily be computed. Table 6 shows sample calculations of two compounds namely 2-cholobenzaldehyde and 3-hydroxypyridine.

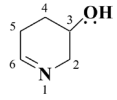












Computation of the ETA Indices

At the beginning, the ETA indices (first generations only) were computed using our in-house GW–BASIC programs namely *KRETA*1 and *KRETA*2 (GW-BASIC programs, 2003) that use distance matrix and VEM vertex count as inputs. Presently, two software platforms allow the computation of ETA indices namely Dragon (version 6) (Dragon version 6, 2010) and PaDEL-Descriptor (an open source software of the NUS, http://padel.nus.edu.sg/software/padeldescriptor/) (Yap, 2011). In Dragon (version 6), only first generation ETA indices can be computed while PaDEL-Descriptor allows the computation of all indices in this scheme. Table 7 presents the list of ETA indices corresponding to the notations used in Dragon (version 6) and PaDEL-Descriptor software.

AN OVERVIEW OF THE MODELED STUDIES

The ETA indices have been subjected to extensive chemometric modeling studies in order to judge their diagnostic potential since the inception. The initial studies reflected the predictive power of the first generation indices only, while after the development of the second generation indices, the application of both generation descriptors have been exemplified. The QSAR studies employing the ETA indices cover a wide variety of chemicals ranging from simple aliphatic hydrocarbons to complex drug molecules. Recently, the ETA indices have also been successfully employed to model relatively novel chemicals like 'ionic liquids'. Table 8 gives an overview of the *in silico* models reported so far using the ETA indices. It may be noted that in all the studies, various other topological non-ETA indices have been additionally used and the ETA indices have been found to produce models of better or comparable statistical qualities in comparison to the models from non-ETA indices. In many of the cases, the quality of the developed equations improved when ETA indices have been used in combination with other non-ETA parameters. Another observation was also very interesting during the modeling of non-specific toxicity endpoints when addition of computed lipophilicity parameter AlogP to the ETA descriptor pool gave better results. It may be noted that the non-specific toxicity of chemicals is largely encoded by the ETA bulk parameter that gives a measure of lipophilicity of the molecules. The toxicity shows either a proportionate or a parabolic relationship with molecular bulk. The toxicity is also influenced by molecular branchedness as encoded by the ETA branching and shape parameters. The ETA functionality parameters additionally show the positive effect of lipophilic heteroatoms like chlorine, bromine etc. and carbonyl oxygen group towards the toxicity. The latter factor is implicated to the Schiff base formation phenomenon with biological amines. The toxicity of chemicals is found to be negatively related to the presence of polar functional groups like hydroxy, methoxy, carboxy etc. In cases of ionic liquids, the toxicity is proportionately related to the chain length of the cationic alkyl chain. However, the same is not applicable in case of modeling AChE enzyme inhibition of eel where the head group is supposed to provide a specific spatial arrangement of the cation containing aromatic core and not for the ammonium or phosphonium core. The QSPR studies show the impact of the ETA molecular bulk parameter which relates with increased partitioning and decreased surfactancy behavior. The ETA parameters also show molecular branching and hydrogen bonding natures to be related with reduced octanol-water partitioning nature. The H-bonding phenomenon is largely attributed to the presence of polar groups like –OH, –O–, $–NH_2$, –NH– etc. However, the ETA H-bonding parameter ψ shows a negative contribution while modeling aqueous solubility of drug like compounds and agrochemicals and that has been justified by cohesive rigidity of such complex molecules due to intra- and inter-molecular H-bonding. The ETA indices for electron richness, branching and resonating lone electron pair are found to be correlated with aromatic substituent constants.

CONCLUSION AND FUTURE AVENUES

The aim of any scientific discipline lies in unraveling the reason hidden inside a system. Since, natural processes are defined by perspectives belonging to different disciplines, interdisciplinary studies are always helpful in deriving logical decisions. Predictive modeling studies aid in constituting rational basis for the physical, chemical as well as biological manifestations of chemical compounds. The chemistry suitably aided by concepts of mathematics and biology helps in unfolding the behavioral pattern of chemicals.

*Table 8. An overview of the modeling studies performed employing ETA indices**

Sl. No.	Studied Relationship	Endpoint	Type of Chemicals	No. of Samples	Chemometric Operation	Representative Value of Metrics	Chemical Attributes Explored using ETA Indices	Ref.
1	QSTR	Toxicity towards *Tetrahymena pyriformis*	Substituted phenols	n_{total}=50	Principal component factor analysis, MLR	Q^2=0.945, R_a^2=0.950	The factors increasing the toxicity of phenols are molecular bulk, branching, η_R, η'_F, $\Sigma\beta'_{ns}$, ETA functionality of phenolic O.	Roy & Ghosh, 2003
2	QSTR	Toxicity towards fish	Substituted benzenes (phenols, anilines, other hydrocarbons)	n_{total}=92	Principal component factor analysis, MLR, all-possible-subsets regression.	R^2=0.885, R_a^2=0.876, Q^2=0.865, F (df) = 92.6 (7, 84), s=0.230	The positive contribution of molecular bulk, presence of chloro, hydroxy, methyl and nitro substituents. Presence of fluoro, ether functionality, amino or nitro functionality in an otherwise unsubstituted ring, nitro group ortho to choloro reduces toxicity.	Roy & Ghosh, 2004a
3	QSTR	Toxicity towards *Tetrahymena pyriformis*	Nitroaromatic compounds	n_{total}=42	Principal component factor analysis, MLR	R^2=0.920, R_a^2=0.910, Q^2=0.880, F (df) = 101.4 (4, 37), s=0.22	Molecular bulk (size), halogen and additional nitro group in the system increases toxicity while toxicity gets decreased by the presence of methyl and hydroxymethyl substituent.	Roy & Ghosh, 2004b
4	QSTR	Acute Toxicity towards *Vibrio fischeri*	Phenylsulfonyl carboxylates	n_{total}=56	Principal component factor analysis, MLR	R^2=0.852, R_a^2=0.837, Q^2=0.726, F (df) = 57.4 (5, 50), s=0.186	The negative impact of steric bulk, branching, chloro substituent, unsaturation, electronegative atoms towards toxicity.	Roy & Ghosh, 2004c
5	QSTR	Acute Toxicity towards *Vibrio fischeri*	Phenylsulfonyl carboxylates	n_{total}=56	GFA	R^2=0.873, R_a^2=0.861, Q^2=0.771, F (df) = 69.0 (5, 50), s=0.172	The parameters reducing toxicity are steric bulk, functionality contribution, chloro group, nitro group.	Roy & Ghosh, 2005
6	QSTR	Acute Toxicity towards *Rana japonica*	Benzene derivatives	n_{total}=51	GFA, FA, MLR, PCRA	R^2=0.915, R_a^2=0.901, Q^2=0.847, F (df) = 65.841 (7, 43), s=0.183	Toxicity is parabolically related to molecular size, increases with the presence of chloro substituent, while gets reduced due to the occurrence of groups like methoxy, hydroxy, carboxy, amino.	Roy & Ghosh, 2006a
7	QSTR	Nonspecific toxicity towards *Saccharomyces cerevisiae*	Substituted benzene derivatives	n_{total}=51	FA, PCA, stepwise MLR, PLS	R^2=0.884, R_a^2=0.874, Q^2=0.851, F (df) = 87.9 (4, 46), s=0.235	The negative contributions of amino & carboxylic acid functionalities on the benzene ring and occurrence of electronegative atom towards the toxicity while positive contributions of presence of chloro group and molecular branchedness.	Roy & Sanyal, 2006
8	QSPR	*n*-Octanol/water partition coefficient	Non-ionic organic compounds	n_{total}=122; n_{train}=92, n_{test}=30	*k*-means clustering, principal component factor analysis, MLR, PLS, stepwise MLR, PCRA	Total: R^2=0.960, Q^2=0.953 Divided: R^2=0.974, Q^2=0.970, R^2_{pred}=0.906	Partion coefficient increases in the presence of molecular bulk and degree of halogen substitution while hydrogen bonding or polar interaction reduces it.	Roy et al., 2006a
9	QSPR	Bioconcentration factors in fish	Non-ionic organic compounds	n_{total}=122	Principal component factor analysis, MLR, PLS, stepwise MLR, PCRA, *k*-means clustering	R^2=0.948, R_a^2=0.944, Q^2=0.847, F (df) = 254.9 (8, 113), s=0.362	Presence of nitro, amino, hydroxyl groups reduces BCF, while it increases by branchedness, molecular volume, and chloro substituents.	Roy et al., 2006b

Table 8. Continued

Sl. No.	Studied Relationship	Endpoint	Type of Chemicals	No. of Samples	Chemometric Operation	Representative Value of Metrics	Chemical Attributes Explored using ETA Indices	Ref.
10	QSTR	Inhibition of seed germination rate of *Cucumis sativus*	Substituted phenols	n_{total}=41	Stepwise MLR, FA-MLR, GFA-MLR, G/PLS, FA-PLS, PCRA	R^2=0.825, R_a^2=0.811, Q^2=0.719, PRESS=2.065	Toxicity proportionately increases in presence of branching, unsaturation and groups like nitro, cholo, bromo while functionalities namely hydroxyl, carboxy, methoxy, ortho-methyl exerts negative impacts. Furthermore, toxicity was also found to possess a non-linear relationship with ETA volume parameter $\sum\alpha$.	Roy & Ghosh, 2006b
11	QSTR	Toxicity towards *Chlorella vulgaris*	Diverse functional organic compounds	n_{total}=91, n_{train}=68, n_{test}=23	*k*-means clustering, stepwise MLR, FA-MLR, PLS, PCRA	Total: R^2=0.928, R_a^2=0.925, Q^2=0.913, F (*df*) = 275.29 (4, 86) Divided: R^2=0.929, Q^2=0.900, R^2_{pred}=0.870	Molecules possessing higher amount of molecular bulk ($\sum\alpha$), electron richness ($\sum\beta'_{ns}$) and lipophilic substituents like chloro or bromo are more toxic.	Roy & Ghosh, 2007
12	QSTR	Human toxicity data (blood/serum conc.)	Organic compounds including pharmaceuticals	n_{total}=26, n_{train}=19, n_{test}=7	Stepwise MLR, *k*-means clustering, FA-MLR, GFA, PLS, G/PLS, PCRA	Total: R^2=0.903, R_a^2=0.895, Q^2=0.834, F (*df*) = 106.88 (2, 23) Divided: R^2=0.724, Q^2=0.639, R^2_{pred}=0.655	Molecular bulk, cholo group (lipophilicity), heteroatom within a chain or ring, unsaturation increase the toxicity while hydroxyl group and branching reduce it.	Roy & Ghosh, 2008
13	QSTR	Cytotoxicity in rat hepatocytes	NSAIDs	n_{total}=15	Stepwise MLR, PCRA, PLS, GFA, G/PLS	R^2=0.919, R_a^2=0.906, Q^2=0.854, F (*df*) = 67.92 (2, 12)	Toxicity increases with molecular bulk and degree of branching. Unsaturation and heteroatom content have additional impact on toxicity.	Roy & Ghosh, 2009a
14	QSTR	Toxicity towards *Tetrahymena pyriformis*	Diverse aromatic compounds	n_{total}=384, n_{train}=288, n_{test}=96	Stepwise MLR, *k*-means clustering, FA-MLR, PLS,	Divided: R^2=0.854, R_a^2=0.846, Q^2=0.821, R^2_{pred}=0.679	The parameters important for the prediction of toxicity are molecular bulk, halogen functionality representing lipophilicity and nitrogen containing functionality giving an account of polarity.	Roy & Ghosh, 2009b
15	QSTR	hERG K^+ channel blocking activity	Diverse functional drugs	n_{total}=67, n_{train}=50, n_{test}=17	Stepwise MLR, *k*-means clustering, FA-MLR, PLS	Divided: R^2=0.658, R_a^2=0.619, Q^2=0.540, R^2_{pred}=0.617	Electron-richness and volume increase hERG K^+ channel blocking activity while groups/fragments containing aliphatic nitrogen atom or –COOH reduce it. The parameter $\sum\alpha$ additionally showed a parabolic relationship with the modeled toxicity endpoint.	Roy & Ghosh, 2009c
16	QSTR	Toxicity towards *Tetrahymena pyriformis*	Aromatic aldehydes	n_{total}=77, n_{train}=50, n_{test}=17	Stepwise MLR, GFA, G/PLS	R^2=0.895, Q^2=0.870, R^2_{pred}=0.902, $r^2_{m\ (test)}$=0.896	Molecular bulk, electronegative substituents, lipophilic substituent increase the toxicity of aromatic aldehydes. The keto oxygen in aldehyde group also imparts their effect towards toxicity.	Roy & Das, 2010

Table 8. Continued

Sl. No.	Studied Relationship	Endpoint	Type of Chemicals	No. of Samples	Chemometric Operation	Representative Value of Metrics	Chemical Attributes Explored using ETA Indices	Ref.
17	QSPR	Octanol-water partition coefficient	Diverse functional organic compounds	n_{total}=168, n_{train}=84, n_{test}=84	Stepwise MLR, PLS	Total (PLS): R^2=0.943, R_a^2=0.940, Q^2=0.933 Divided (PLS): R^2=0.922, Q^2=0.903, R^2_{pred}=0.919	Lipophilicity increases with molecular bulk while it tends to decrease in the presence of branching, relative unsaturation content and hydrogen bonding propensity measure.	Roy & Das, 2011a
	QSPR	Octanol-water partition coefficient	Aliphatic and aromatic compounds	n_{total}=139, n_{train}=70, n_{test}=69		Total (PLS): R^2=0.992, R_a^2=0.991, Q^2=0.989 Divided (PLS): R^2=0.988, Q^2=0.984, R^2_{pred}=0.972	Different electronic features, unsaturation and shape parameters were important for the partition coefficient of aliphatic and aromatic compounds.	Roy & Das, 2011a
	QSPR	Aqueous solubility	Aliphatic and aromatic compounds	n_{total}=193, n_{train}=97, n_{test}=96		Total (PLS): R^2=0.951, R_a^2=0.948, Q^2=0.937 Divided (PLS): R^2=0.918, Q^2=0.897, R^2_{pred}=0.872	Hydrogen bonding propensity and H-bond donor atoms were observed to be the important features for modeling aqueous solubility. However, relative unsaturation content and branchedness were also contributing.	Roy & Das, 2011a
	QSPR	Molar refractivity (R_m)	Aliphatic and aromatic compounds	n_{total}=166, n_{train}=83, n_{test}=83		Total (PLS): R^2=0.990, R_a^2=0.990, Q^2=0.989 Divided (PLS): R^2=0.980, Q^2=0.978, R^2_{pred}=0.993	Electronegativity, molecular bulk and hydrogen bonding propensity were contributing factors towards modeling of molar refraction of chemicals.	Roy & Das, 2011a
	QSPR	Aromatic substituent constant π	Aromatic substituents	n_{total}=98, n_{train}=50, n_{test}=48		Total (PLS): R^2=0.770, R_a^2=0.755, Q^2=0.718 Divided (PLS): R^2=0.795, Q^2=0.736, R^2_{pred}=0.540	Measure of H-bond acceptor atoms or polar surface area, H-bond donor atoms, H-bonding propensity, electron-richness, electronegativity, molecular bulk and branching were the contributing parameters for modeling π.	Roy & Das, 2011a
	QSPR	Aromatic substituent constant MR	Aromatic substituents	n_{total}=99, n_{train}=50, n_{test}=49		Total (PLS): R^2=0.986, R_a^2=0.985, Q^2=0.979 Divided (PLS): R^2=0.977, Q^2=0.967, R^2_{pred}=0.965	MR was related to the impact of molecular bulk, relative unsaturation, electron richness, electronegativity, H-bonding atom count, H-bonding propensity, resonating lone electron pair and branching of the molecules.	Roy & Das, 2011a
	QSPR	Aromatic substituent constant σ_m	Aromatic substituents	n_{total}=97, n_{train}=49, n_{test}=48		Total (PLS): R^2=0.766, R_a^2=0.758, Q^2=0.735 Divided (PLS): R^2=0.750, Q^2=0.677, R^2_{pred}=0.736	σ_m is encoded by shape parameter, electronegativity, relative unsaturation content, resonating lone electron pair, and measure of non-hydrogen bonding bulky heteroatom.	Roy & Das, 2011a

Sl. No.	Studied Relationship	Endpoint	Type of Chemicals	No. of Samples	Chemometric Operation	Representative Value of Metrics	Chemical Attributes Explored using ETA Indices	Ref.
	QSPR	Aromatic substituent constant σ_p	Aromatic substituents	n_{total}=99, n_{train}=50, n_{test}=49		Total (PLS): R^2=0.726, R_a^2=0.717, Q^2=0.682 Divided (PLS): R^2=0.670, Q^2=0.582, R^2_{pred}=0.585	σ_p can be described in terms of molecular branching, electronegativity, resonating lone electron pair, relative unsaturation content and molecular bulk.	Roy & Das, 2011a
18	QSTR	Toxicity towards *Pimephales promelas*	Diverse organic chemicals	n_{total}=459, n_{train}=344, n_{test}=115	*k*-means clustering, Stepwise MLR, GFA	Divided (GFA): R^2=0.763, Q^2=0.751, R^2_{pred}=0.783, $r^2_{m\ (test)}$=0.777	Apart from the positive impact of the computed lipophilicity measure, measures of molecular bulk, electron richness, relative unsaturation content, and branchedness are necessary attributes.	Roy & Das, 2012
19	QSPR	Critical micelle concentration (CMC)	Non-ionic surfactants	n_{total}=54, n_{train}=41, n_{test}=13	Stepwise MLR, GFA, PLS	Divided (PLS): R^2=0.907, Q^2=0.879, R^2_{pred}=0.923, $r^2_{m\ (test)}$=0.912	logCMC value increases with molecular shape, heteroatom content while molecular bulk and branching tends to reduce it.	Roy & Kabir, 2012a
21	QSPR	Critical micelle concentration (CMC)	Cationic surfactants	n_{total}=35, n_{train}=26, n_{test}=9	*k*-means clustering, stepwise MLR, GFA, ANN	Divided (GFA): R^2=0.949, Q^2=0.893, R^2_{pred}=0.904, $r^2_{m\ (test)}$=0.892	Hydrogen bond donor atoms, molecular size and degree of unsaturation affect the CMC of cationic surfactants.	Roy & Kabir, 2012b
20	QSPR	Critical micelle concentration (CMC)	Anionic surfactants	n_{total}=37, n_{train}=28, n_{test}=9	Stepwise MLR, GFA, ANN, PCA	Divided (GFA): R^2=0.957, Q^2=0.938, R^2_{pred}=0.923, $r^2_{m\ (test)}$=0.823	Electronegativity and topological environment impart negative contribution, while lipophilicity and branching show positive impact towards CMC of anionic surfactants.	Roy & Kabir, 2013
22	QSPR	Aqueous solubility	Drug like molecules and agrochemicals	n_{total}=565, n_{train}=282, n_{test}=283	Stepwise MLR, GFA, G/PLS	Divided (G/PLS): R^2=0.802, Q^2=0.793, R^2_{pred}=0.806, $r^2_{m\ (test)}$=0.735	Lipophilicity, unsaturation, hydrogen bonding propensity and polar surface area measure are the responsible chemical features for logS.	Das & Roy, 2013
23	QSTR	Toxicity towards rodent and interspecies toxicity correlation among daphnids, fish and algae.	Pharmaceuticals	Rodent: n_{train}=102, n_{test}=34 Daphnia-algae: n_{train}=65, n_{test}=24 Fish-algae: n_{train}=50, n_{test}=22	Stepwise MLR, PLS	**Rodent:** R^2=0.618, Q^2=0.556, R^2_{pred}=0.550 **Daphnia-algae:** R^2=0.650, Q^2=0.580, R^2_{pred}=0.604 **Fish-algae:** R^2=0.752, Q^2=0.654, R^2_{pred}=0.696	Rodent toxicity is chiefly influenced by the charge distribution and heteroatom atom count. Interspecies correlation models show the influence of different atom-type AlogP fragments, molecular shape, charge distribution and functionality measure.	Das et al., 2013

Table 8. Continued

Sl. No.	Studied Relationship	Endpoint	Type of Chemicals	No. of Samples	Chemometric Operation	Representative Value of Metrics	Chemical Attributes Explored using ETA Indices	Ref.
27	QSTR	Inhibition of *Electrophorus electricus* AChE enzyme	Diverse ionic liquids	LDA: n_{train}=182, n_{test}=110 MLR: n_{train}=148, n_{test}=84	*k*-means clustering, LDA, stepwise MLR, GFA, PLS, molecular docking	**LDA:** Wilk's λ=0.374, R_c=0.791, MCC_{trn}=0.802, AUC-ROC=0.959$_{(trn)}$ & 0.914$_{(test)}$ **MLR:** R^2=0.838, Q^2=0.808, $Q^2_{(F1)}$=0.822, $RMSE_p$=0.248, $\overline{r^2_{m\,(test)}}$=0.762	Increased toxicity is caused by longer alkyl chain length on N atom providing proper spatial conformation, presence of quaternary N atom in ring allowing π-cationic interaction, and distributed electron density in cations due to resonating electrons. Lipophilicity of anion additionally account for the toxicity, *i.e.*, increased enzyme inhibition. However, presence of long chains on free N^+/P^+ causes reduction of the toxicity due to free rotation of chains causing binding hindrance. Toxicity also reduces due to the presence of H-bond donors & acceptors blocking partitioning of molecule.	Das & Roy, 2014b
28	QSPR	Adsorption	Organic compounds	n_{total}=3483, n_{train}=2613, n_{test}=870	*k*-means clustering, PCA, stepwise MLR, PLS	Divided: R^2=0.815, Q^2=0.806, $\overline{r^2_{m\,(LOO)}}$=0.722, $Q^2_{(F1)}$=0.791, $\overline{r^2_{m\,(test)}}$=0.719	The adsorption behavior is characterized by molecular volume, H-bond donor groups, heteroatomic contribution, electronegativity, shape, H-bonding propensity and unsaturation.	Ray & Roy, 2013
29	QSPR	Bio-concentration factor	Diverse chemicals	n_{total}=522, n_{train}=324, n_{test}=198	*k*-means clustering, GFA, PLS	Divided: R^2=0.614, R_a^2=0.611, Q^2=0.597, R^2_{pred}=0.696, $\overline{r^2_{m\,(test)}}$=0.580	Occurrence of fused ring systems and halogen atoms exert positive contribution while electronegativity, H-bond donor groups, polarity and lowered partition coefficient have negative impact on BCF.	Pramanik & Roy, 2014
30	QSPR	Odor threshold	Aliphatic alcohols	n_{total}=53, n_{train}=42, n_{test}=11	*k*-means clustering, GFA, G/PLS	Divided: R^2=0.809, Q^2=0.778, R^2_{pred}=0.813, $\overline{r^2_{m\,(test)}}$=0.679	Odor threshold is potentiated by increased hydrophobicity and reduced electronegativity.	Pal et al., 2014

*Full form of some abbreviations used: **MLR:** Multiple linear regression; **GFA:** Genetic function approximation; **FA:** Factor analysis; **PCA:** Principal component analysis; **PCRA:** Principal-component regression analysis; **PLS:** Partial least squares; **LDA:** Linear discriminant analysis.

Mathematical descriptors are the logical basis for the exploration of the chemical fraternity. Since the introduction of predictor variables, a long way has already been traversed in depicting the chemical behavior and it has been envisaged that theoretically derived chemical descriptors are more than just simple quantification of chemical structures to derive correlations. Since, there is an amalgamation of chemical principles with mathematical algorithms, care should be taken that the encoded information is also helpful in deriving mechanistic interpretation instead of developing only correlations with the endpoint under investigation.

There is also a good amount of arguments regarding the dimensionality of analysis during the development of predictive correlation models. It is quite obvious that two-dimensional analyses are relatively easier to perform and give reproducible results. However, the molecular properties and interactions are also believed to be affected by features like shape, surface area and volume which are three dimensional. Hence, it becomes very interesting if a theoretical basis is generated to incorporate information of three-dimensional perspectives in two-dimensional indices. It may be observed that there is a good correlation and inheritance between these two and three- dimensional features since the features like size, shape, volume etc. are in turn controlled by the property of the individual atoms and bonds constituting a molecule. The three-dimensional geometry is also referred to as molecular topography (Kier & Hall, 1986) and studies have shown the occurrence of quantum chemical basis (Stankevich et al., 1995) as well as Hückel's molecular orbital (Gálvez et al., 1998) features in the topological parameters rendering them reliable predictor parameters in extracting powerful chemical information.

The ETA indices are enriched since they do not rely only on topological distance based measures of hydrogen suppressed molecular graphs. This group of parameters are advantageous as they encode suitable chemical information on different aspects of molecular chemistry, *e.g.*, volume, shape, size, branchedness, polarity, electronegative, electron-richness and hydrogen bonding property and also consider contribution of active hydrogen atoms. So, the ETA indices consider more than just graph theoretical aspects, employing detailed information on the atoms, bonds and the connectivity therein. Technically it will be difficult to assume any single descriptor to encode universal chemical features. Different aspects of chemical information are expressed in modeling different endpoints. In other words, endpoint like aqueous solubility or partition coefficient can be explained by molecular size, branchedness or hydrogen bonding aspects while electronic features and polarity information of a molecule may be of importance while developing predictive models against molar refractivity. The ETA formalism attempts to provide a platform of different chemical attributes so as to enable the designer with broader choice of predictor variables within a single category (Roy & Das, 2011b; Roy & Ghosh, 2010). The ETA parameters are also appended with dynamic chemical foundation suitable for deriving mechanistic basis. Moreover, all the studies performed till date using the ETA indices infer that they contain sufficient diagnostic potential for the development of predictive quantitative models for various classes of chemicals namely aliphatic compounds, aromatic compounds, agrochemicals, drugs and pharmaceuticals, ionic liquids etc. encompassing industrial, laboratory and house hold usage. Like every successful innovation walks through the development of new ideas and concepts, the ETA indices have followed a path of novel chemical exploration and we shall look forward to more nourishment of enriched chemical information in future.

KEY TERMS AND DEFINITIONS

2D-Descriptor: A method where the considered chemical information corresponds to two-dimensional geometry of the molecule.

Chemical Graphs: A method of presenting chemical structures using a "hydrogen-suppressed" molecular skeleton where 'atoms' are denoted by 'vertices' and 'bonds' are represented by 'edges'.

Descriptor: A numerical quantity for the depiction of molecular structure using a suitable algorithm. Used as predictor variables in QSAR modeling analysis.

Extended Topochemical Atom (ETA) Indices: Indices where the topological information has been enriched using suitable electronic, heteroatom count & type, hydrogen-bonding and other essential chemical attributes. These are used as descriptors in QSAR modeling.

Hydrogen-Suppressed: A graph theoretical method of representing chemical structures where the hydrogen atoms attached to carbon and other atoms are not shown. Also termed as hydrogen-depleted.

QSAR Analysis: A method of developing mathematical correlation between a response and descriptors, *i.e.*, predictor variables for a series of chemical data.

Topology: A method assessing chemical structures using distance and connectivity information considering hydrogen-suppressed molecular graph. The distance corresponds to minimum path between vertices.

Chapter 39
Importance of Applicability Domain of QSAR Models

Kunal Roy
Jadavpur University, India

Supratik Kar
Jadavpur University, India

ABSTRACT

Quantitative Structure-Activity Relationship (QSAR) models have manifold applications in drug discovery, environmental fate modeling, risk assessment, and property prediction of chemicals and pharmaceuticals. One of the principles recommended by the Organization of Economic Co-operation and Development (OECD) for model validation requires defining the Applicability Domain (AD) for QSAR models, which allows one to estimate the uncertainty in the prediction of a compound based on how similar it is to the training compounds, which are used in the model development. The AD is a significant tool to build a reliable QSAR model, which is generally limited in use to query chemicals structurally similar to the training compounds. Thus, characterization of interpolation space is significant in defining the AD. An attempt is made in this chapter to address the important concepts and methodology of the AD as well as criteria for estimating AD through training set interpolation in the descriptor space.

INTRODUCTION

Quantitative structure-activity relationship (QSAR) modelling has become an important tool in the new drug candidate design, environmental fate modeling, toxicity and property prediction of chemicals and pharmaceuticals since they offer an economical and time-effective alternative to the medium throughput *in vitro* and low throughput *in vivo* assays (Perkins *et al*., 2003; Selassie, 2003; Walker et al., 2003). A QSAR model is a simple mathematical equation that is evaluated from a set of molecules with known activities/properties/toxicities using computational approaches. Thereafter, the developed predictive QSAR models are also applied by regulatory agencies to evaluate physical, chemical, and biological properties of individual chemical entities using applications specific for decision-making frameworks in risk and safety assessments (Kar & Roy, 2010). The QSAR modeling hypothesis also supports the 3Rs

(replacement, refinement and reduction in animals in research) paradigm due to an increased pressure from social and economic background to trim down the use of animal testing as an important alternative method for future prediction of untested chemical entities (Benigni & Giuliani, 2003).

Robust validation of QSAR models plays a key step for the selection of a predictive model that may be considered for future prediction of new molecules. As numerous numbers of researches have been directed to the design of new molecules with the utilization of QSAR technique, validation of a QSAR model has been certified as the most considerable stride (Carlsen *et al*., 2009) for assessing the quality of data, applicability and mechanistic interpretability of the developed model. Thus, a huge number of investigations are currently directed towards the introduction of more appropriate validation approaches for more accurate and predictive QSAR model development. One important objective of QSAR modeling is to predict activity/property/toxicity of new chemical entities falling within the applicability domain of the developed models. The reliability of any QSAR model depends on the confident predictions of these new compounds based on applicability domain (AD) of the modeled compounds and therein arises the importance of the AD study (Ferreira, 2001).

In order to establish the scientific validity of a QSAR model and to facilitate its acceptance for regulatory purposes, the Organization for Economic Cooperation and Development (OECD) in its joint meeting (OECD, 2007) has agreed to five principles that should be followed during the construction of QSAR models. The OECD Principle 3 which defines the need of an AD expresses the fact that QSARs are unavoidably associated with restrictions in terms of the types of chemical structures, physicochemical properties and mechanisms of action for which the models can generate reliable predictions. The applicability domain of a QSAR model has been defined as the response and chemical structure space, characterized by the properties of the molecules in the training set. The developed QSAR model can predict a new compound truly only when it falls within the applicability domain of the developed model (Netzeva *et al*., 2005). Thus, to identify the interpolation (true prediction) or extrapolation (less reliable prediction) of query compounds is an important task for a QSAR model developer using the information of applicability domain (Netzeva *et al*., 2005).

Viewing the importance of AD in QSAR model validation, we herein focus to get an overview of different traditional as well as relatively new AD approaches used to judge the quality of the QSAR models. This book chapter will be helpful for the QSAR learners in order to have a clear idea on the principles of available AD approaches useful for judging the predictive quality of QSAR models.

BACKGROUND

A QSAR model is essentially valued in terms of its predictability, indicating how well it is able to predict the endpoint values of the compounds which are not used to develop the correlation. The models that have been suitably validated internally and externally can be considered reliable for both scientific and regulatory purposes (Golbraikh & Tropsha, 2002; Tong *et al*., 2004]. QSAR models should be validated according to the OECD principles for reliable prediction. A meeting of QSAR experts held in Setúbal, Portugal in March 2002 formulated guidelines for the validation of QSAR models, in particular for regulatory purposes (Jaworska *et al*., 2003). These principles were agreed by OECD member countries, QSAR and regulatory communities at the 37th Joint Meeting of the Chemicals Committee and Working Party on Chemicals, Pesticides and Biotechnology in November 2004. These principles are best pos-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

sible summary of the most important points that are required to be addressed to find consistent, reliable and reproducible QSAR models (OECD, 2004). Five OECD principles to develop reliable models are:

Principle 1: A defined endpoint;
Principle 2: An unambiguous algorithm;
Principle 3: A defined domain of applicability;
Principle 4: Appropriate measures of goodness-of fit, robustness and predictivity;
Principle 5: A mechanistic interpretation, if possible (OECD, 2004).

In order to provide guidance on the interpretation of the mentioned principles, the OECD has also provided a checklist (OECD, 2004). Thus, the current challenge in the process of development of a QSAR model is no longer in developing a model that is statistically sound to predict the activity within the training set, but in developing a model with the capability to predict accurately the activity of untested chemicals. In spite of high fitted accuracy and apparent mechanistic appeal, some published QSAR models fail rigorous validation tests, and, thus, may lack practical utility as reliable screening tools (Tropsha *et al*., 2003]. In summary, predictive power is one of the most important validation features of QSAR models. It can be defined as the ability of a model to predict accurately the target activity/property/toxicity of compounds that are not used for model development.

In this context, QSAR model predictions are most reliable if they come from the model's applicability domain (AD) which is broadly defined under OECD principle 3. The OECD includes AD assessment as one of the QSAR acceptance criteria for regulatory purposes (OECD, 2004; OECD, 2007). The Setubal Workshop report (Jaworska et al., 2003) presented the following regulation for AD assessment: "The applicability domain of a (Q)SAR is the physico-chemical, structural, or biological space, knowledge or information on which the training set of the model has been developed, and for which it is applicable to make predictions for new compounds. The applicability domain of a (Q)SAR should be described in terms of the most relevant parameters, i.e., usually those that are descriptors of the model. Ideally the (Q)SAR should only be used to make predictions within that domain by interpolation not extrapolation. This depiction is useful for explaining the instinctive meaning of the "applicability domain" approach.

Two general principles to AD estimation have been proposed till date (Nikolova-Jeliazkova & Jaworska, 2005). The first one estimates the interpolation region based on the training set in the model's descriptor space. The second approach relies on similarity analysis according to the premise that a QSAR prediction is reliable if the compound is "similar" to the compounds in the training set. It is interesting to point out that "similarity" is a relative concept as different concepts of similarity are relevant to different endpoints. The similarity approach to AD assessment should be based on measurable key features relevant to the endpoint modelled precisely (Bender & Glen, 2004; Nikolova & Jaworska, 2004).

APPLICABILITY DOMAIN (AD)

The AD (Eriksson *et al*., 2003; Gramatica, 2007; Netzeva *et al*., 2005, Tetko *et al*., 2006) is a theoretical region in chemical space encompassing both the model descriptors and modeled response. In the development of a QSAR model, the domain of applicability of molecules plays a crucial role for estimating the uncertainty in the prediction of a particular compound based on how similar it is to the compounds

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

used to build the model. Thus, the prediction of a modeled response using QSAR is valid only if the compound being predicted falls within the domain of applicability of the model since it is impossible to predict an entire universe of chemicals using a single QSAR model. Again, AD can be described as the physico-chemical, structural or biological space, knowledge or information based on which the training set of the model is developed, and the model is applicable to make predictions for new compounds within the specific domain (Weaver & Paul Gleeson, 2008).

The selection method of the training and test sets has a significant effect on the applicability domain of constructed QSAR model. Thus, while splitting a dataset for external validation, the training set molecules should be selected in such a way that they span the entire chemical space for all the dataset molecules. In order to achieve successful predictions, a QSAR model should always be used for compounds within its applicability domain. Therefore, one can arguably agree that if a new compound falls outside of the AD of the training set molecules, its prediction is not reliable.

APPLICABILTY DOMAIN APPROACHES

There are various AD approaches that have been used by different groups of QSAR researchers worldwide. The most common approaches for estimating interpolation regions in a multivariate space include the following ones (Jaworska *et al*., 2005; Netzeva *et al*., 2005):

1. Ranges in the descriptor space.
2. Geometrical methods.
3. Distance-based methods.
4. Probability density distribution.
5. Range of the response variable.

The first four approaches are based on the methodology used for interpolation space characterization in the model descriptor space. On the contrary, the last one depends solely on response space of the training set molecules. A compound can be identified as out of the domain of applicability in a simple way, if:

1. At least one descriptor is out of range for the ranges approach, and
2. The distance between the chemical and the center of the training data set exceeds the threshold for distance approaches.

The threshold for all kinds of distance methods is the largest distance between the training set data points and the center of the training data set.

Along with the common approaches, Stanforth *et al*., (2007) proposed a cluster-based approach to evaluate the AD of any QSAR model. The method applies an intelligent version of the *k*-means clustering algorithm for modeling the training set as a compilation of clusters in the descriptors space. On the other hand, the test compounds of individual clusters are assigned a fuzzy membership from which an overall distance may be calculated to identify the AD of individual test compounds. A classification-based process involves calculation of regression residuals for identification of good and bad classes suggested by Guha & Jurs (2005).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

All approaches are discussed thoroughly in this section enlightening their main theories to define the interpolation space as well as the threshold criteria for AD used in QSAR modeling. A summary of hypotheses of data distribution and interpolation space of most commonly used AD methods is discussed in Table 1.

Table 1. Summary of hypothesis of most commonly used AD methods

Method		Formula/Equation	Hypothesis on Data Distribution	Shape of the AD Space
Range based		$d(x,y) = x–y$	Uniform	Boundary created by individual descriptor of the training set compounds
Geometric (Convex hull)		-	Uniform and smallest axis-aligned convex region containing all the data points	Convex
Distance-based	Mahalanobis distance/ Hotelling T^2/ leverage	$D_M(x,\mu) = \left(x-\mu\right)^T \sum^{-1} \left(x-\mu\right)$	a) Normal, b) arbitrary variances, and c) arbitrary correlation. Mean μ, Covariance matrix Σ $p\left[x\right] = \frac{1}{\left(2\pi\right)^{N/2}\left\|\sum\right\|^{\frac{1}{2}}} \exp\left\langle -\frac{1}{2} D_M\left(x,\mu\right)\right\rangle$	Ellipses (hyper-ellipses)
	Euclidean distance	$d(x,y) = \sqrt{\sum_{i=1}^{n}(x_i - y_i)^2}$ n=total number of observations for which a pair wise comparison is performed (x_i and y_i), i is the number of descriptors	a) Normal, b) equal variances, and c) uncorrelated variables Mean μ, unit covariance matrix $p\left[x\right] = \frac{1}{\left(2\pi\right)^{N/2}} \exp\left\langle -\frac{1}{2} D_E^2\left(x,\mu\right)\right\rangle$	Spheres (hyper-spheres)
	City block	$d(x,y) = \sum_{i=1}^{n}\left\|x_i - y_i\right\|$	Multivariate uniform	Rectangle
Probability density distribution		$\varphi = \frac{1}{\sqrt{\left(2\pi\right)}s} . \exp\left[\frac{-1}{\left(2s^2\right)\left(x_i - x_j\right)^2}\right]$ where, Φ (x_i and x_j) is the potential induced on x_j by x_i and width of the curve is defined by smoothing parameter s. The cut off value associated with Gaussian potential functions, namely f_p, can be calculated by: $f_p = f_i + (q–j)(f_{j+1} – f_j)$ where, $q = p \times {}^{n}/_{100}$, p is the percentile value of probability density, n is the number of compounds in the training set and j is the nearest integer value of q.	1. Parametric methods use standard distributions such as Gaussian and Poisson distributions. 2. Non-parametric techniques permit the estimation of probability density solely from data.	Captures actual data distribution and no reference data point are considered. For each data point, the method calculates the probability of belonging to the set.

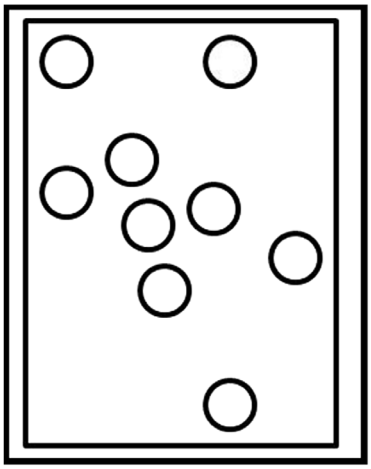
1. RANGES IN THE DESCRIPTOR SPACE APPROACH

1.1 Fixed or Probabilistic Boundaries/Bounding Box



- **Theory:** The ranges of the individual descriptors are considered with a uniform distribution defining an n-dimensional hyper-rectangle developed on the basis of the maximum and minimum values of each descriptor used to build the model with sides parallel to the coordinate axes.
- **Criteria:** This method is simply based on boundary created by individual descriptor ranges of the training set compounds from which the QSAR model is developed. As mentioned earlier, this is based on the highest and lowest values of X variables (descriptors to develop the QSAR model) and Y variable (response for which the QSAR equation is created) of the training set. Any test set compounds, which are not present in any of these particular ranges, are considered out of the AD and their predictions are less reliable (Jaworska *et al*., 2005; Seber, 1984).
- **Drawbacks:**
  - For non-uniformly distributed data, the approach encloses considerable empty space,
  - Empty regions in the interpolation space cannot be recognized, as only the descriptor ranges are considered, and
  - Correlation between descriptors cannot be taken into account (Jaworska *et al*., 2005).

For the 'bounding box' method, the domain of applicability is the smallest axis-aligned rectangular box containing all the data points presented in Figure 1.

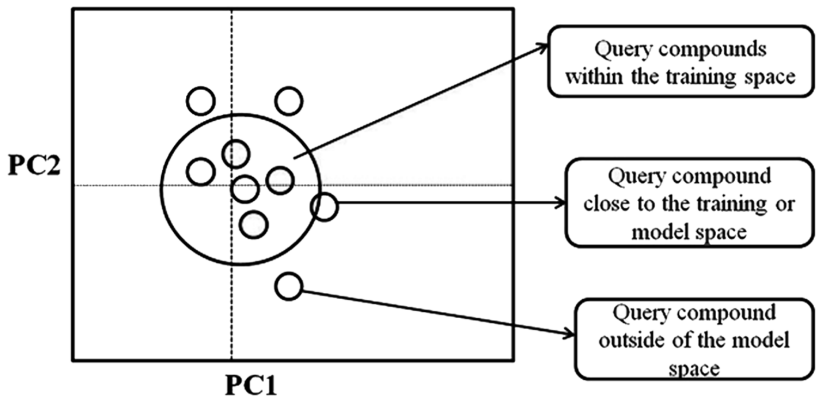
1.2 Principal Component Ranges/PCA Bounding Box

- **Theory:** Principal components convert the original data into a new orthogonal coordinate system by the rotation of axes and enable to correct for correlations among descriptors. Newly formed axes are defined as Principal Components (PCs) representing the maximum variance of the total dataset. The points between the lowest value and the highest value of each PC define an

Figure 1. Bounding box plot

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

M-dimensional (*M* is the number of significant components) hyper-rectangle with sides parallel to the PCs (Nikolova-Jeliazkova & Jaworska, 2005).



- **Criteria:** This hyper-rectangle AD also includes empty spaces depending on uniformity of data distribution (Nikolova-Jeliazkova & Jaworska, 2005). Combining the bounding box method with principal component analysis (PCA) can overcome the setback of correlation between descriptors but the issue regarding empty regions within the interpolation space still remains. It is interesting to point out that the empty space is smaller than the hyper-rectangle in the original descriptor ranges. The most important criterion of this approach remains in the selection of appropriate number of components (Jaworska *et al*., 2005, Worth *et al*., 2005). The PCA bounding box has been used to analyze the AD of the KOWWIN model.

The AD in principal component space is presented in Figure 2. The QSAR model training set is represented by the biggest circle. The predictions of query molecules within the training space are considered reliable. Query compounds which are located outside the training model space would be expected to be less reliably predicted.

1.3 TOPKAT Optimal Prediction Space

- **Theory:** Variation of PCA is implemented by the Optimum Prediction Space (OPS) from TOPKAT OPS (2000). In the PCA approach, instead of the standardized mean value, the data are centered around the mean of individual parameter range ($[x_{max}-x_{min}]/2$). Thus, it establishes a new orthogonal coordinate system which is known as OPS coordinate system. Here, the basic process is same, extracting eigenvalues and eigenvectors from the covariance matrix of the transformed data. The OPS boundary is defined by the minimum and maximum values of the generated data points on each axis of the OPS coordinate system.
- **Criteria:** The Property Sensitive object Similarity (PSS) is implemented in the TOPKAT as a heuristic solution to replicate the data set's dense and spare regions, and includes the response variable (y). Accuracy of prediction between the training set and queried points is assessed by the PSS. Similarity search method is used to evaluate the performance of TOPKAT in predicting the effects of a chemical that is structurally similar to the training structure.

Figure 2. A graphical illustration of the AD in principal component (PC) space

2. GEOMETRICAL METHODS

2.1 Convex Hull

- **Theory:** This approach estimates the direct coverage of an n-dimensional set using the convex hull calculation (Preparata & Shamos, 1991). Convex hull calculation is a computational geometry problem which is performed based on complex but efficient algorithms. The approach recognizes the boundary of the dataset considering the degree of data distribution.
- **Criterion:** Interpolation space is defined by the smallest convex area containing the entire training set.
- **Drawbacks:**
  - Implementing a Convex Hull can be challenging with increasing data complexity, this means that an increase in dimensions contributes to the order of complexity. Convex hull calculation is efficient for two and three dimensions. The complexity swiftly amplifies in higher dimensions. For n points and d dimensions, the complexity is of order O which can be defined as $O = [n^{[d/2]+1}]$ (Preparata & Shamos, 1991),
  - The approach only analyses the set boundaries without considering the actual data distribution, and
  - This approach cannot identify the potential internal empty regions within the interpolation space (Jaworska *et al*., 2005).

For the 'convex hull' method, the domain of applicability is the smallest axis-aligned convex region containing all the data points presented in Figure 3.

Figure 3. Convex hull plot

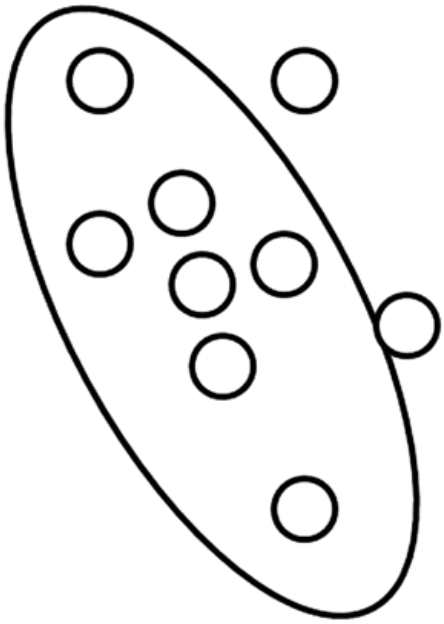
3. DISTANCE-BASED METHODS

Distance-based methods are mainly founded on the 'distance-to-centroid' principle. The ellipsoidal region is centered on the dataset grand mean and has its principal axes based on the eigenvectors of the dataset variance/covariance matrix. In Figure 4, a graphical illustration of 'distance-to-centroid' is presented.

There are various types of distance-based methods which can be used for the determination of AD of QSAR models. We have tried to represent the most commonly used distance-based AD approaches in the following sections.



3.1 Leverage Approach

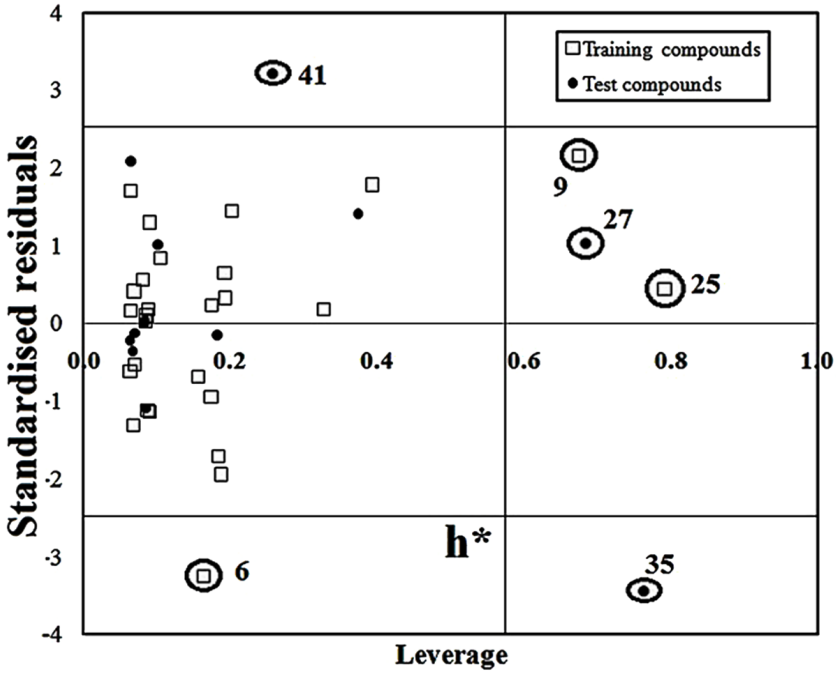
- **Theory:** The leverage (*h*) of a compound in the original variable space is calculated based on the HAT matrix as:

$$H = (X^T(X^TX)^{-1}X). \quad (1)$$

In Equation (1), H is an [n x n] matrix that orthogonally projects vectors into the space spanned by the columns of X (Eriksson *et al*., 2003; Gramatica, 2007). The AD of the model is defined as a squared area within the ±3 band for standardized residuals (σ) and the leverage threshold is defined as $h^*=3(p+1)/n$, where p is the number of variables and n is the number of compounds. The leverage values (h) are calculated for each compound and plotted vs. cross-validated standardized residuals (σ) (Y-axis) referred to as the Willam's plot.

Figure 4. Distance-to-centroid plot

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



The leverage approach assumes normal data distribution. It is interesting to point out that when high leverage points fit the model well (having small residuals), they are called good high leverage points or good influence points. Those points stabilize the model and make it more accurate. On the contrary, high leverage points, which do not fit the model (having large residuals), are called bad high leverage points or bad influence points.

- **Criteria:** Graphically, the Williams plot (mostly used for the leverage approach) verifies the presence of response outliers and training set chemicals that are structurally very influential in determining model parameters. The data predicted for high leverage chemicals in the prediction set are extrapolated and could be less reliable. Here, we have tried to simplify the concept with a pictorial representation of Williams plot in Figure 5.

It is interesting to point out that this figure has been drawn based on arbitrary data to show the every possibility of AD assessment in training and test set compounds. Assessing Figure 5, one can draw the following conclusion:

1. Compound number 6 of the training set possesses standardized cross-validated residual value greater than -3σ unit, but it lies within the critical HAT (h*) value of 0.58. This compound may have flawed observed value and it can be identified as an outlier due to a wrong value of response variable. Therefore, compound number 6 is a response outlier.
2. Compounds with serial numbers 9 and 25 belonging to the training set are characterized by high leverage values, but they lie within the fixed ±3σ limit of the ordinate. The mentioned chemicals

Figure 5. Williams plot

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

are not response outliers (not Y outliers), but influence the applicability domain to span over larger area and hence can be marked as influential chemicals or X outliers.

3. Compound number 35 belonging to the test set is wrongly predicted having standardized cross-validated residual value greater than -3σ unit) as well as completely outside of the AD as defined by HAT vertical line (higher leverage value than the critical value).
4. On the contrary, one of the test set compounds (41) belongs to AD as it lies within the critical HAT value but the prediction for this compound is not precise (greater than 3σ unit).
5. The test set compound with serial number 27 is within the ±3σ limit of the ordinate, but possess higher leverage value ($h > h^*$). As we can see from Figure 5, this compound is surrounded by other two influential training set chemicals (serial numbers 9 and 25), therefore its prediction can be assumed to be somewhat reliable or dependable though it lies outside the AD.

3.2 Euclidean Distance

- **Theory:** This is one of the major distance based AD assessment approaches. Like other distance-based approaches, it calculates the distance from every other point to a particular point in the data set. The distance scores are calculated by the Euclidean distance norm. A distance score, d_{ij}, for two different compounds X_i and X_j can be measured by the Euclidean distance norm. The Euclidean distance can be expressed by the following equation:

$$d_{ij} = \sqrt{\sum_{k=1}^{m} (x_{ik} - x_{jk})^2} \,. \tag{2}$$

The mean distances of one sample to the residual ones are calculated as follows:

$$\overline{d}_i = \sum_{j=1}^{n} d_{ij} \Big/ n-1, \tag{3}$$

where, i=1,2,….,n.

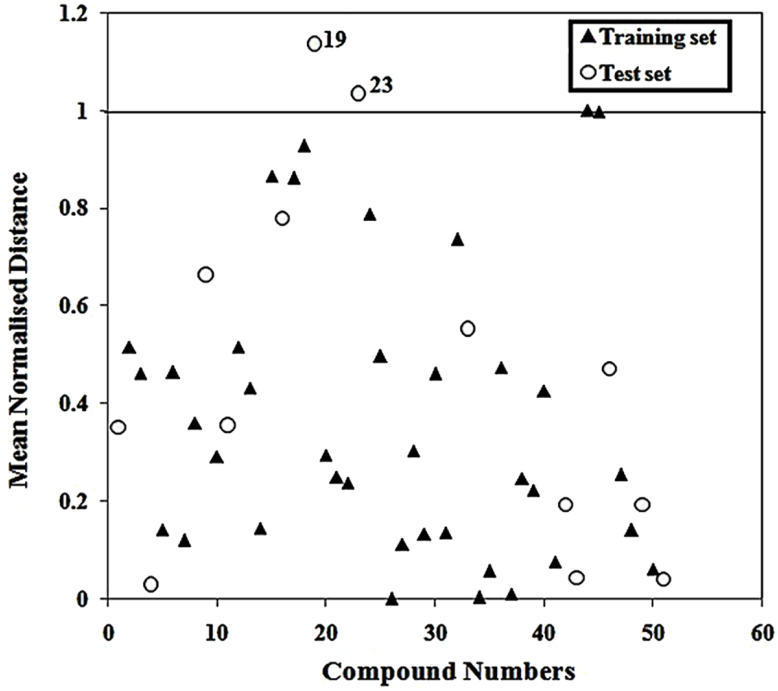
The mean distances are then normalized within the interval of zero to one. It is applicable only for statistically independent descriptors (Jaworska *et al*., 2004).

- **Criteria:** Compounds with distance values adequately higher than those of the most active probes are considered to be outside the domain of applicability. The mean normalized distances are measured for both training and test set compounds. The boundary region created by normalized mean distance scores of the training set are considered as the zone of applicability domain for test set compounds. If the test set compounds are inside the domain/area covered by the training set compounds, it means that these compounds are inside the applicability domain, otherwise not.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

An example of Euclidean plot is presented in Figure 6. Based on the assessment of the Euclidean plot, one can conclude that test set compounds 19 and 23 are outside of the applicability domain created by the training set compound from which the QSAR model has been developed.

3.3 Mahalanobis Distance



- **Theory:** The Mahalanobis distance approach considers the distance of an observation from the mean values of the independent variables but not taking the impact on the predicted value. It offers one of the unique and simple approaches for identification of outliers. Mahalanobis distance is unique because it automatically takes into account the correlation between descriptor axes (Hair *et al*., 2005).
- **Criterion:** The threshold value does not have any rule of thumb. However, observations with values much higher than those of the remaining ones may be considered to be outside the domain.

3.4 City Block Distance

City-block distance is simply the summed difference across dimensions and is calculated from the following equation:

$$d(x,y)=\sum_{i=1}^{n}\left|x_i-y_i\right|. \tag{4}$$

Figure 6. Euclidean distance plot for AD study of an arbitrary QSAR model

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

It examines the absolute differences between coordinates of a pair of objects (x_i and y_i). City-block distance assumes a triangular distribution. The method is particularly useful for the discrete type of descriptors. It is used only for training sets which are uniformly distributed with respect to count-based descriptors (or fragment mapping counts) (Jaworska *et al*., 2004).

3.5 Hotelling T^2 Test

- **Theory:** The Hotelling T^2 method is a multivariate student's *t* test and proportional to leverage and Mahalanobis distance approach. It assumes a normal data distribution like the leverage approach (Hair *et al*., 2005). The method is used to evaluate the statistical impact of the difference on the means of two or more variables between two groups. Hotelling T^2 corrects for collinear descriptors through the use of the covariance matrix. Hotelling T^2 measures the distance of an observation from the center of a set of X observations. A tolerance volume is derived for Hotelling T^2.
- **Criterion:** Based on the *t* value, the significant compounds within the domain are determined.

3.6 K-Nearest Neighbors Approach

- **Theory:** The approach is based on similarity search for a new chemical entity with respect to the space created by the training set compounds. The similarity is identified by finding the distance of a query chemical from nearest training compound or its distances from *k*-nearest neighbors in the training set. Thus, similarity to the training set molecules is significant for this approach in order to associate a query chemical with reliable prediction (Sheridan *et al*., 2004). Like other methods, descriptors are used for calculate the similarity between training and test molecules.
- **Criterion:** If the calculated distance values of test set compounds or query molecules are within the user defined threshold set by the training set molecules, then the prediction of these compounds are considered to be reliable.

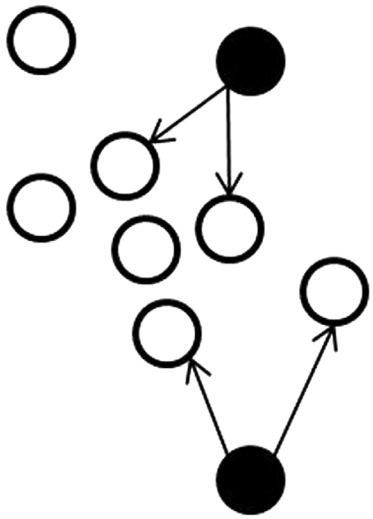
How One Can Find the Similarity to the Molecules of the Training Set

1. Considering all the descriptors, the mean similarity of a test set molecule to the most similar *k* members of the training set can be found. A variation of this is to calculate this similarity using only the subset of descriptors in the training set.
2. The similarity of the test set molecule to the descriptor centroid of the training set.

How to Decide the Neighboring Test or Query Compounds in the Training Set

1. The simplest method is to pick a similarity cutoff above which the test set molecule and a training set molecule can be considered "neighbors" and count the molecules that exceed that cutoff.
2. Another complicated approach is explained by Sheridan et al. (2004) which demonstrated that "A more complicated approach is to define a falloff function f(Similarity) that defines how much of a neighbor a training set molecule is as a function of similarity to the test set molecule. The number of neighbors is the sum of f (Similarity) over all members of the training set. For instance, we use a linear function where a molecule is 1.0 of a neighbor at similarity 1.0 and 0.0 of a neighbor at a similarity 0.6; anything between is linearly interpolated."

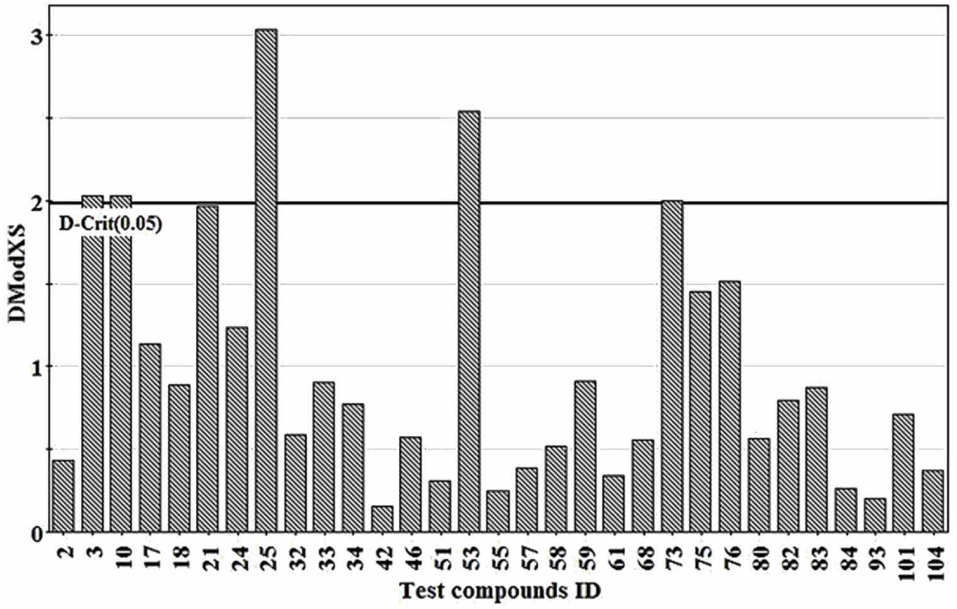
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



A k-nearest neighbors plot is presented in Figure 7, where the distance of a point to the domain is taken as the average distance to the k- nearest data points.

3.7 DModX (Distance to the Model in X-Space)

- **Theory:** This is another important distance based AD finding approach for QSAR models. This approach was developed by Wold *et al*., (2001) and usually applied for partial least squares (PLS) models. The basic theory lies in the residuals of Y and X which are of diagnostic value for the quality of the model. As there are number of X-residuals, one needs a summary for each observation. This is accomplished by the residual standard deviation (SD) of the X-residuals of the corresponding row of the residual matrix E. As this SD is proportional to the distance between the data point and the model plane in X-space, it is also usually called DModX (distance to the model in X-space). Here, X is the matrix of predictor variables, of size (N*K), Y is the matrix of response variables, of size (N*M) and E is the (N*K) matrix of X-residuals, N is number of objects (cases, observations), k is the index of X-variables (k = 1, 2,..., K) and m is the index of Y-variables (m = 1, 2,..., M).
- **Criteria:** A DModX value larger than around 2.5 times the overall SD of the X residuals (corresponding to an F-value of 6.25) indicates that the observation is outside the applicability domain of the model. In the DModX plot, the threshold line is attributed as D-critical line and this plot can be easily drawn in SIMCA-P software for any PLS model (SIMCA-P 10.0, 2002).



An example of DModX plot is presented in Figure 8 where the plot is constructed at 95% confidence level by SIMCA-P. The DModX values of 26 test compounds are within the critical value of 1.986. Chemical **10** along with the compound numbers **3**, **25**, **53** and **73** are outside the evaluated critical value indicating that these compounds are outside of the applicability domain of the developed model.

Figure 7. K-nearest neighbors plot

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 8. DModX plot for PLS based QSAR model

3.8 Tanimoto Similarity

The Tanimoto index is a measure of similarity between two molecules based on the number of common molecular fragments (Tetko *et al*., 2008). In order to calculate the Tanimoto similarity, all unique fragments of a particular length in two compounds are calculated. The Tanimoto similarity between the compounds *J* and *I* is defined as:

$$TANIMOTO\left(J,K\right)=\frac{\sum_{i=1}^{N}\left(x_{J,i}\cdot x_{K,i}\right)}{\sum_{i=1}^{N}\left(x_{J,i}\cdot x_{J,i}\right)+\sum_{i=1}^{N}\left(x_{K,i}.x_{K,i}\right)-\sum_{i=1}^{N}\left(x_{J,i}.x_{K,i}\right)} \quad (5)$$

where, *N* is the number of unique fragments in both the compounds, $x_{J,i}$ and $x_{K,i}$ are the counts of the *i*-th fragment in the compounds *J* and *K*. Based on equation 3, the distance between two compounds *J* and *K* is "*1– TANIMOTO(J, K)*" and the distance of a compound to the model is the minimum distance between the investigated compound and compounds from the training set of the model.

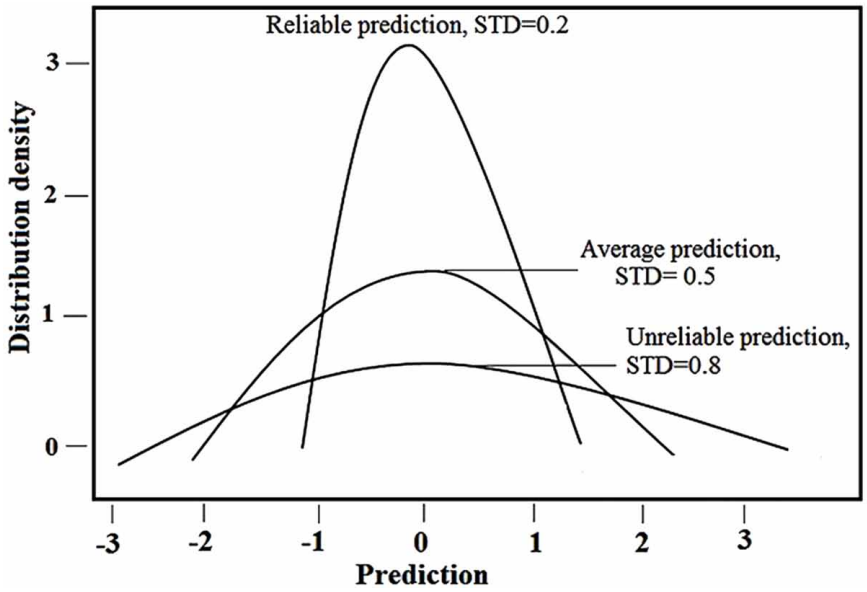
3.9 Standard Deviation of the Ensemble Predictions (STD)

In order to estimate the uncertainty of the model, standard deviation of the predictions obtained from an ensemble of models can be utilized. The basic principle behind this idea is very simple and it depicts that if different models give significantly different predictions for a particular molecule, then the prediction for this compound is more likely to be unreliable. The sample standard deviation can be ideally used as an estimator of model uncertainty.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

As an example, consider that $Y(J) = \{y_i(J), i=1..N\}$ is a set of predictions for a compound J given by a set of N trained models, the corresponding distance to model STD can be defined by the following equation:

$$d_{STD}(J) = stdev\left(Y\left(J\right)\right) = \sqrt{\frac{\sum\left(y_i\left(J\right) - \bar{y}\right)^2}{N-1}} \,. \tag{6}$$



Based on the type of an ensemble used to evaluate the standard deviation, the STD approach can be classified into several subtypes. (a) Consensus STD or CONS-STD for models developed based on different machine learning techniques, (b) Associative neural networks or ASNN-STD for an ensemble of neural network models, and (c) BAGGING-STD for an ensemble of models formed utilizing the bagging technique. The distance based method STD has been verified to provide outstanding results for discrimination of highly accurate predictions for regression models (Manallack *et al*., 2003; Tetko *et al*., 2008).

A graphical illustration of the STD approach has been given in Figure 9. Here, reliable prediction has a low prediction spread and unreliable prediction has higher prediction spread.

3.10 Correlation of Prediction Vectors (CORREL)

The basic theory of this approach is based on the correlation of vectors of ensemble's predictions for the target compound and compounds from the training set (Tetko, 2008). Similar to the STD method, this measure is relevant only for ensembles of models. More specifically, CORREL measure for the target compound J is calculated according to the following expression:

Figure 9. STD graph for AD estimation

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$d_{CORREL}\left(J\right) = 1 - \max_{i=1\ldots n}\left[corr\left(y\left(\vec{T}_i\right), y\left(\vec{J}\right)\right)\right]. \quad (7)$$

In Equation (7), $y\left(\vec{T}_i\right)$ and $y\left(\vec{J}\right)$ define the vectors of ensemble's predictions for the training set compound *Ti* and the target compound *J*, *corr* is Spearman rank correlation coefficient between the two vectors and *N* is the number of compounds in the training set. A low value of CORREL (that indicates the high Spearman correlation coefficient) specifies that for target compound *J,* there is a compound *T* from training set for which predictions of the ensemble of models are strongly correlated. If a compound *T* has the same descriptors as the target compound *J*, then predictions of models will be identical for both molecules and thus resulted *CORREL(J)* will be 0. Compounds having high correlation coefficient values are considered to be "closer to the model". The Spearman correlation outperformed several alternative measures (as e.g. Euclidean distance and Pearson correlation coefficient) due to its higher accuracy and practical requirements to store ensemble predictions for all training set molecules (Tetko & Tanchuk, 2002).

3.11 Concordance of a Classification Ensemble

The highest number or the relevant percentage of the models that produce the same prediction can be used as a measure of the concordance of an ensemble (Chen *et al*., 2005). As an example, if there are 5 models that give predictions {a; b; a; a; a}, then the concordance is 4 (or 80%). The measure that is opposite to the concordance (*i.e.* a- CONCORDANCE) can be used as a distance to model. The idea behind this method is similar to that of the standard deviation (STD) distance to model approach, but is adapted for classification models and qualitative predictions.

4. PROBABILITY DENSITY DISTRIBUTION

- **Theory:** Probability density distribution is one of the most advanced approaches for defining AD, based on estimating the probability density function for the given data. The approach is classified into two classes. The first one is a parametric method which assumes a standard distribution such as Gaussian and Poisson distributions, and the second one is a non-parametric method which does not rely on such assumptions considering the data distribution (Jaworska *et al*., 2005; Netzeva *et al*., 2005).

These methods are executed by estimating probability density of the compounds followed by identifying Highest Density Region which consists of a known fraction (as set as user input) from the total probability mass (Netzeva *et al*., 2005). A potential is formed for each compound in the training set such that it is highest for that molecule and decreases with increasing distance. Once the potential is evaluated for all the compounds, global potential is obtained by summing up the individual potentials thus indicating the probability density (Forina *et al*., 1991; Jouan-Rimbaud *et al*., 1999).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

The most important feature of these methods is their capability to identify the internal empty space. The actual data distribution can be revealed by generating concave regions around the interpolation space borders.

- **Criteria:** Here, Gaussian function is demonstrated. Given two molecules x_i and x_j, it can be determined as below:

$$\varphi = \frac{1}{\sqrt{(2\pi)}s}.\exp\left[\frac{-1}{\left(2s^2\right)\left(x_i - x_j\right)^2}\right] \tag{8}$$

where, Φ (x_i and x_j) is the potential induced on x_j by x_i and width of the curve is defined by smoothing parameter s. The cut off value associated with Gaussian potential functions, namely f_p can be calculated by methods based on sample percentile (Jouan-Rimbaud *et al*., 1999):

$$f_p = f_i + (q - j)(f_{j+1} - f_j) \tag{9}$$

with $q = p \times {}^{n}/_{100}$, where p is the percentile value of probability density, n is the number of compounds in the training set and j is the nearest integer value of q. Test compounds with potential function values lower than the set threshold are considered outside the AD.

5. RANGE OF THE RESPONSE VARIABLE

Based on the distribution plot or considering the range of the response variable, compounds can be identified as outside the AD. In a series of compounds, if the response value of a particular test compound is largely different from the mean response value of the training set compounds, then the compound can be considered as out of the AD.

6. MISCELLANEOUS APPROACHES

Along with the above-mentioned strategies to determine the AD of constructed QSAR models, there are several miscellaneous approaches introduced in the recent times. Here, we have tried to discuss these approaches briefly. The use of these approaches has been very limited compared to the classical AD methods. The below-mentioned methods are especially used for interpolation space characterization in the model descriptor space.

6.1 Stepwise Based Approach

- **Theory:** Stepwise based approach for evaluating the AD of a QSAR model is proposed by Dimitrov *et al*. (2005). This approach is useful for reflecting mechanistic rationality and transparency of the QSAR model. This approach is processed in four stages in a chronological manner. The first stage

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

"General requirements domain" consists of checking of the variation of the physicochemical properties of the query chemicals in the training set compounds. The second stage "Structural domain" defines the structural similarity which is found within the chemicals that are correctly predicted by the model. The third stage "Mechanistic domain" takes into account of the mechanistic interpretation of the modeled phenomenon to define the domain of applicability. In this third step, the model domain merges the reliability of specific functional groups assumed to cause the effect and the domain of explanatory variables. Here, the latter is defined by the parameter interpolation space. In the fourth and final stage "Domain of metabolic stimulator", if stimulated metabolism of chemicals is a part of the developed QSAR model then the dependability of simulated metabolism is considered in assessing the reliability of the predictions.

- **Criterion:** An external compound is compulsory to satisfy all the conditions specified within the mentioned four stages to be considered within the AD. The approach is considered as a rigorous one as a chemical is assessed for similarity, metabolic and mechanistic check to address the reliability of predictions and permitting a better assessment of model's AD (Dimitrov *et al*., 2005).
- **Drawback:**
  - In order to determine the AD of the QSAR model, one would need a lot of information regarding the structural attributes of compounds, mechanism of action for particular response as well as their metabolic activation. In regular practice of developing QSAR models, this is lacking in major cases.
  - The method is time consuming as well as critical as a lot of variables are involved in this AD assessment approach.

6.2 Decision Trees and Decision Forests

This approach identifies the AD in terms of prediction confidence and domain extrapolation based on the consensus prediction of Decision Trees (DT) and Decision Forests (DF). The basic principle is to minimize the overfitting which can be attained by merging the DTs and keeping the differences within different DTs to maximum possible. Predictions from all the combined DTs are averaged in order to find the prediction confidence for a particular molecule, while domain extrapolation provides the prediction precision for that compound outside the training space (Netzeva et al., 2005; Tong et al., 2003, 2004).

6.3 Kernel-Based Applicability Domain

Machine learning tools are becoming an important method to evaluate the molecular activities/properties without the help of *in vitro* experiments. The major drawback of these methods is that most of them do not provide any information using the knowledge contained in the model though they are predicted adequately by the model. As a result, in machine learning based QSAR modeling, the estimation of the reliability of a model-based prediction is an important question (Fechner *et al*., 2009).

Most machine learning approaches for QSAR heavily depend on a vectorial representation of the molecules. Thus, the applicability domain is expressed as a subspace of the vector space with one dimension for individual descriptor used. However, this vectorial concept cannot be directly applied to kernel-based techniques like support vector machines. So, these methods have to rely on an implicit feature space which is only defined by the applied kernel similarity and with unknown dimensions. Therefore the domain of applicability of a kernel-based model has to be defined by means of the kernel.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

This also permits us to employ the structured similarity measures like the Optimal Assignment Kernel and its extension, instead of a numerical encoding. This method makes it possible to depict the complex chemical structure of many drugs better than the methods which are processed by using descriptors.

The concept of kernel density estimation has incorporated additional information in a trained model. The added information can be achieved by using a weighted average kernel similarity of a predicted molecule to the training data set. The weights can be attained either by utilizing the knowledge contained in the learned model or by methods that describe the feature space structure using the kernel (Fechner *et al*., 2009).

6.4 Intelligent *K*-Means Clustering

An intelligent version of the k-means clustering algorithm-based measure of distance-to-domain for QSAR models was designed by Stanforth *et al*., (2007) to obviate the difficulties of the existing methods (like convex hull, bounding box etc.) in terms of primitiveness and computational complexity. This measure combines the modeling of the training set as a collection of the intelligent k-means clusters algorithm in the descriptor space with a new interpretation of a conventional optimization criterion in fuzzy clustering which leads to a modified harmonic mean measure. A test compound is assigned fuzzy membership of each individual cluster, from which an overall distance may be calculated. Stanforth *et al*., (2007) demonstrated that this approach is more stable than existing methods and more indicative of the prediction error.

k-Means clustering is prepared based on the approximation of each point in a dataset by the centroid of that point's cluster. This estimation can be quantified by decomposing the data scatter into contributions that are explained and unexplained by the cluster model as presented in the following equation (Mirkin, 2005):

$$\sum_{i\in T} x_i \cdot x_i = \sum_{k=1}^{k} N_k c_k \cdot c_k + \sum_{k=1}^{k} \sum_{i\in C_k} \left(x_i - c_k\right)\cdot\left(x_i - c_k\right) . \tag{10}$$

In Equation (10), $\{x_i: i \in T\}$ is the training set and the k clusters C_k have sizes N_k and centroids c_k, respectively. This suggests an optimization of the so-called square-error k-means criterion

$$\sum_{k=1}^{k} \sum_{i\in C_k} \left(x_i - c_k\right)\cdot\left(x_i - c_k\right) . \tag{11}$$

Equation 11 holds for any inner product in the descriptor space.

k-Means clustering requires an initialization step to indicate the number of clusters k and the preliminary positions of their centroids. The initialization of the intelligent k-means algorithm has been achieved by the principle of Anomalous Pattern Clustering (APC) (Mirkin, 2005; Smellie, 2004). The principle can be demonstrated in the following way.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

1. Two initial centroids are specified as follows: the first one is considered as the data gravity centre where components are grand means of the corresponding components in the entire dataset, and the second is an entity which is the furthermost away from the gravity centre.
2. It is interesting to point out that the first point (grand mean) centroid never changes, so that the only changeable centroid is the second one.

The computational complexity proved to be quite acceptable for this method. Assessment of the domain of applicability using clusters affords a much faster and easier calculation than k-NN. Not only that, this one is more prudent in terms of additional stored model parameters, without negotiating the acuity of the measure.

PRACTICAL EXAMPLES OF DETERMINATION OF AD

In order to show an example of determination of the AD for a regression based QSAR model, we have shown in Table 2 a set of hypothetical X-Y data and a correspoding QSAR model developed with multiple linear regression (MLR) tool. The model consists of three descriptors. Here, we have shown the calculation and determination of parameters most commonly used in simple AD approaches like fixed or probabilistic boundaries (bounding box), range of the response variable, leverage method and Euclidean distance based method. All these methods can be used by any QSAR researchers without help of any professional software.

1. **Leverage Approach:** Based on the calculated leverage (h) and standardized residual values, we have constructed Williams plot (Figure 10). Here, the standardized residual (SR) value is calculated based on the following equation:

$$SR = \frac{\mathrm{Re}\,sidual\ \ value - Average\ \mathrm{Re}\,sidual\,value_{(Training)}}{S\tan dard\ \ deviation\,of\ \mathrm{Re}\,sidual\,value_{(Training)}}. \tag{12}$$

Then Williams plot is constructed taking standardized values in Y-axis and leverage values in X-axis. As the number of descriptors is three and number of compounds in the training set is eleven, the critical leverage (h*) value is = [3*(3+1)]/11=1.09. Taking into consideration the criteria described in section 3.1, one can firmly conclude that based on the leverage approach for the studied QSAR model, all the query compounds are within the AD.

2. **Euclidean Distance-Based Approach:** First, Euclidean distance scores are calculated (based on Equation 2) for the total set of compounds and then the mean distance scores (based on Equation 3) are calculated. The mean distances are then normalized within the interval of zero to one. From the normalized mean distances, it is clear that not a single test compound resides outside of the AD. The Euclidean plot (Figure 11) is then developed taking the mean normalized distance in Y-axis and compound numbers in X-axis.

3. **Fixed or Probabilistic Boundaries (Bounding Box) and Range of the Response Variable:** Both approaches are strictly dependent on the boundary created by independent and response variables of the training set compounds. Scrutinizing the descriptor values for the training and test sets, one can easily identify that not a single test set compound falls outside the AD boundary created by the independent variables. On the contrary, only one compound (14) can be considered outside of the AD boundary when someone is taking in consideration the response variable range. Therefore, one can conclude that considering both methods, only one compound (14) resides outside the AD though it is lying very close to the boundary created by response variable.

While taking into consideration the above mentioned methods for the identification AD for a single QSAR model, one may remember that no single method of AD determination can be considered as the universally the best one. It may also be noted that the results of one specific method may not match with those from another approach as each method is based on different statistical algorithm for the determination of AD. Thus, multiple methods should be applied before coming to a final conclusion regarding AD of a QSAR model.

FUTURE RESEARCH DIRECTION

It is generally believed that no single AD approach can be relied as universally ideal one to identify the interpolation region for any QSAR model. Extensive and fruitful research is being carried out on the development of some new approaches or modification of already existing approaches to make them more acceptable and reliable ones. The following points should be considered in future research regarding AD studies.

1. A global similarity test should be developed to identify whether the structural features of a new external test compound are enclosed in the training set of compounds from which the QSAR model is developed.
2. There should be a conceptual framework for the assessment of AD for any QSAR model by the regulatory agencies and QSAR experts as no further modification has been done in the OECD guidelines after its establishment.
3. Some effort is needed to investigate the acceptable confidence limits for various AD approaches. Confidence limits could be a useful addition to the AD to predict the new set of compounds more confidently.
4. In order to make the AD estimation more user friendly, QSAR developers have to build up automated software tools where one can easily develop interpolation space as well as scatter plots for respective AD study.
5. There is a need of proper awareness of the AD concept and its implementation in the development of QSAR models. Without a proper AD study, no QSAR model should be accepted by the journals as well as regulatory agencies, as acceptability of any QSAR model is decidedly related with AD.
6. The QSAR model development and the assessment of AD (regarding algorithm and interpretation) should be transparent and it is the major responsibility of the model developer and the regulatory agency to make it clear to the readers and QSAR learners.

CONCLUSION

Applicability domain of a QSAR model is estimated by determining interpolation regions as defined by the training data set in model descriptor space but the region varies depending on the implemented approach. It is interesting to point out that all the implemented AD approaches have their own potential and weakness. Few methods have complex algorithms behind the identification of interpolation regions, on the contrary some have strong and easy statistical background behind the AD estimation. Therefore, it is totally dependent on the model developer how he/she chooses the specific approach according to his/her need to define the applicability domain for the model more accurately and in robust way.

The basic principle of any AD approach is to find out the number of test set compounds which are falling outside of the defined domain of applicability. It is important to note that if someone uses different AD approaches for developed QSAR model from a single dataset, the result may vary in a big way and none of these established approaches can be considered universal one. Therefore, it is always recommended to assess the results from different available possible strategies before assessing a new compound set to get the result with full confidence.

Distance-based approaches are largely used over the other approaches by QSAR developers in recent times. In case of other approaches, the number of test compounds outside the AD is much higher as they are concentrated towards the training set extremities. The distance from training space is significant in defining the model's AD for test set compounds. Again, bad predictions for test compounds are also considered as outside the AD with most of the approaches. The thresholds values are also not fixed for many approaches which may lead to vary the number of compounds outside the AD. So, these issues should be considered more carefully by the QSAR fraternity and regulatory bodies to make the AD studies more transparent and robust ones.

The following points should be considered by any QSAR model developer while considering AD studies to make his/her QSAR model more robust, predictive and reproducible:

1. The utmost important aspect of any QSAR model is its prediction capability for new set of compounds. The AD study has emerged as one of the key and compulsory validation criteria considering the reliability of predictive capability of QSAR model for a new set of compounds.
2. Considering the basic principle of AD approaches, one has to rely on the AD of the QSAR before estimating activity/property/toxicity of any chemical or pharmaceuticals by the developed QSAR model.
3. The core of AD for any specific QSAR model is the training space which is constructed by the training set of compounds. Therefore, the selection of the training set is very crucial aspect as it should consist of the characteristics of the total dataset to reflect the effect of each compound in the developed model.
4. The response value or endpoint of the QSAR model is determined experimentally. So, the reliability of these values (experiments should be performed in same condition for same endpoints) should be thoroughly checked before constructing the QSAR models. As AD is also dependent on the developed QSAR model, error in response value will mislead the QSAR model which will lead to erroneous interpolation space for AD.
5. There is always a chance of uncertainty related with the assessment of AD for any QSAR model. If the constructed QSAR model is not reliable, one cannot get confidence in AD assessment. Again,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

mechanistic aspects are rarely considered in the model development by the modeler to make the fact more uncertain one.

6. Estimation of AD by various approaches is highly dependent on a number of issues like the model dimensionality, used descriptors, response value as endpoints, underlying data distribution and last but not the least algorithm of AD determination. So, there is always a chance of large number of assumptions in the AD study.

KEY TERMS AND DEFINITIONS

3Rs: The 3Rs represent the three phrases "Reduction", "Replacement" and "Refinement". Replacement corresponds to the use of non-living materials to substitute conscious living higher animals. Reduction refers to the decrease in number of animals, and Refinement means reduction in the harshness of inhuman methodologies to be applied onto the experimental animals. *In silico* approaches like QSAR is an important alternative tool to support the 3Rs approach.

Applicability Domain: The applicability domain (AD) is a theoretical region explained by physicochemical, structural or biological space and evaluated by the model descriptors and modeled response.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

In simple explanation, AD is the knowledge or information based on which the training set of the model is constructed, and the model is applicable to make predictions for new compounds within the specific domain.

Multiple Linear Regression: Multiple linear regression (MLR) attempts to model the relationship between two or more explanatory variables and a response variable by fitting a linear equation to observed data.

Partial Least Squares: Partial Least Squares (PLS) is a generalization of regression by which strongly correlated and/or noisy or numerous X variables can be handled meticulously. The linear PLS model finds "new variables" (which can be considered as latent variables or X scores), which are linear combinations of the original ones. To avoid the problem of overfitting, a strict test for the significance of each consecutive PLS component is necessary and then stopping when the components are non-significant.

Principal Component Analysis: Principal Component Analysis (PCA) sums up all variation in X into a few more informative new variables called T scores. These new variables are linearly weighted combinations of the original X-variables. The weighting profiles are called loadings, P. For each score variable, the influence (weight) of the original variables is found by looking at its corresponding loading profile.

QSAR: Quantitative structure-activity relationship (QSAR) is a statistical modelling approach that correlates the molecular structure to a specific activity or property or toxicity derived either *in vitro* or *in vivo*. A simple mathematical relationship in any kind of QSAR method can be demonstrated as the following equation: *Biological activity = f (chemical structure or property)*. QSAR is largely used in drug discovery, environmental fate modeling, property and biological activity prediction of new, untested compounds from the molecular structures of compounds.

Randomization: Randomization is a validation technique which is performed in order to ensure the robustness of the developed QSAR model. The values of the dependent variable (Y) are randomly shuffled and new QSAR models are developed keeping the independent variable matrix unchanged. This method is of two types: process randomization and model randomization performed at varying confidence levels. The process is also known as Y-scrambling or Y-randomization technique.

Standard Deviation: Standard deviation (SD) can be defined as the measure of the deviation or dispersion of a set of data from its mean. SD can be calculated as the square root of variance.

Validation: Validation is one of the backbone steps for *in silico* models, which includes evaluation of issues such as data quality, robustness, predictability of the model and mechanistic interpretability in addition to statistical judgment. Validation strategies are largely dependent on various statistical validation metrics.

Virtual Screening: Virtual screening (VS) is a computational technique used in drug discovery to explore various existing libraries of small drug molecules in order to identify the promising structures which are most likely to bind to a drug target, especially a protein receptor or enzyme.

ABSTRACT

Molecular dynamics simulation is an important tool to capture the dynamicity of biological molecule and the atomistic insights. These insights are helpful to explore biological functions. Molecular dynamics simulation from femto seconds to milli seconds scale give a large ensemble of conformations that can reveal many biological mysteries. The main focus of the chapter is to throw light on theories, requirement of molecular dynamics for biological studies and application of molecular dynamics simulations. Molecular dynamics simulations are widely used to study protein-protein interaction, protein-ligand docking, effects of mutation on interactions, protein folding and flexibility of the biological molecules. This chapter also deals with various methods/algorithms of protein tertiary structure prediction, their strengths and weaknesses.

INTRODUCTION

It is difficult to perform each and every experiment practically. For example, before going for any mission astronauts are well trained and for that training they are exposed to similar kind of climatic conditions and difficulties that they expect to face on their mission. So, for these kinds of training the spatial conditions were imitated at small scale in the training centre of the space agency. Similarly, imitating conditions of real life is defined as modelling and simulation is used to visualise the operation of the model over time. These techniques give the idea of behaviour of real systems in different scenario and the way they would adapt to these conditions. Here main thrust area of the discussion is computational Molecular Dynamics (MD) Simulation of biological system where large scale computations are used to simulate the biological behaviour.

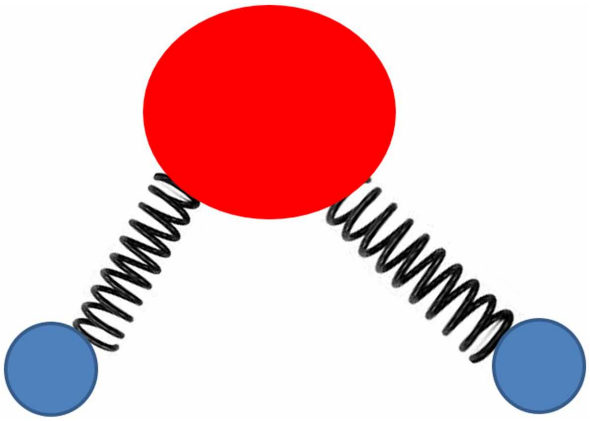
MD Simulation is an approach that gives the opportunity to explore the assemblies of molecules at microscopic level and their kinetic behaviour with time which is not possible to decipher from conventional experiments (Alder & Wainright, 1959). Biological systems are very complex and the functions of cells mainly depend on various possible interactions that further depends on its three dimensional structure (Alberts et al., 2002). Being dynamic, the functions of bio-molecules also depend on various kinds of motions (Karplus & McCammon, 2002; Wynsberghe, Van, Chen & Cui, 2008). Biological molecules exhibit a wide range of time scales over which different specific processes occur. Among these atomic fluctuations, side chain motions and loop motions come under local motions (0.01 to 5 Å) which generally takes 10^{-15} to 10^{-1} s to finish. The processes for example, helix motions, domain motions (hinge bending), and subunit motions come under rigid body motions (1 to 10Å) that generally takes 10^{-9} to 1s. Some other processes, helix coil transitions, dissociation/association and folding/unfolding come under large-scale motions (> 5Å) that takes 10^{-7} to 10^{4} s to finish. It is very difficult to visualize most of the changes that take place in very short time span, by macroscopic experiment but by mimicking the *in vivo* conditions computationally and using MD simulation, computer can save these types of changes as different frames or snapshots that can be further visualized and analyzed. Martin Karplus, Yong Duan, Peter Kollman, Arieh Warshel, Andrew J McCammon, Wilfred Gunsteren, H J C Berendsen, Andrew Leach, Michael Levitt and C.L. Brooks are the pioneers and major contributors of molecular dynamics simulation of biological molecules. In 2013, Nobel Prize was awarded to pioneers of molecular dynamics simulations: Martin Karplus, Michael Levitt and Arieh Warshel that itself said about the recognition and application of molecular dynamics simulation. The objectives of this chapter comprise explanation of the molecular dynamics simulation theories, requirement of molecular dynamics for biological studies and application of molecular dynamics simulations. Moreover this chapter also focuses on various methods/algorithms for tertiary protein structure prediction.

BACKGROUND

Alder and Wainright are pioneers of MD simulation. They introduced these techniques in late 1950's to study the interactions of hard sphere (Alder & Wainright, 1957; Alder & Wainright, 1959). Later in 1964, Rahman carried out first simulation using realistic potential for liquid argon (Rahman, 1964). In 1970s, Rahman and Stillinger used the first realistic system (liquid water) for simulation (Rahman & Stillinger, 1971). However, the first simulation on protein was performed in 1977 (McCammon, Gelin & Karplus, 1977). In 1980s rapid calculations on biomolecules, thermodynamics analyses (free energy calculations) and protein-ligand simulations were added (Wong & McCammon, 1986). In 1990s, Duan and Kollman tried to reveal the folding mechanism of smaller villin protein using molecular dynamics simulation which is considered as land-mark achievement of this field (Duan & Kollman, 1998). The NCBI contains almost 30,000 publications with key-words molecular dynamics simulations. Continuous development of potential and sampling techniques now allow us to perform the simulation to micro-second and even milli-second scale. Here it is noteworthy that in simulation these milli-second scales are supposed to be very large that contradict the real experiment because in simulation co-ordinates are generated at femto-second level. Moving from femto seconds to milli seconds scale give a large ensemble of conformations that can reveal many biological mysteries. Recently quantum mechanics (QM) combined with molecular mechanics (MM) is also being applied rapidly for the molecular interaction. Gaussian is one of the popular software that allows electronic structure modelling of the system. The

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



ONIOM package of Gaussian allows considering the molecules as different layers for extensive QM calculations of the area of interest and MM is applied for the rest part of system. GAMESS (Schmidt et al., 1993; Gordon, Dykstra, & Schmidt, 2005), Jaguar (Bochevarov et al., 2013), JDFTx (Sundararaman, Gunceler, Letchworth-Weaver & Arias, 2012), Quantum ESPRESSO (Giannozzi et al., 2009) etc. are other softwares used for QM calculations. A new addition in the simulation is Replica Exchange Molecular Dynamics (REMD) developed by Sugita and Okamoto that facilitates large sampling of energy landscape (Sugita & Okamoto, 1999). In this method, set of replica for the system was prepared and randomly initialized at different temperatures and then based on metropolis criteria the temperature was exchanged. This method is used to sample high dimensional rough energy landscape. Thus, molecular dynamics simulation can be a ray of hope to study the bio-molecules in detail. However, applying MD simulation to reveal the mysteries of biological world is not straight forward, since it requires optimal models that mimic the cellular environment, physical applications that can provide the motions to the model and large scale computations. But the development of more robust algorithm and theory for modeling, docking-scoring, energy-calculations etc. make the molecular dynamics simulation more robust. Here all these requisites are described in detail.

MOLECULAR MODELING

In molecular dynamics simulation the molecules are considered as "ball on spring" model that suits the dynamic behaviour. Various atoms are represented based on their atomic radii (Figure 1). Structure of bio-molecules can be generated in two different ways; either by supplying x, y and z coordinates followed by algorithms which are required to put right atoms at right place or by deducing the coordinates from the knowledge of the geometry of the molecules. If three dimensional structure of molecules are available as NMR or X-ray crystallography structure, it can act as model but when the structures are not available then one should look for the alternative option i.e. depend on the computational algorithm to find the reliable 3D structure.

There are 83955074 protein sequences in the latest release of UniProtKB/TrEMBL as of 1st oct 2014, while the Protein Data Bank (PDB) contained only 103735 protein structures till 30th Sep, 2014. Thus,

Figure 1. Ball and Spring model of water molecule

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

experimental structure is not available for the vast majority of protein sequences. A list of the number of different types of molecules in PDB and their experimental methods by which the structure is determined are tabulated in Table 1. Therefore, the computational prediction of structure of proteins is must to fill the gap between the protein sequences available in public domain databases and their experimentally solved structures.

Three major methods used for the modelling of molecules are as follows:

Ab-inito Method

Ab initio structure prediction predicts the native conformation of a protein from the amino acid sequence alone. *Ab initio* prediction requires a free energy function sufficiently close to the true potential for the native state having lowest free energy minima. *Ab initio* structure prediction not only needs the free energy function but also needs the method for searching conformational space for low energy minima. Potentials can be of two types which could be used in evaluating the free energy of the peptide chain and the surrounding solvent. First one is molecular mechanics potentials which models the forces that predict the protein conformation using physically based functional forms. Examples of molecular mechanics potentials are van der Waals interactions and usually represented using a standard 6–12 potential. Another example of molecular mechanics potentials is electrostatic, which are represented by Coulomb's law with partial charges derived from QM calculations on peptide substructures. Another type of molecular mechanics potentials is called protein structure-derived potentials or scoring functions which are derived from experimental structures from the PDB (Sippl, 1995).

In *ab intio* modelling searching conformational space is also a difficult and challenging task for computational biologist. Molecular dynamics is one of the methods, generally used for searching conformational space which directly integrates Newton's equations of motion to derive the motion of a molecule in a given potential. Molecular dynamics is most often used for the study of protein folding pathways (Duan & Kollman, 1998).

A variety of methods may be used to perform broad conformational space searches through low-resolution structures; including Metropolis Monte Carlo based simulated annealing (Simons, Kooperberg, Huang & Baker, 1997), evolutionary algorithms (Bowie & Eisenberg, 1994) and genetic algorithms (Pedersen & Moult, 1997). Simulated annealing (SA) (Kirkpatrick, Gelatt & Vecchi, 1983; Simons et

Table 1. Current PDB holding as on 30th Sep, 2014

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

al., 1997) is probably the most popular conformational search method. Simulated annealing initially executes high temperature Monte Carlo simulation, followed by a series of simulations subject to a temperature-lowering schedule in which conformational search efficiency is not so impressive compared to other more sophisticated methods.

A single search is unlikely to find the global minimum of the free energy landscape, and may yield a structure that could be trapped in a local minimum which needs improvements in potential functions and makes identification of the most accurate models possessing the lowest free energy i.e. global local minima.

One of the best-known ideas for *ab initio* modelling is probably the generation of tertiary protein models by assembling small fragments (mainly 9-mers) taken from the PDB library (Bowie & Eisenberg, 1994). Based on the similar concept ROSETTA was developed (Simons et al. 1997), which was extremely successful and made the fragment assembly approach popular in the research area.

Ab initio modelling methods typically generate lots of structures during the simulation. How to select appropriate models structurally close to the native state is an important and challenging issue in bioinformatics/computational biology. Model Quality Assessment Programs (MQAP) was then developed in order to select the model closest to native structure (Fischer, 2006). In general, modelling selection approaches can be classified into two types, i.e. the energy based and the free-energy based. For the energy-based model selection methods, (1) physics-based energy function; (2) knowledge-based energy function; (3) scoring function describing the compatibility between the target sequence and model structures are the major contributors.

QUARK is a one of the programme for *ab initio* protein structure prediction, which aims to construct the correct protein 3D model from amino acid sequence only. QUARK models are built from small fragments (1-20 residues long) by replica-exchange Monte Carlo simulation under the guide of an atomic-level knowledge-based force field (Xu & Zhang, 2012).

TOUCHSTONE II is another new approaches to *ab initio* protein structure prediction. In this method conformational search is accelerated by newly developed parallel hyperbolic sampling algorithm with a composite movement set used in the Monte Carlo simulation processes (Zhang, Kolinski & Skolnick, 2003).

Threading

With the rapid growth in PDB and the improvement in structure prediction methods, Template-based modelling such as homology modelling and protein threading are proved powerful and key method for protein structure prediction. However, when sequence identity falls in the twilight zone (<30%), then it becomes difficult to identify good model by homology modeling. In such cases threading is popular for giving a better solution. The term "threading" was first coined in 1991 by David Jones. Threading is also called fold recognition which uses a detailed 3-D representation of protein structure. The idea behind threading was to "thread" a sequence of amino acid side chains onto a backbone structure (a fold). Thereafter the proposed 3-D structure was evaluated by using a set of pair potentials and a separate solvation potential. Threading is one of the very few methods available which can predict the fold for a protein in the absence of an evolutionary relationship. The threading or fold recognition method relies on the observation that the number of folds in nature appears to be limited and that many different remotely homologous protein sequences adopt remarkably similar structures. For a structure prediction by threading firstly, we should have a sequence of interest and a library of templates or known structures. Then query

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

sequence is aligned with the various structural folds in the database, and then these subsequences are threaded and finally the best model is ranked with the help of suitable scoring function. Methods such as HHpred (Söding, Biegert & Lupas, 2005), MUSTER (Wu & Zhang, 2008)., Phyre2 (Kelley & Sternberg, 2009) I-TASSER and GenThreader are some of the popular threading based methods which combine homologous information with a variety of structure based information for remote homolog detection.

HHpred is the first fold recognition server which is based on the pairwise comparison of profile hidden Markov models (HMMs). Most conventional sequence search methods search sequence databases such as UniProt or the Non Redundant (NR) database while HHpred searches alignment databases, like Protein Data Bank (PDB), Structural Classification of Proteins (SCOP), Pfam, SMART, COGs and CDD. HHpred is very fast and performs uniformly well for single-domain as well as multi-domain query sequences (Söding et al., 2005). HHpred is also integrated with the prediction of domain boundaries.

MUSTER (MUlti-Sources ThreadER) is a new protein threading algorithm available as web-server which identifies the template structures from the PDB library. It generates sequence-template alignments by combining sequence profile-profile alignment with multiple structural informations such as secondary structure, structure fragment profiles, solvent accessibility, dihedral torsion angles and hydrophobic scoring matrix (Wu & Zhang, 2008).

The Phyre server is another popular threading programme which uses a library of known protein structures taken from the SCOP database and augmented with newer depositions in the PDB (Kelley & Sternberg, 2009). The sequence of each of these structures is scanned against a nonredundant sequence database and a profile constructed and deposited in the 'fold library'.

I-TASSER server (Zhang, 2008) is an on-line web-server for protein structure and function predictions. Here 3D models of the proteins are built based on multiple-threading alignments by LOMETS and iterative template fragment assembly simulations. In I-TASSER function predictions are achieved by matching the 3D models with BioLiP protein function database (Zhang, 2008).

GenThreader method uses a traditional sequence alignment algorithm to generate alignments which are then evaluated by a method derived from threading techniques where each threaded model is evaluated by a neural network in order to produce a single measure of confidence in the prediction (Jones, 1999). The speed of the method, sensitivity and very low false-positive rate makes it ideal and popular for automatically predicting the structure of all the proteins in a translated bacterial genome (proteome).

Homology Modeling

The first homology based model was constructed in 1969 when a wire and plastic models of bonds and atoms of α-lactalbumin was constructed by using the coordinates of a hen's egg-white lysozyme and followed by adjusting physically where two proteins exhibited 39% of sequence identity (Browne et al., 1969).

The main steps that are required to create a homology based model are summarized in following steps: (1) identification of templates structure for modelling (2) target-template sequence alignment; (3) building a model for the target based on the alignment, identity between template and target etc. (4) evaluation/validation of the model.

Some of these highly specialized, popular and frequently used homology based modeling tools/ softwares are summarized below:

3D-JIGSAW is a web-based server which generates 3D models for proteins based on homology of known structure. 3D models for proteins can be generated either in completely automatic mode by means

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

of a web server or by individual modules of the program which may be executed separately followed by generation of the homology model. Templates are ranked according to the query coverage, their sequence identity and their crystallographic resolution (Bates, Kelley, MacCallum & Sternberg, 2001)

ESyPred3D is an automated homology modelling web server which implements four steps of homology modelling approach including database searching to identify structure homolog, target template alignment, model building as well as optimization and model evaluation (Lambert, Léonard, De Bolle, & Depiereux, 2002). EsyPred3D program performs better alignment by using neural networks, where alignments are obtained by combining, weighting and screening the results of several multiple alignment programs.

EasyModeller is a GUI version of MODELLER homology modeling programme in the backend. It is freely available and its usage requires pre installed MODELLER, PERL as well as PYTHON. A maximum of six templates can be used in case of multi-template based modeling in EasyModeller (Kuntal, Aparoy & Reddanna, 2010). MODELLER is one of the best method known as satisfaction of spatial restraints which is motivated by NMR spectroscopy data processing. It uses a set of geometrical criteria to produce probability density functions (pdfs) for the location of each atom in the protein used for modeling.

Geno3D is an automatic web server that uses distance geometry, simulated annealing and energy minimization algorithms to build the protein 3D homology models (Combet, Jambon, Deléage, & Geourjon, 2002). Geno3D performs homology modelling in five consecutive steps: (i) identifying homologous proteins with known 3D structures by PSI-BLAST sequence similarity programme; (ii) All potential templates are displayed with an option to choose one or more than one template structure (iii) Alignment of both target and template sequences are performed; (iv) Retrieve dihedral angles and other geometrical restraints for corresponding atoms between the target and the template; (v) 3D structure prediction of the protein by distance geometry.

CPHModel is also an automatic web server where template selection is performed on the basis of profile-profile alignment which is also guided by secondary structure and exposure predictions. In the recent version, improvement in the alignment algorithm is done by structure dependant gap penalty (Nielsen, Lundegaard, Lund & Petersen, 2010).

SWISS-MODEL is another automated web server for building protein structure homology model where template identification is carried out using various options like BLAST, PSI-BLAST and HMM-HMM-based searching (Guex & Peitsch, 1997). To estimate the quality of model(s), 'Structure Assessment' section provides stereochemistry check, global model quality and local model quality estimation.

PHYSICS BEHIND MOLECULAR DYNAMICS SIMULATION

Molecular simulation is mainly based on classical or Newtonian mechanics. However as mentioned earlier now quantum mechanics are also being incorporate in MD but still it is not possible to apply quantum mechanics to the entire bio-molecules. The difference between molecular mechanics and quantum mechanics is that molecular mechanics considered atom as smallest unit whereas in quantum mechanics explicit model of electrons are considered. Here we will discuss molecular mechanics in detail. In molecular mechanics atoms together with nucleus and electrons are considered as point charge with its associated mass. The bonded interactions are represented as Hook's law (spring connected with two atoms) and modelled as harmonic oscillator, whereas non bonded interactions are represented as Coulomb's interactions (electrostatic interaction) and Lennard-Jones potential (van der Waals interaction). Force-field

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

contains the necessary building blocks for the calculation of energy and force that include bonded and non bonded interactions. Molecular mechanics force-fields are based on the four fundamental principles:

1. Born-Oppenheimer approximation: According to this approximation, speed of electrons is considered as independent from the speed of nucleus. Electrons move with much higher speed as compared to the nuclei and the nuclei are considered to be static with respect to electron.
2. Each type of bond has natural bond length and bond angle and deviation in this increases the steric energy of the system. The mathematical model of a molecule will adjust its nuclear position to yield a new geometry with lower energy according to the force-field.
3. Third principle is the set of equations that describe the potential energy of the surface of the molecule. The potential energy equations are derived from classical physics in such a way that give the best match with experimental data. After evaluating the parameters for a set they are fixed and generalized for similar compounds.
4. Fourth is the atom type that includes electronic distribution and hybridizations.
5. Generalized Force-field Equations:

$$U(\vec{R}) = \sum_{bond} K_i^{bond}(r_i - r_o)^2 + \sum_{bond} K_i^{angle}(\theta_i - \theta_o)^2 + \sum_{dihedral} K_i^{dihe}[1 + \cos(n_i\phi_i + \delta_i)] + \sum_i \sum_{j \neq i} 4\varepsilon_{ij}[(\frac{\sigma_{ij}}{r_{ij}})^{12} - (\frac{\sigma_{ij}}{r_{ij}})^6] + \sum_i \sum_{j \neq i} \frac{q_i\, q_j}{\sum r_{ij}} \quad (1)$$

In the above equations the first two terms defined the deformations in bond length and bond angle from its equilibrium position r_o and θ_o. Harmonic forms of these terms consider the correct chemical structure but it is unable to depict the chemical change e.g. bond breaking. Third term, dihedral illustrates rotation around the chemical-bond. Non-bonded interactions are described by van der Waals and electrostatic terms. Fourth term express the van der Waals' attractive and repulsive interactions in the form of Lennard Jones potential. Last term illustrates the Coulombic electrostatic potential.

Force-field has a defined set of parameters for each atom that include atomic mass, partial charge, atomic radii, equilibrium bond-length, bond angles, dihedrals, spring constant etc. Based on these parameters force-fields are able to differentiate atoms and their probable interactions. Most of the force-field e.g. AMBER (Case et al., 2014), CHARMM (Brooks et al, 1983), OPLS (Jorgensen, Maxwell & Tirado-Rives, 1996), GROMOS (Scott et al., 1999) etc. considered fixed partial charge (non-polarizable force-field) of atoms that ignores the effect of local electrostatic environment. Recently few polarizable force-fields have been developed that consider the surrounding effect of electrostatic potential either by introduction of electronic structure theory such as X-Pol (Xie & Gao, 2007) or induced dipole e.g. PIPF (Xie, Pu, Mackerell & Gao, 2007), DRF90 (Swart & Duijnen, 2006) or by considering atom as point charge carrying particle attached through spring like harmonic potential to other atoms e.g. CHARMM polarized force-field (Baker, Anisimov & Mackerell, 2012), AMBER polarized force-field (Ponder et al., 2010) etc. For, bio-molecular interactions use of polarizable force- field is still in its early stage and main reason for this is its expensive computational demand.

Newton's Law in Molecular Dynamics Simulation

Time evolution of the system in molecular dynamics simulation is determined by the Newton's law of motion.

$$F = \frac{dP}{dt} = m\frac{d^2r}{dt^2} \tag{2}$$

Various algorithms for time integration have been developed that use Newton's law and acts as an engine for molecular dynamics simulation. Few algorithms are discussed.

Verlet Algorithm

This is the most basic and most commonly used algorithm in molecular dynamics. This is actually the two third order Taylor expansion for the position r(t), one forward and another backward in time.

$$r\left(t+\Delta t\right) = r(t) + v(t)\Delta t + \frac{1}{2}a(t)\Delta t^2 + \frac{1}{6}b(t)\Delta t^3 + O(\Delta t^4) \tag{3}$$

$$r\left(t+\Delta t\right) = r(t) - v(t)\Delta t + \frac{1}{2}a(t)\Delta t^2 - \frac{1}{6}b(t)\Delta t^3 + O(\Delta t^4) \tag{4}$$

By adding above two equations

$$F = \frac{dP}{dt} = m\frac{d^2r}{dt^2} \tag{5}$$

$$r(t + \Delta t) = 2r(t) - r(t - \Delta t) + a(t)\Delta t^2 + O(\Delta t^4) \tag{6}$$

It can be clearly observed in Equation 6 that error in verlet algorithm is in the range of Δt^4. From Newton's law acceleration is force divide by mass and force is also the function of t. So, the above equation can be written as:

$$r\left(t+\Delta t\right) \cong 2r(t) - r\left(t-\Delta t\right) + \frac{\Delta t^2}{m}f(t) \tag{7}$$

The above equation is termed as Verlet equation.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Velocity Verlet Algorithm

In the verlet algorithm the velocity was not included; it was cancelled during the summation of Equation 3 and 4. However, it is not required during simulation but it is required to calculate kinetic energy that can be used to test the conservation of the total energy that verifies whether simulation is proceeding correctly or not. Velocity can be computed from the positions using following equation

$$v(t) = \frac{r(t+\Delta t) - r(t-\Delta t)}{2\Delta t} \tag{8}$$

Error associated with this equation is in the range of Δt^2 rather than Δt^4 in verlet algorithm.

Velocity verlet scheme shows better implementation of basic algorithm of Verlet. Here positions, velocities and accelerations are calculated at time (t+Δt) in the following ways

$$r\left(t+\Delta t\right) = r(t) + v(t)\Delta t + \frac{1}{2}a(t)\Delta t^2 \tag{9}$$

$$v\left(t+\frac{\Delta t}{2}\right) = v(t) + \frac{1}{2}a(t)\Delta t \tag{10}$$

$$a(t+\Delta t) = -\left(\frac{1}{m}\right)\nabla U(r(t+\Delta t) \tag{11}$$

Leap-Frog Algorithm

To overcome the error of velocity verlet, leap-frog algorithm was developed. In leap-frog algorithm, positions and velocities are calculated at interleaved time interval. Here position is integer time step while velocity is integer plus half time step.

$$v\left(t+\frac{\partial t}{2}\right) = v\left(t-\frac{\partial t}{2}\right) + \frac{f(t)}{m}\partial t \tag{12}$$

$$r(t+\partial t) = r(t) + v(t+\frac{\partial t}{2})\partial t \tag{13}$$

The disadvantage of leap-frog algorithm is that position and velocity are not calculated at same time so it is difficult to calculate total energy at any time point. However, it can be estimated from the following equation

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$v(t) = \frac{v\left(t + \frac{\partial t}{2}\right) + v\left(t - \frac{\partial t}{2}\right)}{2} \tag{14}$$

Langevin Dynamics

It is based on stochastic differential equation termed as Langevin equation. In real world the molecular system is not present in the vacuum, cellular environment causes friction and the surrounding movement may perturb the system. Langevin dynamics allows incorporations of these effects in molecular dynamics simulation. It also controls the temperature of the system. So we can say that langevin dynamics mimics the viscosity of solvent but it does not include electrostatic and hydrophobic effect of the solvent. For a system of N particles having mass M and coordinates X= X (t), the langevin equation is

$$M\ddot{X} = -\Delta U(X) - YM\dot{X} + \sqrt{2YK_{B}TMR(t)} \tag{15}$$

In the above equation notations have their standard meaning.

Velocity Initialization (Maxwell-Boltzman Distributions)

To carry out molecular dynamics simulation, we need to provide initial position and velocity. Initial position is obtained from its cartesian co-ordinates of the initial geometry of the system. Initial velocity comes from Maxwell- Boltzman Distributions for specific temperature by selecting random direction.

$$E = \frac{1}{2}mv^2 = \frac{3}{2}NK_{B}T \tag{16}$$

$$v = \frac{\sqrt{3NK_{\mathrm{B}}T}}{m} \tag{17}$$

Generally, the simulation is carried out at constant temperature. To control the temperature during simulation, the equation of motion is coupled with thermostat or heat-bath. This process allows the kinetic energy of the system to be increased if the calculated instantaneous temperature is low (i.e., heat is added to the system). It also allows the kinetic energy of the system to be decreased if the calculated temperature is high (i.e., heat is removed from the system). Berendsen method is the most common approach to control the temperature of the system. In this method, the coupling between the system and the thermostat effectively leads to control temperature by scaling the velocities of the particle at regular time interval by a factor c.

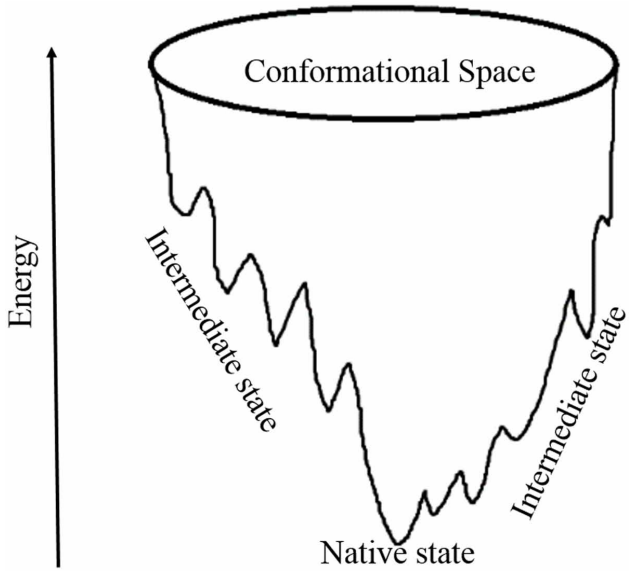
$$c = \sqrt{1 - \frac{h}{\tau}\left(1 - \frac{T_{0}}{T}\right)} \tag{18}$$

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Here h is the time step, T is the current simulation temperature, T_0 is the desired temperature, τ is an empirical constant that controls the thermostat.

However, in any constant temperature simulation the temperature exhibits fluctuations since the velocity is rescaled with time. But thermostat keeps the average temperature constant.

Energy Minimization



Energy minimization is also known as geometry optimization. Molecules can have multiple conformations and it always tends to be in lowest possible energy state that is the most stable state. If the entire conformational space is considered as energy well then there are large numbers of local minima (intermediate states) and one global minima (native state) (Figure 2). Energy minimization is mathematical expression that searches its nearest local minima by crossing the activation energy barrier.

The energy minimization depends on its initial conformation. Various algorithms are available for minimization e.g. Sander from AMBER, SD, Conjugant Gradient, ABNR from CHARMM etc. Before simulation it is required to optimize the geometry of the system.

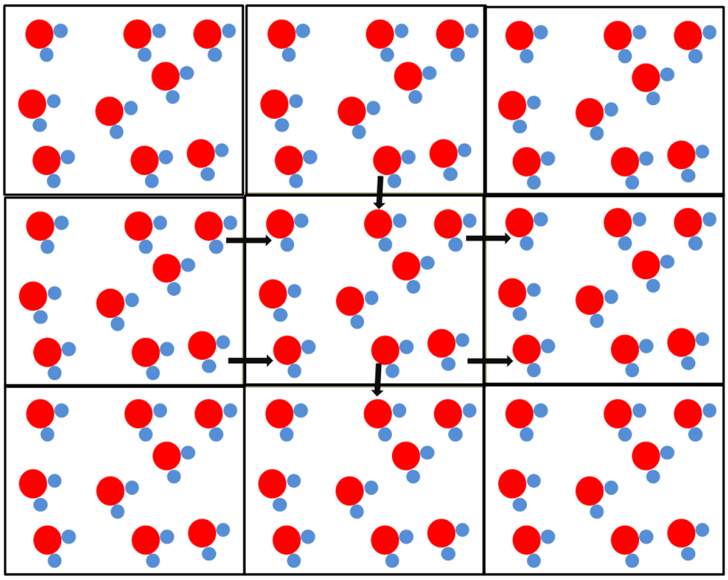
Explicit and Implicit Solvation

As discussed earlier, MD simulations are performed to mimic the real environment. To study the biomolecules, it is important to consider the cellular environment. The major portion of cell (around 75%) consists of water molecules and rest of the portions consist mainly of organic compounds (carbohydrates, proteins and lipids) but to avoid the complexity, simulation is generally carried out within the water box. Size of water box should be enough to accommodate the system to be studied. Generally for smaller proteins (around 150 AA), the cubical water box includes around eight thousands of water molecules and the number of molecule will increase for the larger system. So, computationally it is not always feasible

Figure 2. Representation of conformational space of protein. Lower energy corresponds to stable structure.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

to consider all the molecules explicitly during simulation. For that, implicit solvation model is used. In implicit solvation model mathematical expressions are used that create solvent like environment. It considers solvent as a continuous medium that can miss certain important interactions mediated by the solvent molecules but nevertheless it gives very good approximation and is used in many researches. Now-a-days, well setup labs having high performance computers (HPC) even allow explicit simulation for larger system.



Periodic Boundary Conditions (PBC)

During the simulation of system inside a box, there is a possibility that the particles can move out of the box during simulation because of the dynamicity. To avoid this, generally a trick is applied in which replica of the box were created to cover the original box from all sides and whenever the particle moved out from the central box another will enter from the adjacent replica with the same speed (Figure 3).

Particle Mesh Ewald Method

Electrostatic potential is a long range potential. But after certain distance it becomes weaker and vanishes smoothly. So, in order to reduce the calculations, cut-off can be applied to the electrostatic potential. But cut-off does not allow the smooth fall of potential because it will become zero after certain assigned distance leading to artifacts in calculation. For, that Particle Mesh Ewald method (Darden, Perera, Li, & Pedersen, 1999) was used that divide the long range electrostatic interactions into two parts: one as short range contributions and another is long range contribution. Short range contribution is calculated in real space while long range contribution is calculated using Fourier transformations. It also allows rapid convergence of energy.

Figure 3. Representation of Periodic Boundary Condition: Removal of atoms or molecules is supposed to be filled from opposite direction during Simulation.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

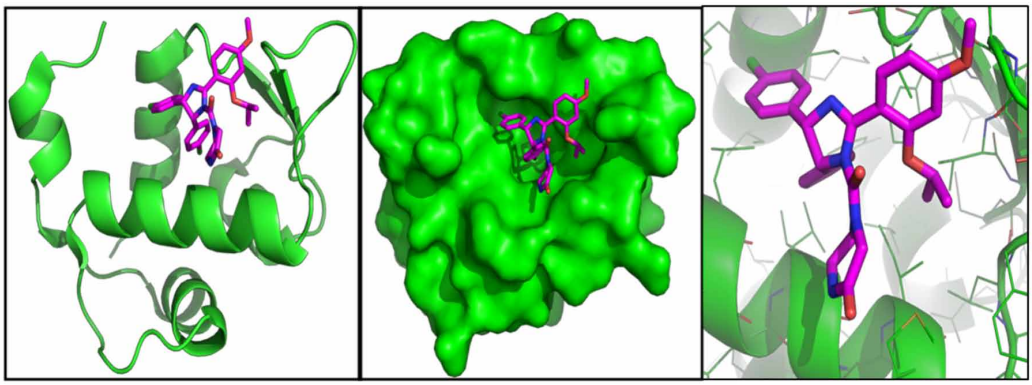
Generalized steps involved in Molecular Dynamics Simulation are as follows:

1. Protein Structure File (PSF) generation
2. Energy calculation and Minimization
3. Preparatory stage involve heating and equilibration
4. Production run
5. Analysis

Protein Structure file contain all the information that are required to apply the force-field. The information that is required to generate the PSF files (atomic connectivity and partial charge, atom type etc.) come from topology and parameter file. These topology and parameters files are specific for a force-field. For standard molecule such as protein, DNA and RNA standard topology and parameters files are available. But for small molecule that act as ligand these topology and parameters files are not available rather various servers are available e.g. CHARMM-GUI (Jo, Kim, Iyer & Im, 2008), PARAM-CHEM (Vanommeslaeghe, Raman & MacKerell, 2012) etc. that can produce these files for ligand according to their atomic arrangement. After PSF generation the geometry of the structure is optimized (remove steric clash if any) by minimization (already mentioned above). During heating the temperature of the system is linearly increased from 0 to 300 K. At each integration step the velocity is re-assigned from Maxwell Boltzmann's distribution that increases the temperature. After heating to 300 K the system was equilibrated to ensure the stability. After equilibration the production run is invoked and the actual analyses are performed on the trajectory for production run.

Analysis

The major information that can be retrieved from molecular dynamics simulation are changes of atomic level interactions that may or may not lead to change in the secondary structure, changes in binding affinity in terms of binding free energy and its components, transportation and folding of molecules etc. which further gives the clue for the cellular functions.



STRUCTURAL VISUALIZATION

Various visualization tools are available that gives the pictorial representation of atomic level interactions and how it varies with time over the trajectory of Molecular Dynamics Simulation. VMD (Visualization Molecular Dynamics) (Humphrey, Dalke & Schulten, 1996), Discovery Studio, Chimera (Pettersen et al., 2004), PyMoL (DeLano, 2002), Arguslab, Swiss-PDB-Viewer (Guex & Peitsch, 1997) etc. are example of visualization tools. The structural view gives the microscopic (atomic level) detail of the interactions among protein-protein, protein-ligand, protein-DNA etc. (Figure 4). This information also tells about the type of interaction and based on that it can further be improved or even diminished by applying proper mutation in the molecule.

This type of study has now-a-days become very popular in therapeutics. Apart from that, visualization software also tells about the secondary structure of protein that depends on the interactions. It is similar to the curling of hair: disulfide bonds formation in keratin allows curling of hair and when the interac-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 4. Different representations (cartoon, surface and lines) of protein (green colour) with ligand (magenta colour), prepared by PyMoL (visualization software). Co-ordinates were retrieved from Protein Data Bank (PDB ID: 4HG7).

tion is disrupted hair becomes straight. In many cases it was reported that the formation or disruption of certain interactions effect the secondary structure. To quantify the structural changes various kinds of time series calculations are performed that are briefly mentioned below.

TIME SERIES CALCULATION

These includes generally root-mean square deviation (RMSD), root mean square fluctuation (RMSF), radius of gyration (RGYR), surface-accessibility (SA), secondary structure (phi-psi calculations) etc. These calculations tell about the atomic and molecular level changes over time period. Root mean square deviation gives the idea whether the system is stable or not over simulation whereas root mean square fluctuations give the idea about flexibility of particular residue over time period. Radius of gyration is the measure of root mean square distance of the system from its centre of mass; this is also used to get the idea of fluctuations of the system. Surface accessibility gives the idea about which portion of the system can be reachable for the solvent based on its three dimensional conformation. In biological system solvent play important role in the interactions of the molecules and binding affinity can vary with solvent accessibility.

Thermodynamics Calculations

Theory of cellular functions and drug-designing mainly depends on the selective and specific binding of molecules. These selectivity and specificity further depends on the thermodynamics and kinetics behaviour of the system. Detail knowledge of thermodynamics give better understanding of the molecular interactions by dictating almost every physical property and also allow desired modifications for improvement of molecular activities (e.g. drug-design). It can reveal many critical scientific issues such as folding, transportation and interactions of molecules which are further responsible for cellular functions. Docking-screening and virtual screening is the most significant method to study the binding affinity of the system. In 1972, Platzer et al. have used empirical energy calculations of isolated chymotrypsin with

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

various amides that showed good correlation with the available experimental data (Platzer, Momany & Scherega, 1972). But it does not involve the kinetics behaviour of the system in contrast to the cellular environment, where molecule shows dynamic behaviour. To include the dynamicity, another approach is used to calculate the thermodynamics calculations over the trajectories obtained from simulation. From this approach, one can find out the dominating energy components (e.g. Bonded: covalent, H-bond etc. or Non-bonded: electrostatic, van der Waals etc.) and based on that, interactions can be modified (increased or decreased). These calculations are more accurate (ref- jmed chem) but computationally expensive. The statistical mechanical theory with molecular dynamics simulation has been combined to calculate the free energy and compare the binding affinity of various inhibitors of trypsin (Wong & McCammon, 1986). Lambda Dynamics (LD) method is another approach developed (Kong & Brooks, 1986) that use coupling parameter as a dynamics variable to increase the efficiency of free energy calculations. Linear Interaction Energy (LIE) is an empirical approach developed by Åqvist's group (Åqvist, Medina & Samuelsso, 1994) which was elaborated later (Lamb, Tirado-Rives & Jorgensen, 1999). In this method separate sampling of free and bound ligand were performed and the difference of van der Waals and electrostatic energies between the ligand and its surrounding was calculated. Chemical Monte Carlo / Molecular Dynamics (CMC/MD) developed by Ericksson et.al (Ericksson, Pitera & Kollman, 1999) also used for energy calculation. This is a stochastic free energy calculation and it allows the comparison of 5-10 similar kind of molecules at a time. In this method simulated system are divided into two different regions: monte carlo region and surrounding region. It is used to compare multiple side chain at a single position of protein and peptide (Pitera & Kollman, 1998). MM-PBSA is another robust approach developed by Srinivasan et. al. (Srinivasan, Cheatham, Cieplak, Kollman, & Case, 1998) that is based on the concept of LIE but here energy calculations can be performed by the sampling of only complex system. This method is widely used for the relative prediction of binding affinities (Kuhn & Kollman, 2000; Kuhn, Gerber, Schulz-Gasch, & Stahl, 2005). But if the system has large conformational change, it will miss out those important changes. For these kinds of systems, MM-PBSA is done on separate sample of complex and uncomplex. This approach also suffers high computational demand. Molecular Mechanics with Generalized Born and Solvent Accessibility (MM-GBSA) is another method to calculate binding energy by combining molecular dynamics and free energy scoring schemes (Lyne, Lamb, & Saeh, 2006; Zoete, Irving & Michielin, 2010, Rastelli, Del Rio, Degliesposti & Sgobba, 2010; Hayes et al., 2011). Poisson Boltzmann (PB) and Generalized Born (GB) used different but similar kind of mathematical equations to roughly mimic the solvent (polar and non-polar component) without considering the solvent molecule explicitly. MM-PBSA is considered as more accurate and slow over MM-GBSA. Binding energy and change in binding energy is calculated from equation (19) and (20) respectively.

$$G = E_{\text{int}\,ernal} + E_{vdw} + E_{electrosttaic} + E_{Solvation}^{Polar} + E_{Solvation}^{Nonpolar} - TS \tag{19}$$

Here, it should be noted that salvation terms also include the entropy of solvent and TS represent the entropy of solute. Entropy calculation of solute is non-trivial thing. Normal Mode Analysis (NMA) (ref) is the widely used and most appropriate methods available till now for entropy calculations. However, NMA is highly expensive method and generally it is done on few hundred frames of the sample and average values are used.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$\Delta G^{\circ}_{Binding} = < \Delta G^{\circ}_{complex} > - < \Delta G^{\circ}_{receptor} > - < \Delta G^{\circ}_{ligand} > \quad (20)$$

Free energy perturbation (FEP) and Thermodynamics integration (TI) are the methods used to calculate the absolute binding free energy. These methods are however considered as more accurate than MM-PBSA and MM-GBSA but its use is limited due to high computational demand.

COMPUTATIONAL CHALLENGES

Molecular dynamics simulation requires high performance computations. To mimic biological molecules one needs to consider the cellular environment that consists of a number of molecules and solvent. But to consider exact cellular environment computationally, is not possible because it will include huge number of atoms and molecules that is computationally not feasible and even if very efficient computation is used to consider entire molecule then the process become much complex and one is unable to get insight about all the molecules together. So, generally the system of interest is selected and solvated into virtual water box and detailed interactions is studied. To achieve global minima (native state) is also a challenge for molecular dynamics simulation, generally the system stuck in local minima although many molecules have also found to be shown its function in local minima. For this, generally the work need experimental support e.g. if the structure (NMR or crystal structure) of similar interactions are available and their binding affinity is known then one can benchmark the MD protocol by reproducing the structure or similar trends of affinity and then further proceed with those trajectory to explore the interactions (e.g. mutation can be done to improve the interaction, transition state of protein folding can be explored). If the trajectory is unable to reproduce the experimental trend for particular system then sometimes it is difficult to establish any new things based on the simulation study. But it doesn't mean that the simulation is entirely wrong, it may happen that simulation is showing something that was unexplored by experiments and it can be some clue for new kind of study and experiments. To cross-check the simulation generally independent trajectory are analyzed and average data from these independent trajectories reflect the properties of the system.

APPLICATIONS OF MOLECULAR DYNAMICS SIMULATIONS

Molecular dynamics simulations have wide applications. It is regularly used in meteorology and climatology, video games, film industries as well as in scientific world. Here major focus is to know its application to study the biomolecules. Following are the applications of molecular dynamics simulation:

Atomic Level Insight into Molecular Interactions with Time

Molecular dynamics Simulation give the dynamic pictures of atomic level insight of various biomolecular interactions. This property of MD enables to predict various possible cellular behaviours. Based on this, possible modifications of existing ligand as well as new ligands are proposed that leads us to the new era of drug-designing.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Molecular Docking

Molecular dynamics simulation is widely used to study the protein-protein, protein-ligand, DNA-protein and DNA-ligand interactions. Researchers generally want to study the effect of new kind of molecular interactions that can act as inhibitor. For this kind of study generally virtual screening or docking is performed followed by molecular dynamics simulation to know the effect of interactions with time (Alonso, Bliznyuk, & Gready, 2006). Glide (Friesner et al., 2004), Gold (Jones, Willett & Glen, 1995; Jones, Willett, Glen, Leach & Taylor, 1997), Auto-dock (Morris et al., 1998; Storiffer, Ni & McCammon, 2000), FlexX (Rarey, Kramer, Lengauer, & Klebe, 1996) etc. are well known docking softwares. Docking is a computational method to fit a molecule into other, in various possible orientation or 'pose'. The sofwares use algorithm to calculate the dock score based on the contact surface, electrostatics etc (Kroemer, 2007) and good score is supposed to have good binding affinity. In virtual screening, docking was performed for larger data and the molecule that have shown good dock score were selected for further study. It can be further studied by *in-vitro*, *in-vivo*, pre-clinical and clinical trials. As each of these processes is time taking and expensive, the docked structure can further be filtered by thermodynamics and structural analyses over the trajectories obtained from molecular dynamics simulation.

Protein Folding

Protein folding is the most mysterious aspect of biology. Anfinsen's experiment (Anfinsen, Haber, Sela & White, 1961) revealed that the three dimensional structure of protein is guided by its amino-acid sequence but the mechanism of protein-folding is still unknown. Molecular dynamics simulation was used to study the folding mechanism of small (36 amino acids) sub-domain of villin protein (Duan & Kollman, 1998). This was a landmark implementation of molecular dynamics simulation in biological field, although is computationally expensive for larger proteins but definitely a ray of hope towards the understanding of folding mechanism.

Effect of Mutation on Interactions

To know the effect of particular amino-acid in binding, the residue is mutated and comparative study of simulated trajectories (before and after mutation) is performed. From the atomic level insights into protein-ligand interactions, the modifications in the ligand can also be proposed to improve the affinity further.

Flexibility of Molecules

Flexibility of biomolecules directly regulates its intercourse, which is the key factor of cellular function. As, molecular dynamics simulation give the dynamic picture of the system so it also reflects the flexibility to some extent. There are few techniques such as Principal Component Analysis (PCA), Elastic Network Model (ENM), Anisotropic Network Model (ANM) etc. that can extrapolate the major contributing motions of the system (Bakan & Bahar, 2009).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

FUTURE RESEARCH DIRECTIONS

Molecular Dynamics Simulation has opened a wide scope of study and research on biological system (e.g. atomic level interactions, drug-designing, protein folding etc.). But the entire theory is based on the reliability of model, force-field and various analysis techniques used to perform thermodynamics calculations. Despite many established and well accepted techniques there is lots of scope for its improvement and to reduce the level of approximation. For example MM-GBSA is a widely accepted method to check the trend of the binding affinity of different ligand with proteins but the value obtained from it is some-time far from experimental data and its values are not acceptable. Development of more robust algorithms should be at the priority list in future research that can be used synergistically with other experimental data to reveal many mysterious biological happenings.

CONCLUSION

Molecular Dynamics Simulation is a technique that gives the dynamic picture of the system. Development of high performance computation (e.g. Message Passing Interface), modeling, physical applications and analyses techniques allow the molecular dynamics simulation of biological molecules such as proteins, nucleic acids, carbohydrates etc. and their interactions with each other or small molecules inhibitors. It is used to solve the mysterious biological problems that occur within femto-second to milli-second time scale (e,g. Atomic and molecular interaction, folding etc.). It also provides insights into atomic level interactions which are related to the functions of the molecule. It discloses the detail information about the contributions of various energy components in the binding of molecules that further help to improve the affinity. We can say that using appropriate model and physical applications, molecular dynamics simulation can solve the chemistry of biological event. But still lots of improvement are required to improve the algorithms which are based on various approximations. Accurate modelling is also a crucial portion of the simulation process. Various available methods for modelling were discussed. Moreover, among the tertiary structure prediction methods homology or comparative modelling is the most accurate method for structure prediction. Besides the development of algorithms and computations, the role of macroscopic (or real world) experiments could not be ignored to solve the biological mystery. Macroscopic experiment and molecular dynamics (microscopic experiment) are synergistic processes. Various macroscopic experiments (such as Ki, ΔG, IC50, EC50, energy of the system etc.) allow validating the modelled structures that can further reveal atomic level interactions, flexibility, local and global motions etc. through microscopic (molecular dynamics simulation) experiment.

Overall, the chapter explores basic concepts that can help to enhance the communications among biologist, physicist, chemist and computation experts. Thus in the present scenario the inter connection among various disciplines of science is crucial for avoiding scientific boomerang and thereby leading to sustainable development.

KEY TERMS AND DEFINITIONS

***Ab Initio* Modelling:** A de novo method to predict the protein structure by the general laws of physics and chemistry.

Drug Design: An inventive process of finding new medications based on the knowledge of a biological target.

Homology Modeling: (**Comparative Modelling):** A method to constructing an atomic-resolution *model* of the "target" protein from its amino acid sequence and an experimental three-dimensional structure of a related *homologous* protein (the "template").

Molecular Docking: "Best-fit" orientation of a ligand that binds to a particular protein of interest.

Molecular Dynamics: (MD) is a computer simulation of physical movements of atoms and molecules in the context of N-body simulation of biological systems.

Molecular Modelling: A technique for deriving, representing and manipulating the structures of molecules, which are dependent on these three dimensional structures.

Protein Threading: Method of computational protein structure prediction which is used to model those proteins which have the same fold as proteins of known structures.

ABSTRACT

A most challenging part in docking-based virtual screening is the scoring functions implemented in various docking programs in order to evaluate different poses of the ligands inside the binding cavity of the receptor. Precise and trustable measurement of ligand−protein affinity for Structure-Based Virtual Screening (SB-VS) is therefore, an outstanding problem in docking studies. Empirical post-docking filters can be helpful as a way to provide various types of structure-activity information. Different types of interaction have been presented between the ligands and the receptor so far. Based on the diversity and importance of PLIF methods, this chapter will focus on the comparison of different protocols. The advantages and disadvantages of all methods will be discussed explicitly in this chapter as well as future sights for further progress in this field. Different classifications approaches for the protein-ligand interaction fingerprints were also discussed in this chapter.

INTRODUCTION

The number of protein-ligand complex structures from both in silico and experimental methods have highly increased during the past decade. This was due to advances in structure-based drug design in pharmaceutical industry, high-throughput NMR technology, crystallography and structural genomics. In the public domain, availability of over 5000 small molecule complexes within databases is the result of many effective studies performed in this field (Deng, Chuaqui, & Singh, 2004).

Utilizing this experimental and in silico information depends highly on the ability to organize, analyze and mine the structural data, based on virtual chemical library screening (Deng et al., 2004).

The most important merit of virtual screening as a complementary approach to the traditional high-throughput screening is to give insights into molecular recognition in biological systems as well as to facilitate the design of novel therapeutics (Kelly & Mancera, 2004). However, some pitfalls are observed in virtual screening studies, which can be summarized as bellow (Scior et al., 2012):

1. **Detecting High Affinity Molecules by Virtual Screening:** Virtual screening is not considered as a successful tool for identifying high affinity substances. Since reaching highly attracted compounds to particular target is possible during the optimization process.
2. **Certainty of Inquiries:** The setting chosen to select potent materials from a large number of substances are very arbitrary and may depend on the performance of screening.
3. **An Expectation the False Binding Site:** Possibility of binding to exactly correct poses is low in fact. Actually, a few studies revealed exactly true prediction of binding modes.
4. **Predicting Water Mediated Interactions:** Possibly there is many water mediated hydrogen bonds between ligand and receptor. Prediction of count, situation and orientation of these interactions is very ambitious.
5. **Allosteric or Multiple Binding Sites vs. Single Ones:** Many receptors possess allosteric or multiple binding sites, but VS approaches are unable to predict the affinity to an allosteric binding site.

Retrieving useful and crucial information for rational drug discovery is not facile due to an overwhelming number of 3D X-ray and NMR structures. In order to perform virtual screening, these prospective ligands need to be filtered in order to reduce their number for more precise and intensive studies. (Kelly & Mancera, 2004).

Up to now, a variety of approaches have been developed to capture structural knowledge ranging from 2D ligand filters and pharmacophores to 3D interaction constraints and pharmacophoric features (Nandigam, Kim, Singh, & Chuaqui, 2009). All these methods can be used to limit poses generated from ligand receptor docking. Although analyzing a few structures by in silico methods is now considered as a usual practice, mining and making comparisons between a huge number of protein-ligand complexes needs special care such as simplification of the 3D information. Among the most useful simplification processes for analyzing protein-ligand interactions is the conversion of atomic coordinates into simpler 1D or 2D fingerprints (Desaphy, Raimbaud, Ducrot, & Rognan, 2013). Moreover, because binding information is encoded as 1D fingerprint strings, pattern identification of the fingerprints can be done using machine learning and clustering methods. This approach is beneficial in enhancing the ability to make useful implications that are not apparent by looking at individual structures (Nandigam et al., 2009).

BACKGROUND

Fingerprints are easy to generate and can manipulate, compare and, therefore, enable a systematic analysis of large data sets. They are largely used to describe and compare molecular objects (small molecular weight ligands, pharmacophores, proteins and protein-ligand binding sites) and can be used as descriptors. This feature of fingerprints makes it possible to use them by drug design programs as well as in silico screening tools. These fingerprints are frequently manipulated in either ligand based, structure

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

based and combined approaches of drug design. They can solve problems related to finding conserved interaction patterns, explain interaction features qualitatively and perform efficient post docking processing. (Desaphy et al., 2013)

Implementations of fingerprinting methods assist scoring functions to rank the predicted ligand-protein interactions in order to select those candidates that have a greater chance of success in vitro. It also permits us to perform further analyses and similarity comparisons between these structures.(Kelly & Mancera, 2004)

Different protein ligand interaction fingerprints have been developed so far. Based on this approach, the residues involved in the interaction must be determined. In the first step, it is of great importance to consider different interactions of the ligand poses within the target for generation of a suitable algorithm. (Deng et al., 2004; Singh, Deng, Narale, & Chuaqui, 2006) Different types of interaction have been presented between the ligands and the receptor. (Chourasia, Sastry, & Sastry, 2011; Crowley & Golovin, 2005; Dalkas, Teheux, Kwasigroch, & Rooman, 2014) A common interaction observed between the ligand and protein is called cation-π interactions.(Crowley & Golovin, 2005) This interaction is made between a positively charge group such as quaternary nitrogen inside ligands with aromatic side chains of the protein such as PHE or TYR. (Crowley & Golovin, 2005). In addition, the positive charge amino acids such as LYS or ARG can form this type of interaction with aromatic fragments of the ligands. Cation-pi interaction refers to a cation fragment on the axis perpendicular to aromatic ring. (Crowley & Golovin, 2005; Dalkas et al., 2014) The hydrogen bonding interaction can be formed between a hydrogen donor and an acceptor. Two distance and angle terms normally are being considered in calculation of this interaction. π-π interaction is another interaction between the aromatic fragment of the ligand and aromatic side chain. (Dalkas et al., 2014) This interaction is among the most discussed interactions in the literature. Two different types of face to face and edge to face π- π can be investigated in docking studies. (Dalkas et al., 2014) The distance between two aromatic planes centers is normally defined as 4 Å in both types. Ionic interaction is an interaction between two groups of different charges. This interaction as well as hydrophobic and metal complex interactions have only a distance criterion. (Marcou & Rognan, 2007)

The next step for generating the bit strings is highly dependent to interactions criteria. As depicted in Figure 1, each residue is represented by a seven long bit string based on the following criteria. (Singh et al., 2006)

1. Is it in contact with the ligand or not?
2. Are any main chain atoms in contact with the ligand?
3. Are any side chain atoms involved in the binding?
4. Are there any polar interactions?
5. Are there any non-polar interactions?
6. Is the residue providing hydrogen bond acceptor?
7. Is the residue providing hydrogen bond donor?

And for nine-bit strings described as 1-any contact 2-backbone 3-side chain 4-polar 5-hydrophobic 6-H-donor 7- H-acceptor 8-aromatic 9-charged interactions (Figure 2).(Mordalski, Kosciolek, Kristiansen, Sylte, & Bojarski, 2011)

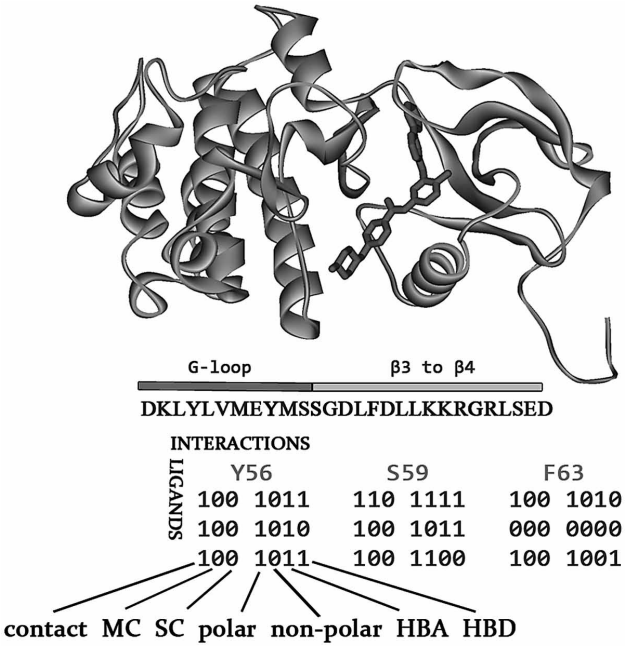

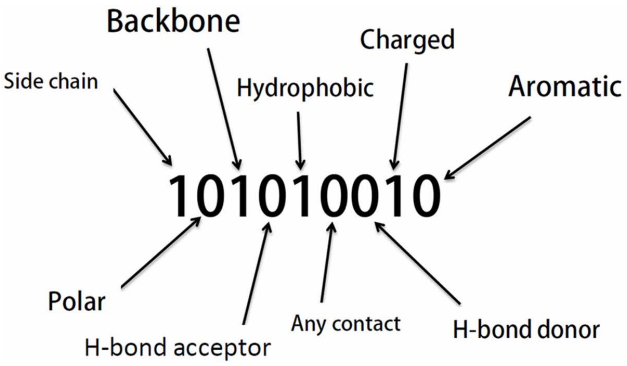

Figure 2. An example of a nine bit string

PROTEIN-LIGAND INTERACTION DESCRIPTORS

The primary methods for presenting molecular fingerprints were based upon chemical composition and structures of the molecules, First approach in ligand-protein interaction fingerprints was explained by Bajorath et al (Bajorath, 2008). The idea behind this project was that all atoms in a ligand do not take a similar role for the activity (Tan, Batista, & Bajorath, 2010). As a powerful method, interaction annotated fingerprint was more successful than the previous 2D or 3D descriptors since descriptors related to protein cavity, and those related to ligands were merged as a single fingerprint profile (Crisman, Sisay, & Bajorath, 2008). Different machine learning methods were able discriminate between true and false complex of ligand and protein (Wang et al., 2011). As an instance, this method was used in identifica-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

tion of novel ligands for oxytocin receptor and showed to be more useful than ligand based 2D and 3D descriptors (Weill et al., 2011).

Further studies by Rognan and Deng introduced two novel topological scoring methods based on molecular interaction fingerprints (IFPs). This was a novel approach to represent the properties of a ligand and a better descriptor to quantify docking success. (Deng et al., 2004; Desaphy et al., 2013)

In contrast with traditional methods based on calculating the properties of the ligands from their chemical and structural components, the structural interaction fingerprints (SIFTs) represent a ligand by its interaction in the binding site of the protein. This requires knowledge for the binding mode of each ligand inside its target protein. Basic implementation of this method has revealed effectiveness in the post processing of docking studies and as a filter during a virtual chemical library screening process. (Mordalski et al., 2011)Standard descriptors for protein cavities and their cognate ligands can also be concatenated into a single fingerprint and then used as input to train machine learning algorithms. The results can be used to discriminate true from false complexes. The structural interaction fingerprints show several promising features (Desaphy et al., 2013):

1. Enhancing the quality of pose prediction in docking experiments.
2. Clustering protein-ligand interactions for a panel of related structures according to the diversity of their interactions with a target subfamily.
   3 Assisting target-based library design.

In fact, IFPs are simple bit strings that convert 3D information of protein-ligand interactions into 1D bit vector representations that can be quickly compared with each other.

In this regard, the first step includes identification of all the residues involved in protein-ligand inter-molecular interactions. Next step is dedicated to classify the calculated interactions. Each bit can denote either the presence (1) or absence (0) of a particular discrete property such as hydrogen bond, hydrophobic or van der Waals contact. The obtained data might be utilized for ligand analysis as well describing protein binding sites and classification approaches (Nandigam et al., 2009).

Since these bit strings represent interactions between the ligand and the receptor, they can be divided as data pieces containing the contact information for all individual amino acids. In some works, seven-bit strings were used to describe those associations, while nine-bits are used in others (Desaphy et al., 2013). The fingerprint approaches are different in terms of their bit string definition and the type of interaction considered in each implementation (Desaphy et al., 2013). The initial fingerprinting approach at the residue level considered only hydrophobic and hydrogen bond contacts. This concept which was based on residues has later evolved to a new one based on the role of atoms for hydrogen-bond sites. A new concept of weighting for showing the importance of detected interactions was introduced by Kelly and Mancera (Kelly & Mancera, 2004).

The idea of this approach was to use a ligand from a co-crystal structure as a reference to score docking poses of other ligands by fingerprint similarity. The SIFT approach was shown to outperform traditional scoring functions in virtual screening and was applied successfully to cluster docking poses of individual ligands. Several extensions of the algorithms were implemented up to now, extending the accuracy of the definition of the interactions used for the fingerprint, evaluating the approach for virtual screening, scaffold docking, or the use of profile SIFTs for virtual screening (Deng et al., 2004). The largest obstacle for this approach is that a reference ligand is mandatory (Renner, Derksen, Radestock,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

& Mörchen, 2008).Docking based screening were capable of generating impressive results and many novel hits were introduced by the time being. The performance of these scoring functions can nonetheless be improved through the inclusion of tools such as clustering methods based on structural similarity.

DIFFERENT IMPLEMENTATIONS, DIFFERENT SOLUTIONS

A virtual screening can cover the ligand protein interaction for more than thousands of small molecules in a data set. The key point in performing a successful virtual screening is to comprehend the correct binding sites of the receptor as well as the most favorable binding mode for the ligand (Lyne, 2002). As described the most common method to visualize the 2D ligand-protein interaction was using softwares such as LIGPLOT (Wallace, Laskowski, & Thornton, 1995). As the number of docking poses are increasing in virtual screening studies, using other automated methods for analysis of ligand protein interactions becomes crucial (Stierand, Maaß, & Rarey, 2006). The methods must be smart enough to compare the interaction patterns of each ligand and distinguish those poses with more interactions in the active site.

Structural Interaction Fingerprints (SIFT)

This is a fingerprinting approach for mining, analyzing, organizing as well as visualizing huge number of structural binding data. The basic algorithm for generating this fingerprint is to convert structural data of ligand protein interactions in to a vector which represents every bonding as well as its nature (Deng et al., 2004). Since the binding information for each ligand is encoded as 1D string, advanced filters such as machine learning clustering methods can be implemented for further analysis of the bit strings. The statistical analysis used in any fingerprinting approach can be readily used in other methods for more comparison (Learning, 2010). In SIFT method, at first key residues that are involved in all ligand protein complexes of that target are identified. The next step includes representing all key residues by means of bit strings based on their interactions with the ligands. The first bit is the master bit which determines whether any interactions exist. The second and the third bits are related to the interactions with the main chain and the side chain, respectively. The next four bits are identifying the type of the interactions. The fourth and the fifth bits are "on" or "off" according to polar and non-polar type of the residues involved in the binding. "On" values at positions 6 and 7 of the bits are determined based on the presence of donor or acceptor functional groups in the residues (Chuaqui, Deng, & Singh, 2005). The combination of all bit strings generates a unique pattern for each complex of the ligand-protein.

In order to validate this method, docking simulations were performed by four popular docking programs (FlexX, Glide, Gold, and Surflex) for generation of poses in case of three data sets. A set of 40 compounds with low-molecular-weight from the Protein Data Bank, a collection of 40 scaffolds from protein ligands, and a database of 19 scaffolds extracted from true cdk2 inhibitors.(Deng et al., 2004)

Drugscore

Drugscore-FP is also a ligand-protein interaction fingerprint that is generated by atom score partitioning of docked inhibitors as 1D vector. Similar to the previous methods, simple distance metrics allow measuring the similarities between the fingerprints of docked structures from co-crystal structures. Furthermore, drugscore makes it possible to produce family based fingerprint profiles similar to SIFT method. The

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

profiles of interaction by drugscore identify similarities and dissimilarities related to each target. The most advantage of Drugscore-FP is that near-native-docking-poses are better identified compared to SIFT and Drugscore-CSD methods. This finding was discovered using a customized dataset by Wang et al. Finally, it was seen that drugscore can be considered as a powerful filter to recognize similar binding profiles and its efficiency was verified using cross-validation studies (Pfeffer, Neudert, & Klebe, 2008).

Based on this fingerprint many x-ray structures were studied to find out their interaction patterns, which are effective for designing inhibitors with potency and selectivity. As described, the primary fingerprinting methods presented a simple overview for the protein ligand interactions, wherein all interactions are presumed to have an equal impact. But in fact, the roles of different residues are not similar in the interactions. For example, in kinase targets the interactions at hinge regions are more important for the activity compared to those in other parts of the enzyme. This was therefore a great pitfall for fingerprinting approaches and a motivating factor for the researchers to invent new algorithms for interaction fingerprinting. To overcome this limitation, Nandigan et al presented weighted structure interaction fingerprint (w-SIFT) (Nandigam et al., 2009).

Weighted Structure Interaction Fingerprint (w-SIFT)

Based on this method the ligand-protein interactions are generated as a weighted profile in such a way that the weight of each interaction determines its importance. For example, hydrogen bonding might be different weighted from polar or non-polar interactions. Therefore, by considering the interaction data distinct from each other and determining the importance of each interaction a more realistic fingerprint can be obtained. It was also possible to consider the weight of each interaction so that a reasonable correlation between experimental activity and docking results would be obtained. These equations can be used for further analysis of drug design. To obtain the profile, the weight values must be calculated in a training set based on the correlation between experimental activity and interaction fingerprints. The weighted profile includes non-negative values within the range 0 to 1. The value, 0 belong to positions which do not have any 1 values in any of its SIFTs while 1 goes to position with at least one 1 value in that position. This type of weighting is so that those interactions which are frequently observed in high potent compounds are taking more weights. On the other hand, the interactions which are frequently observed in less active compounds are taking fewer weights in the w-SIFT profile. w-SIFTS with more weights are therefore denoting the more potent inhibitors of protein. In this method tanimoto distances are finally used to compare between different w-SIFTs (Nandigam et al., 2009).

As seen in Table 1, another version of SIFT (R-SIFT) is a fragment based method for screening combinatorial libraries.

Structural Protein-Ligand Interaction Fingerprints (SPLIF)

Another algorithm is based on calculating structural protein-ligand interaction fingerprints (SPLIF) for each docking pose and comparing it with the reference ligand-protein complex (Da & Kireev, 2014).

SPLIF presents quantitative measurement of whether a docking pose interacts with the protein target in a similar way as its known ligand and can diminish the false negative active compounds with poor initial docking scores.(Da & Kireev, 2014) A trial benchmark study of 10 diverse data sets extracted from the DUD-E database has been carried out to evaluate the ability and efficiency of this protocol. SPLIF can be considered as an interaction fingerprint with the ability to explicitly encode structural

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

information as well as capturing all types of ligand−protein interactions (e.g., stacking, polarization, cation-π, CH-π). (Da & Kireev, 2014)

In this regard, if the distances between two atoms are less than the predefined threshold, they are considered as being in contact with each other. Afterwards, for each protein-ligand pair, the protein and the ligand atoms are expanded to circular fragments. The third step is retrieving the 3D coordinates for the ligand-protein complex and assigning "on" and "off" bit for the contacts. A privilege for this type of fingerprinting compared to that discussed before is that in the previous algorithm the interactions types need to be encoded by empirical rules at each step. For example, in case of two parallel aromatic fragments a pi-pi interaction is anticipated.(Crowley & Golovin, 2005; Dalkas et al., 2014)

These types of interactions are merely considered if the specific criteria for them are accepted by the application. On the other hand, SPLIF is calculating any contacts between the receptor and the ligand. The ability to generate 3D fingerprints is nowadays implemented in many softwares (Vilar, Cozza, & Moro, 2008). These 3D fingerprints are utilized to express the binding mode of the ligand in the binding cavity of the receptor. These 3D fingerprints are useful in studying small sets of ligands. In case of virtual screening or studying the binding mode for a large data set, 1D bit strings must be taken.

In addition, due to analysis efficiency of IFs, they are considered as an important toolbox in post processing of docking results. Many softwares such as Schrodinger and MOE have implemented these criteria for analysis of docking results (Vilar et al., 2008).

Protein Ligand Interaction Fingerprint (PLIF)

This is a residue based interaction fingerprint developed by chemical computing group implemented in MOE software (Clark & Labute, 2007). The interaction fingerprint is generated by a presence or absence of 6 types of intermolecular interactions including hydrogen bond with donor side chain, hydrogen bond with side chain acceptor, hydrogen bond with backbone donor, and hydrogen bond with backbone acceptor, ionic attraction and surface contact. Each type of interaction can be defined as either weak or strong. Accordingly, for each residue a 12 bit string is encoded based on interaction type and strength. As described one of the most important applications of PLIF studies is their ability to be used in virtual screening or binding mode detection. Different interaction fingerprints have been developed so far. The efficiency and applicability of a PLIF algorithm are dependent upon the bit string definition implemented in the software (Clark & Labute, 2007).

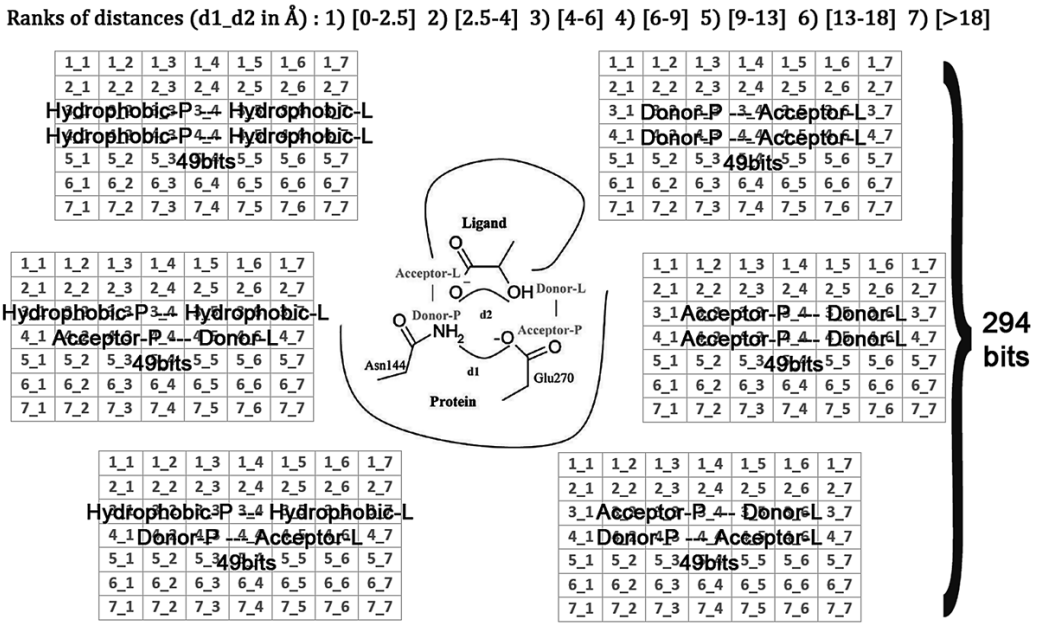
A pitfall of many fingerprint methods is that a bit is related to each active site residue atom. This limits the analysis to highly homologue active sites. To overcome this problem cavity independent fingerprinting methods have emerged (Pérez-Nueno, Rabal, Borrell, & Teixidó, 2009).

Atom Pairs Based Interaction Fingerprint (APIF)

A novel fingerprinting approach called APIF (Atom Pairs based Interaction Fingerprint) which is based on atom pairs contacts for encoding protein-ligand interaction fingerprints is an example of cavity independent fingerprinting approach (Clark & Labute, 2007).

APIF has been validated by means of enrichment factor wherein poses with a similar pattern of contact towards crystallographic data were ranked as top poses. Its application as a post processing strategy using four targets HIV protease, Carboxypeptidase, trypsin and estrogen receptor α has been revealed.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



Comparison of GOLD score and APIF by means of enrichment factor has demonstrated its applicability in docking studies (Clark & Labute, 2007).

APIF algorithm was developed in SVL language as implemented in MOE package.(Pérez-Nueno et al., 2009) To generate the 1D fingerprint, first the center site is defined based on a 10 Å radius. In the next step the interactions between the protein and the ligands are calculated. Hydrogen bond acceptor, hydrogen bond donor and hydrophobic contact features of the ligand or receptor atoms can produce 6 combination types (Figure 3). Different distance zones are also expressed in the next step. Accordingly, based on different zone clusters and contact maps a 7*7*6=294 bit string is generated for each pose of the ligand (Figure 3) (Clark & Labute, 2007).

Fingerprints for Ligand and Protein (FLAP)

FLAP is a fast and efficient algorithm for describing small molecules in the active site. It includes using a reference frame work of 4 point pharamcophores for the ligand conformations which represent the shape of the molecule in the active site. In the first step, GRID force field is used for calculation of interaction fields for identification of target location for small molecules with favorable energy values. The second step includes generation of a 4 point pharmacophore based on molecular interaction fields (MIFs). This technique can be used for comparison of protein families without aligning them or further knowledge. It can be also used for descriptor generation in chemometrics analysis as well as docking procedure. On average the optimum number of the interactions between the receptor and ligand is considered to be at least 4. The first example of using FLAP in structure based virtual screening (SBVS) was in designing ligands for xa factor, where its efficiency and speed were shown to be more than the scoring functions implemented in GOLD and GLIDE (Baroni, Cruciani, Sciabola, Perruccio, & Mason, 2007).

Figure 3. An illustration of how APIF produces a 294 bit string for each pose of the ligand

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Pharmacophore Interaction Fingerprint (Pharm-IF)

Pharm-IF is another method which calculates ligand protein interaction in three steps. In the first step, the interactions are identified in the complex of ligand and receptor. Then the interaction pairs are extracted based on pharmacophore features for each ligand. The most important interactions types in this method are hydrogen bond with ligand acceptor, hydrogen bond with ligand donor, ligand anion with ionic interaction, ligand cation, with ionic interaction and hydrophobic interactions. Similar to MOE in PLIF method it is also possible to consider the weak interactions.

Pharm-if is different from the algorithm implemented in MOE in terms of the two following criteria:

1. Hydrophobic interactions are recognized when two atoms have an overlap greater than 1% of their total surface.
2. Since it is possible that the hydroxyl groups inside either ligand or receptor take role in formation of hydrogen bonds, the role of each atom is ignored. It is believed that the superior results of this method are caused by these reasons.

Pharm-if can be considered as an extended method based on 3D geometry of ligand pharmacophores for docking poses. As a perspective, the area of research in the field of protein ligand interaction fingerprints is focused on the bellow subjects:

- The orientation of interactions (for example, hydrogen bonding from ligand or protein)
- Interaction strength
- Considering atom sites for generation of bit strings rather than residues (Sato, Honma, & Yokoyama, 2009).

As summarized in Table 1, different binding site dependent and independent methods have been developed for ligand-protein interaction fingerprints. While binding site dependent methods are very sensitive and effective, cavity independent methods can be efficient in developing structure activity relationship and virtual screening.

ANALYSIS OF THE FINGERPRINTS

After construction of the bit strings using any fingerprinting approaches for every docking poses, some methods should be recruited to measure their similarities for further analysis. Traditionally, four kinds of similarity coefficient have been used to evaluate equivalence of bit stings: 1) Euclidean distance 2) Manhattan distance 3) Tanimoto coefficient 4) Simple matching coefficient. A and B are numbers of bit sets in the two interaction finger prints and C is the number of common bits (Pérez-Nueno et al., 2009). Equation of Euclidean distance is:

$$\sqrt{A + B - 2C} \tag{1}$$

Equation of Manhattan distance is:

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$A + B - 2C \tag{2}$$

Simple matching coefficient, as called, simply shows the number of common bits in two bit strings so simple matching coefficient is C.(Pérez-Nueno et al., 2009)

Tanimoto coefficient (Tc) is the most regularly executed method to obtain similarity of bit stings among aforesaid approaches. Tc for evaluation of similarity between two sets of bits is:

$$Tc(A,B) = \quad A \cap B \; / \quad A\,UB \tag{3}$$

which $\left|\, A \cap B \,\right|$ is number of common ON bits in both A and B (previously defined as C), while $\left|\, AUB \,\right|$ is the number of bits in either A or B.(Deng et al., 2004) We can rearrange (3) as below: (Kelly & Mancera, 2004)

$$\frac{C}{A+B-C} \tag{4}$$

Since this method only considers ON bits, the results can be affected by unwanted size dependent effects. Therefor to bypass this disadvantage, Tc was developed as Modified Tanimoto coefficient (MT) (Kelly & Mancera, 2004)

To assess OFF bits, Tanimoto complement coefficient (T_0) can be defined as:

$$\frac{D}{A+B-2C+D} \tag{5}$$

where A, B and C are for the Tc and D shows the number of OFF bits in both A and B

ON bits are considered by Tc and OFF bits are considered by T_0, so by combining these two equations, modified Tanimoto (MT) is achieved as below:

$$\alpha Tc + (1-\alpha)T \tag{6}$$

where α is:

$$\frac{2-P}{3} \tag{7}$$

where P is:

$$\frac{A+B}{2n} \tag{8}$$

where n shows the total number of bits in A or B.(Kelly & Mancera, 2004)For example, in case of two bit strings 1100110 and 1010110. The calculation of similarity co-efficient for these bit strings are as below:

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Euclidean distance (1) $\rightarrow \sqrt{7+7-(2\times 3)} = 2.82$

Manhattan distance (2) $\rightarrow 7 + 7 - 6 = 8$

Simple matching coefficient = C $\rightarrow = 3$

Tanimoto coefficient (3) $\rightarrow \dfrac{3}{7+7-3} = 0.27$

Modified Tanimoto (6) $\rightarrow$ T0 $= \dfrac{2}{7+7-4} = 0.2 \rightarrow$ p $= \dfrac{7+7}{14} \rightarrow \alpha = \dfrac{2-1}{3} = 0.33 \rightarrow$ Mt $= 0.224$

Some types of scoring functions as designed for GOLD software can be obtained from Tanimoto coefficient and the original GOLD score presented by the software. According to the bellow equation:

SCORE 2 – Tanimoto = SCORE 1 – Tanimoto × GOLD score function (9)

Based on this scoring system, after docking procedure, compounds that don't have any relation to expected binding mode will be allocated (Mpamhanga, Chen, McLay, & Willett, 2006).

Clustering Methods

After calculation of similarity distances for the fingerprints in case of every docking poses, they should be subjected to further analysis.(Renner et al., 2008) One way to visualize the data is to represent them as lower-dimensional models. Projection methods are hired to represent the distribution of the poses in high dimensional descriptor space into lower dimensional ones; e.g. two dimensional.(Renner et al., 2008) There are some methods called *clustering methods* for this purpose. In other words, these methods arrange data based on their similarity.

The classification methods can be categorized as two types unsupervised (clustering methods) and supervised classification methods (Höppner, 1999).

Based on the separation patterns clustering methods can be categorized as below:

- **Well-Separated:** In this type, each cluster contains objects that are similar to each other and are completely different from the objects from another cluster. Sometimes a threshold should be considered to define rate of similarity among objects. However, this type of clusters can be utilized when data has the potential of generating natural clusters with reasonable distances. In other words, similarity distance between objects of two different clusters should be more than the distances between objects of one cluster.
- **Prototype Based:** In this type, each cluster has a prototype that is representative for other objects of its cluster. In other words members of a cluster congregate around these main objects. For continuous data, prototype is generated via a *centroid* that is calculated through averaging members of a cluster. On the contrary, for categorical data where a centroid cannot be defined, a *medoid* should be hired which is the most representative member of its cluster. Prototype based cluster is also called a center-based cluster.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

- **Graph Based:** The data are presented in a graph, where the nodes of the graph are objects of each cluster and relation between these nodes are illustrated by links. In this regard, a cluster can be defined as a connected component. In fact, a cluster contains members which are well connected with each other but completely irrelevant with members of other clusters. This type of cluster is useful when clusters are irregular and intertwined. But the pitfall of this method is that two clusters can be displayed as a merged one when noise is present in the data set. In other words, noise can play the role of a bridge between two distinct clusters.
- **Density Based:** In this type, a cluster can be defined as a dense region of data that is bordered by a region of low density. This clustering approach can be applied even when outliers and noises are present since they will be vanished into a low density region so any relation cannot be recognized between two distinct clusters.

Two of the most important tools used for clustering of docking fingerprints are presented as below: SOM –HCA – PCA – K-means – DBSCAN.(Bouvier, Evrard-Todeschi, Girault, & Bertho, 2010; Singh et al., 2006; Yan, Nie, Wang, & Wang, 2013)

Self-Organizing Map (SOM)

It is a sort of artificial neural network (ANN) presented by Kohonen, trained to organized complex, high dimensional, nonlinear data into a regular, understandable, low-dimensional (usually two dimensional) display. In other hand, this tool represents some kind of abstraction which reveals data more intelligible (Kohonen, 1998).

SOM often includes a two dimensional grid of nodes. This method orders models into a graph where similar models are closer than dissimilar ones (Kohonen, 1998).

For example YAN et al. used SOM for classification of Aurora kinase inhibitors. They collected 512 compounds of Aurora-A and -B inhibitors and classified them into three classes using Self-Organizing Map (SOM). These classes were dual Aurora-A and Aurora-B inhibitors, selective inhibitors of Aurora-A and selective inhibitors of Aurora-B. The prediction accuracy of the model (based on the training/test set splitting using SOM method) for the test set was 92.2% (Yan et al., 2013).

Hierarchical Clustering Analysis (HCA)

It's a method for clustering data as a dendrogram by state of similarity (Maimon & Rokach, 2005). This method follows two general strategy to organize the data:

- **Agglomerative:** It's a bottom-up approach that begins from each cluster and then they merge as one moves up *hierarchy.*
- **Divisive:** It's a top-down one which is started in one cluster and then divide into detailed clusters. In other words, there is an evolution from less detailed data into more ones.

A measure of dissimilarity between sets is needed for ordering clusters and deciding how clusters should be merged or divided, usually a metric measure of distance is hired (Maimon & Rokach, 2005).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

For instance, Singh et al. utilized this approach in computing the similarity metric (Tanimoto coefficient) between all of the fingerprints and then used a hierarchical clustering algorithm to group similar interaction fingerprints together (Singh et al., 2006).

There are three methods for merging of clusters in HCA:

- **Single Link (Neighbor Joining):** This method as the most common strategy calculates distance between two closest points of two neighbor clusters. This metric is then considered as distance between these clusters.
- **Average Link:** This method calculates distances between the centroids of the clusters.
- **Complete Link:** It considers distance between farthest points of two neighbor cluster.

A limitation of HCA is that it is sensitive to outlier points and some pretreatment of the data set is therefore needed before analysis.

K Means

K-means is widely utilized as a suitable clustering method. In this method at first, K cluster centroids should be defined. After that, data will be clustered by means of vicinity of two clusters centroids. This procedure is iteratively repeated until best reasonable clusters are obtained based on the selected K. Selection of K values must be done with care based on validation methods such as cross-validation. The aforementioned method can be merely utilized for numerical data and the samples should be compared using metrics such as Euclidean distance or city-block.

As seem for HCA, K-means is also sensitive to outlier points. This sensitivity can lead to disorganized cluster centroids.

The results obtained by K-means method can be inserted into a diagram called Voronoi. The cells in this diagram are called voronoi cells (Mpahnga-CHAP 8- celera).

PCA (Principal Component Analysis)

It is considered as an analysis approach for detection of patterns in the sets of data and represents data in a way which makes it possible to reveal similarities and differences between the samples.

Since finding pattern in high dimensional space is difficult, PCA can be useful in analyzing data at a low dimensional space. In other words, PCA is a tool for decreasing number of numerical data without any distract cluster structures.

In this method, major component can be determined. After that, data will be decomposed and transferred from a big high dimensional space into a lower one without loss of data.

DBSCAN (Density Based Spatial Clustering of Applications with Noise)

In this method, space should be divided into low and high density region. Number of cluster will be determined automatically by means of some special algorithms. Low density spaces will be considered as noise and should be removed. Since some parts of data will be missed, this method is not considered as a complete clustering approach. (Höppner, 1999)

APPLICATIONS OF FINGERPRINTS AND FUTURE PERSPECTIVES

Accordingly, IFs have great potentials in scaffold hopping based on the interaction pattern of the reference ligand. This feature can be used in virtual screening to find ligands with different chemotype from the reference ligands but similar interaction patterns (Venhorst, Núñez, Terpstra, & Kruse, 2008).

Two complementary tools namely Ishape and Grim have been also developed to align protein-ligand complexes based on the intermolecular interactions obtained by the described software.

While Ishape is working by the overlap of the interactions using Gaussian function, Grim is utilizing a standard detection for providing pattern graphs. The fingerprint has focused on three main areas (Desaphy et al., 2013):

- Alignment of protein-ligand complexes based on their interaction profiles.
- Making algorithms for post-processing of docking poses according to known interaction.
- Virtual screening of bioisosteric derivatives with similar interaction behaviors.

As the applicability of IF in many studies was revealed, they became popular to score and rank docking results for more accruable hit identification. Many docking programs such as DOCK are based on using energy values of electrostatic (columbic) and steric (vanderwaals) terms. Since energy values could not always explain the best pose of the ligand foot print similarity can be a useful measure for comparison between different poses. In a study performed by Balius et al. FPS (footprint similarity) was developed for DOCK software (Balius, Mukherjee, & Rizzo, 2011). Validation of FPS was done by means of pose identification, cross-docking, enrichment and virtual screening. FPS can be explained as residue based decomposition of electrostatic, steric and hydrogen bond interactions between the ligand and the protein. Generation of bit strings was designed in such a way to make a 2D pharmacophore based on contribution of each residue in the binding cavity. Calculation of FPS was according to calculation of *x*i (interaction energy between the ligand and the ith residue). Where N denotes the number of residues in the receptor ($\vec{x} = \{x1 \ldots xN\}$). Different methods such as pearson and Euclidean distance were used for comparison of the generated bit-strings (Balius et al., 2011). A feature of this method is that it is also based on energy terms compared to those methods using interactions. For example in SIFT the tanimoto comparison are being used for the bit-strings which are merely based on presence or lack of the seven type interactions for each residue. SIFT was designed to be used in library design, dataset enrichment and identification of the natural ligands.

Most scoring functions, implemented in different docking programs, are based on energy terms rather than considering the right orientation, location and geometry of the poses. It's noticeable that these scoring functions alone are not sufficient to obtain accurate energy values for ligand-protein interaction. Identification of true binding modes for the ligands is also another challenging task in docking studies. Actually, most of them are based on approximations in their calculation. Many current limitations of docking are the results of implemented solvation, entropic and electrostatic terms for different protein systems. One strategy to overcome these problems is therefore developing different algorithms for post-processing of docking simulation results.(Kelly & Mancera, 2004)

An interaction fingerprint based scoring function is AuposSOM (Mantsyzov, Bouvier, Evrard-Todeschi, & Bertho). The efficiency of AuposSOM for Surflex-Dock 2.0 from the Sybyl 1.2 package was reported. In this implementation, the contacts between the ligands and the protein include hydrophobic, hydrogen bonding and coulombic interactions. The resulted vectors of contacts will be subsequently

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

analyzed using SOM (self-organizing map) as implemented in AuposSOM software (Bouvier et al., 2010; Mantsyzov et al.). Since a bit is defined for an active site/atom/residue, the previously described methods are therefore limited to analyze interactions with highly homologous active sites sharing a fixed number of cavity-lining atoms/residues. To overcome this limitation, cavity independent fingerprints do not consider absolute but only the relative positions of pairs of protein-ligand interacting atoms. Based on this method for the case of each interaction (hydrophobic, aromatic, hydrogen bond, ionic bond, metal complexation) a psuedoatom is centered either on the interacting ligand atom, the interacting protein atom, or the geometric center of both interacting atoms. (Desaphy et al., 2013) Finally, a 210 digits fingerprint is obtained by counting all possible triplets of interaction for pseudoatoms within the six distance ranges and gathering the data of the most frequent triplets. This bit string can be used to compare any pair of protein-ligand complexes. This fingerprinting approach has been tested in case of 10 000 drug like protein-ligand complexes and made it possible to compare the interaction pattern similarity and ligand or binding site pairwise similarity. Based on this approach it was verified that the interaction pattern similarity depends on binding site similarity.

CONCLUSION

Rather than the two and three-dimensional visualization of the ligand-protein interactions, generation of bit-strings are implemented in some applications. Different protocols of protein-ligand interaction fingerprints (PLIF) have been proposed so far. While some algorithms like SIFT are dependent to the binding site of the receptor, other methods such as Pharm-IF and APIF are independent from the binding cavity. Binding site dependent methods are very sensitive and can be used for detection of the correct

Table 1. Different fingerprinting methods; used algorithms and advantages

	Method	Algorithm	Features
Binding site dependent IFP	w-SIFt (weighted IFP)	• Considering bit frequency in SIFT • Weighted profiles	• Finds interactions that are critical for compound potency • Interpretable position dependent scoring function for ligand protein interactions
	r-SIFt (R-group IFP)	• Incorporating binding information based on different fragments of a combinatorial library • Bits “on” or “off” changes based on their interaction of a ligand with either a specific R group or the core fragment	• Very sensitive and effective in separating different binding modes • Made combinatorial library analysis possible
Binding site independent IFP	APIF	• Map distance ranges for quadruplet interaction based on interaction patterns • Prepare an illustration of binding site as a 294 bits string • Calculates the fingerprints based on the relative positions of the interacting protein -ligand atom pairs	• Independent on the binding site • Comparable to current scoring functions • Showed better screening efficiency performance than the residue-based IF
	Pharm-IF	• Pharm-IF is calculated from the distances of pairs of ligand • Pharmacophore features that interact with protein atoms	• Independent on the binding site • Comparable to current scoring functions • Detected patterns of ligand pharmacophores would • Facilitate an understanding of the SAR of the target protein

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

binding mode of the ligands. On the other hand binding site independent methods can be utilized for developing pharmacophore models for the ligands. PLIF patterns can be applied in developing more 3D descriptors for QSAR analysis as well as designing post-processing filters for virtual ligand screening projects. For a more convenient analysis, classification methods should be taken to provide an overview of the similarities between different docking results. Validation results of these methods with respect to experimental data seem to be crucial in making decisions about the usefulness of any of these presented algorithms in drug design studies.

Chapter 42
Protein–Protein Docking:
Are We There Yet?

Horia Jalily Hasani
University of Alberta, Canada

Khaled H. Barakat
University of Alberta, Canada

ABSTRACT

Protein-protein docking algorithms are powerful computational tools, capable of analyzing the protein-protein interactions at the atomic-level. In this chapter, we will review the theoretical concepts behind different protein-protein docking algorithms, highlighting their strengths as well as their limitations and pointing to important case studies for each method. The methods we intend to cover in this chapter include various search strategies and scoring techniques. This includes exhaustive global search, fast Fourier transform search, spherical Fourier transform-based search, direct search in Cartesian space, local shape feature matching, geometric hashing, genetic algorithm, randomized search, and Monte Carlo search. We will also discuss the different ways that have been used to incorporate protein flexibility within the docking procedure and some other future directions in this field, suggesting possible ways to improve the different methods.

INTRODUCTION

Protein-protein interactions play key roles in several biological processes. These processes involve many essential mechanisms ranging from signal transduction and cellular transport to gene expression and immune responses. All these processes are mediated by selective and potent protein-protein interactions (Waksman & Sansom, 2005). Furthermore, many diseases have been associated with either an over-activated or an under-regulated protein-protein interaction and the cure for these diseases has been focused on either inhibiting or stimulating these interactions, respectively. For example, the p53-MDM2 interaction is associated with a severe down regulation of the p53 pathway. An inhibitor for this interaction (e.g. nutlin3) can reactivate the p53 pathway, forcing cancer cells to undergo apoptosis (Barakat, Gajewski, & Tuszynski, 2012; Barakat, Issack, Stepanova, & Tuszynski, 2011; Barakat, Mane, Friesen,

DOI: 10.4018/978-1-5225-1762-7.ch042

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

& Tuszynski, 2010; Chène, 2003; Kojima et al., 2006). The more we know about such crucial interactions, the more we can build vital protein networks and apply this knowledge to identify treatments for many diseases. Moreover, characterizing these interactions at the atomic level can help in rationally designing new therapeutic agents that can either enhance or inhibit these interactions. Constructing a three dimensional structure of such protein complexes is an essential step toward identifying their binding interface and recognizing any hot spots that can be targeted for their regulation (Elcock et al. 2001; Kann, 2007; Kortemme & Baker, 2004).

For the last few decades X-ray crystallography, nuclear magnetic resonance (NMR) spectroscopy and electron microscopy have been the main source to predict such structures. Despite their accuracy, efficiency and the huge amount of details they can provide, they are expensive and very labour and skill demanding. A simple comparison between protein structure and gene sequence databases would simply reveal the great discrepancy between the two. That is, although hundreds of thousands of gene expressions have been characterized, only less than thirty thousand protein structures have been determined so far and most of these structures are either redundant or describe only apo (unbound) proteins (Villoutreix et al., 2014). Moreover, protein complexes are more difficult to crystallize than the individual proteins, consequently, they are less represented in Protein Data Bank (PDB) (Berman et al., 2000) and constitute only a small fraction of the experimentally determined structures. This huge discrepancy and lack of structural details motivated many computational groups to fill this gap and suggest a new, rapid and cheap way to predict these interactions (Barakat & Tuszynski, 2011; Barakat, Houghton, Tyrrell, & Tuszynski, 2014; Barakat, Mane, & Tuszynski, 2011; Gógl et al., 2015; Nillegoda et al., 2015; Pedotti, Simonelli, Livoti, & Varani, 2011; Taylor et al., 2015). One solution they provided which is also the focus of this chapter is protein-protein docking.

Protein-protein docking simulations date back to the early 90s (Katchalski-Katzir et al., 1992), soon after the development of many protein-ligand docking techniques. Although the concept of docking in both cases is similar, there are still key differences that prevented the direct technology transfer between the two problems. For example, since proteins are continually dynamic and usually undergo huge structural changes, their modeling is not as easy as that of a small molecule and requires more precise predictions. Furthermore, proteins are large and have complex shapes making them harder to simulate than ligand-protein interactions (Ravikant & Elber, 2011; Sheinerman et al. 2000). On the other hand, the concept of a binding site is usually inapplicable to protein-protein interactions and in many cases proteins interact through 'hot spot' areas on their surfaces. Identifying these binding locations is particularly difficult and requires highly innovative methods. In this context, the search methods in protein-protein docking simulations are somehow different from those being used in small molecule docking (Keskin, Ma, & Nussinov, 2005). However, the reader should keep in mind that although protein-protein docking is in many ways different from protein-ligand docking, some of its reflections might be mentioned in this chapter, if applicable.

In this chapter, we will first outline the concept of docking in general, with an emphasis on the different approaches. We then briefly review the theoretical concepts, principles and specific features of the search strategies and scoring functions implemented in different programs, highlighting their strengths as well as their limitations. We will also discuss the different methods of incorporating protein flexibility within the docking procedure. After these descriptive review sections, we will guide the reader through a number of case studies and recent successes that illustrate some of the significant applications of protein-protein docking algorithms. We will also discuss the existing challenges and limitations in current algorithms and highlight some potential future directions and possible improvements in this

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

field. We hope that this brief, yet comprehensive review chapter provides researchers interested in this area with current state-of-the-art technologies in this field.

THE "DOCKING PROBLEM"

The so-called protein-protein "docking problem" refers to the task of docking two individual protein structures and predicting their biologically relevant complex. It can be classified into two different approaches; "bound docking" where two proteins from a co-crystallized complex are separated and then reassembled using a computational docking algorithm or "unbound docking" (Wiehe, Peterson, Pierce, Mintseris, & Weng, 2008) where individually solved structures of two proteins are docked together to predict their most probable mode of binding. The bound docking approach has no investigational significance, but it is frequently employed to test and validate the different docking algorithms while developing a new method. Unbound docking, on the other hand, is the approach employed by the current docking programs and is a valuable tool that can predict complexes from individual proteins for producing new knowledge at the atomic level. Unbound docking is far more complicated than bound docking. This is because the two proteins, which come together to form a complex, may undergo some conformational changes upon binding, which needs to be predicted correctly (Vakser, 2014; Ravikant & Elber, 2011). In this section, we will focus mainly on the unbound docking approach involving two different methods, namely rigid-body docking and flexible docking. Initially, we will have a closer look at these two approaches and then will focus more on rigid-body docking and its different aspects.

Rigid-body docking treats the two proteins as rigid entities. In this case, the side chains and backbone of the two interacting proteins are kept fixed with no bond angles or distances allowed to change upon docking. Although this method offers a rapid way to predict the formed complex, it completely ignores any possible conformational rearrangements that may occur upon complex formation. This sampling approach adopts a simplistic, yet structurally meaningful, technique. It projects the protein coordinates onto a low-resolution three-dimensional grid and then calculates the overlap between the two grids of the interacting proteins (Ehrlich & Wade, 2001). Flexible docking, on the other hand, takes into account such conformational changes by allowing minimal movements of the side chains or the backbone of the proteins at high resolution. Rigid-body docking includes six degrees of freedom; three translations and three rotational in the Cartesian coordinates, whereas flexible docking is usually preceded by transforming the Cartesian coordinates into internal coordinates, which involves more variables compared to rigid docking (Guo, Li, Ma, & Wang, 2013; Vakser, 2014).

It is noteworthy to mention that in many cases, no significant conformational changes take place upon the binding of the two proteins and a "lock-and-key" approach would be sufficient to address their interaction (Betts & Sternberg, 1999). This usually occurs when the two protein structures are not fluctuating too much, particularly at their binding interface. In this case, employing a rigid docking protocol to study these interactions would be adequate and can predict, with an acceptable degree of accuracy, their mode of binding. However, to predict higher resolution structural details at the interface some degree of flexibility is required, and the more protein dynamics incorporated during the docking simulation, the more structural details can be revealed. In this case, flexible docking comes into play and more details on that are described in the next sections.

It is important to emphasize the significance of incorporating experimental data within the docking procedure. This type of data not only helps in validating the docking outcomes, but also can help in

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

identifying the potential binding interface of the two proteins, reducing the search space to a manageable region (Grinter & Zou, 2014; Wodak & Méndez, 2004). In this context, a number of docking algorithms can restrict the search space to a specific region and therefore feeding these algorithms with a minimal knowledge of the binding site residues called, 'hot spots' can significantly improve the search process (Grimm et al., 2005; Grosdidier & Fernández-Recio, 2012).

DOCKING STEPS: SAMPLING AND SCORING

Within the scope of the two classes (rigid-body docking & flexible docking) discussed above, the process of docking is implemented through two main interconnected steps: *sampling* which will search for all possible binding modes between the two proteins and *scoring* for the differentiation between correct, near-correct or incorrect poses. In the following two sections, we will describe these two processes in details, giving examples of different software packages employing the different methods. We will then describe how protein flexibility is incorporated during docking and post-docking approaches. Finally, a brief evaluation of the different docking techniques will follow.

Sampling Techniques

We will begin by briefly introducing the sampling stage. The reader is referred to the references included her and the references within for a more details on this area of research. The sampling stage of docking involves generating a large number of alternative poses for the proteins by sampling all the possible binding modes. The correct prediction of the complex is more of a near-native approximation than an accurate native (co-crystalized) complex of the two proteins, which is computationally impossible to generate (Smith & Sternberg, 2002). Standard search methods are computationally expensive and lead to a huge number of solutions; most of them are physiologically irrelevant. It is for this reason more sophisticated sampling approaches and strategies are usually incorporated to correctly predict realistic solutions at this stage. This includes exhaustive global search methods as adopted by fast Fourier transform (FFT) algorithms, local shape feature matching used in geometrical hashing and genetic algorithms, randomized search employed in Monte Carlo (MC) search or Boolean operations and effective energy gradients to determine new atomic positions (Ehrlich & Wade, 2001; Huang, 2014). Table 1 lists the most commonly used software packages used for protein-protein docking with their respective sampling techniques. Although the focus of this chapter is particularly on protein-protein docking, there are a number of small-molecule docking programs optimized to become applicable to protein-protein docking and therefore, they will be discussed in various sections to illustrate the different aspects of docking.

Some recently developed and/or optimized protein-protein docking programs are DockTrina (docking triangular protein trimmers) (Popov, Ritchie, & Grudinin, 2014), ATTRACT (Vries & Zacharias, 2013), MEGA-DOCK (Matsuzaki et al., 2013), F(2)Dock 2.0 and GB-Rerank (Chowdhury et al., 2013), Swarm-Dock (Moal, Torchala, Bates, & Fernández-Recio, 2013). In addition to the programs listed in Table 1, there are numerous docking programs, which facilitate the use of docking algorithms by availing online servers. Some of them include: ClusPro (Comeau, Gatchell, Vajda, & Camacho, 2004), GRAMM-X (Tovchigrechko & Vakser, 2006), ZDOCK SERVER (B. G. Pierce et al., 2014), 3D-GARDEN (Lesk & Sternberg, 2008), PatchDock & SymmDock (Schneidman-Duhovny, Inbar, Nussinov, & Wolfson, 2005), HADDOCK (Dominguez, Boelens, & Bonvin, 2003), RosettaDock (Gray et al., 2003), FIBERDOCK

Table 1. The most commonly used protein-protein docking programs with their method of sampling

Name of Software	Method of Sampling	References
ZDOCK, FTDOCK, GRAMM, F2DOCK, DOT, Cell-Dock	FFT-correlation	(Chen et al., 2003; Gabb et al.,1997; Vakser, 1995; Bajaj et al., 2011; Mandell et al., 2001; Pons et al., 2012)
HEX, FRODOCK	FFT- Spherical Harmonics	(Ritchie & Kemp, 2000; Garzon et al., 2009)
PatchDock, LZerD	Geometric Hashing	(Duhovny et al., 2002; Venkatraman et al., 2009)
BIGGER, SKE-DOCK, SoftDock	Direct Search in Cartesian Space	Palma et al., 2000; Terashi et al., 2007; Jiang & Kim 1991)
DOCK	Distance Geometry Algorithm	(Kuntz et al., 1982)
DARWIN	Genetic Algorithm	(Taylor & Burnett, 2000)
RosettaDock, ATTRACT, ICM	Monte Carlo Search	(Gray et al., 2003; Zacharias, 2003; Fernandez-Recio et al., 2002)
HADDOCK	Based on both Biochemical/ Biophysical Information and MC Search	(Dominguez et al., 2003)

(Mashiach, Nussinov, & Wolfson, 2010), FIREDOCK (Mashiach, Schneidman-Duhovny, Andrusier, Nussinov, & Wolfson, 2008), pyDockWEB (Jiménez-García, Pons, & Fernández-Recio, 2013), pyDockSAXS (Jimenez-Garcia, Pons, Svergun, Bernado, & Fernandez-Recio, 2015) and ATTRACT web interface (Vries, Schindler, Chauvot de Beauchêne, & Zacharias, 2015).

Fast Fourier Transform (FFT) correlation approach is regarded as one of the most popular and widely used techniques of rigid-body search, developed in 1992 by Katchalski-Katzir and coworkers (1992). This technique allows an accelerated exhaustive global search of the binding orientations over six degrees of freedom in 3D translational plus 3D rotational space. The popularity and wide usage of this technique is attributed to its ability to rapidly perform an exhausted sampling of all the possible binding modes of the interacting proteins. In this method, the two proteins (receptor protein and ligand protein) are discretized onto two different 3-dimensional grids each with the size N * N * N (where N is the number of grid points), and each point on the grid with coordinates *l,m,n* is assigned a value based on its geometric characteristics (a $_{l,m,n}$). This includes a value of one for grid points on the surface of the protein, a value of zero for points outside of the protein surface and a value of ρ for points located within the protein core structure (where ρ usually has a negative value). The complementarity of shape function *C* (p,q,r) between the two proteins is then evaluated from the Equation 1, shown below:

$$C(p,q,r) = \sum_{l=1}^{N}\sum_{m=1}^{N}\sum_{n=1}^{N} R(l,m,n) \times L(l+p, m+q, n+r)$$

The translational space is then sampled by calculating a correlation between the two discrete grids. FFT correlation has been employed in a number of docking programs: FTDock (Gabb, Jackson, & Sternberg, 1997), GRAMM (Vakser, 1995), DOT (Mandell et al., 2001), ZDOCK (R. Chen & Weng, 2002), F2DOCK (Bajaj, Chowdhury, & Siddahanavalli, 2011) and Cell-Dock (Pons et al., 2012). The basic approach is the same for all of them and the difference lies in the way the proteins are projected onto the grids.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

A successful modification of the FFT algorithm is the spherical Fourier transform-based search, initially introduced in the program HEX (Ritchie & Kemp, 2000), which employs spherical harmonics to rapidly search the complete conformational space of the proteins. Another exhaustive sampling technique employs a direct search in Cartesian space to identify the correct binding mode between two proteins using 3D Cartesian grid space. This technique has been adopted in many docking packages including SOFTDOCK (Jiang & Kim, 1991), BIGGER (Palma et al., 2000), SKE-DOCK (Terashi et al.,2007). The program BIGGER (Palma et al., 2000) for example, employs a surface implicit method based on Boolean operations, in which the molecular shape of the two proteins is mapped onto a 3D grid in Cartesian space. Each point on the grid is assigned a value of '1' if it is on the protein core and a '0' if it is outside. Geometric fitting between the two proteins is then performed by shape matching directly in the Cartesian space. The advantage of this technique over FFT-based methods is the ability to have more control over the search process because of the direct operation in Cartesian space, which allows inclusion of protein flexibility and biological information (Huang, 2014).

Geometric hashing techniques are another type of global protein-protein docking search using a shape-explicit algorithm. The technique is based on finding a set of shape descriptors on the molecular surface of the proteins (one of them called the receptor and the other the ligand). Following that, a set of local coordinate frames is defined, for which the positions of nearby critical points are used as indices hashed into a table. The hash table stores the current coordinate frame of each protein. After superimposing the local coordinate frames of the ligand and the receptor, the positions of the critical points of the ligand in proximity of the receptor are then used to scan the hash table for the corresponding ligand reference frames (Smith & Sternberg, 2002). Several programs employ different shape descriptors. For example patch descriptors are used in PatchDock (Duhovny, Nussinov, & Wolfson, 2002) and 3D Zernike descriptors are adopted by LZerD (Venkatraman, Yang, Sael, & Kihara, 2009). High shape similarity is revealed by the frequency of correspondences to a specific frame. The method has been improved by introducing surface softness as a tolerance value of about 1.5 A in the coordinates.

Genetic algorithm is the basis for a number of other successful docking algorithms. This generally involves a real-space search method, which is based on a local shape feature matching. The DARWIN (J. S. Taylor & Burnett, 2000), for example, includes a solvent accessible area (SAA) for the proteins with normals, surface curvature and associated hydrogen bonding character. The complementarity between the curvatures and normals are scanned for the two proteins to find the most probable binding mode. The 'chromosome' of the genetic algorithm (GA) consists of the relative positions and orientations of the molecules (6D space).

Randomized search is another broad category of sampling techniques. Monte Carlo (MC) search is one of the approaches in which sampling of all possible conformations with a technique like FFT correlation is replaced with a random approach. As such, random translational and rotational orientations for the two proteins are performed and the final positions are selected based on a Metropolis criterion. This is then followed by a multistage optimization of the side-chains and rigid-body orientations based on MC simulations (Gray et al., 2003). The advantages of MC methods over FFT methods includes the allowance of more physical decoy distribution, arbitrary energy functions and structural flexibility to some additional extent (Lorenzen & Zhang, 2007). RosettaDock (Gray et al., 2003) is an efficient protein-protein docking software that is based on the MC method. Some other software based on randomized search are HADDOCK (Dominguez et al., 2003), ICM-DISCO (Fernandez-Recio, Totrov, & Abagyan, 2002) and ATTRACT (Zacharias, 2003).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

More recent practical successes in sampling techniques, include the recent work of Zhang et al. (2015), who identified a variation of MC search for the RosettaDock package to improve the sampling stage towards a more efficient identification of the near native docking geometries. This variation involves combining the well-tempered ensemble method with a 2-dimensional temperature and Hamiltonian replica exchange scheme (WTE-REMC). A comparative study of the results from different docking protocols of Rosetta, using the same set of targets has shown the enhanced performance of WTE-REMC in exploring the phase space.

HADDOCK (High Ambiguity Driven Protein-Protein Docking) software (Dominguez et al., 2003) is implemented with a different scheme for the randomized search process. It employs a data-driven approach and supports various types of biochemical and/or biophysical data sets such as chemical shift perturbation data from NMR titration experiments or mutagenesis data. HADDOCK is able to handle almost full flexibility (side-chain and backbone) and incorporate explicit water during the modeling process. In addition, the software provides a user-friendly web server (De Vries, Van Dijk, & Bonvin, 2010), which is accessible through four interfaces: Easy, Expert, Guru and parameter file upload interfaces, for different levels of expertise and type of application allowing more control and modification on the docking process. Several CAPRI experiments (Janin, 2013), have confirmed the profound ability of HADDOCK in precise predictions of protein-protein complexes based on experimental information. In addition it is stated that HADDOCK has generated about 70 protein-protein complexes in PDB (Grosdidier & Fernández-Recio, 2012).

Scoring Functions

The large numbers of possible conformations (poses) generated from the sampling stage are ranked using a scoring function that involves the assessment of the overall favorability of a protein-protein complex and/or a score between the two proteins in the bound form. The final docking results comprise of the top ranked complexes, which are in order of their binding score (Huang, 2014). These different scoring methods can be categorized into different groups based on the basis they are derived from; for example the *forcefield-based* scoring functions employ non-bonded interaction terms as the scoring method. *Empirical* scoring functions, on the other hand make use of regression methods to differentiate between the different poses. *Knowledge-based* scoring functions use statistical atom pair potentials from the structural databases as the scoring method. Yet, another category is the *heuristic* scheme of scoring, which makes use of chemical scores or geometrical scores such as contact/surface scores, or shape complementarity scores (Ehrlich & Wade, 2001; Muegge & Rarey, 2001)

Docking programs use different scoring functions that largely vary from one algorithm to the other. Usually, a docking program makes use of a composition of different scoring functions to increase the efficacy and accuracy of the ranking process. For instance, although shape complementarity between the interacting proteins is regarded as a simple, inexpensive and powerful scoring function, it does not necessarily distinguish near-native from non-native complexes and is thus combined with other functions such as electrostatic field, hydrophobic complementarity, desolvation free energy, etc. (Szilagyi et al., 2005). An example of implementing such composite scoring functions is the ZDOCK program (R. Chen & Weng, 2002). FTDOCK (Gabb et al., 1997) and DOT (Mandell et al., 2001), which combine electrostatic and geometric scores but in different ways. FTDOCK uses geometric matching in the initial stage and then filters the docked poses based on their electrostatics scores in later stages. In the DOT algorithm, two types of scoring methods are used in conjunction. The GRAMM package performs the

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

scoring through a geometric surface matching approach by involving the hydrophobic contacts between the two proteins. PyDock (Cheng, Blundell, & Fernandez-Recio, 2007) uses an energy function based on ICM potentials, composed of van der Waals, Coloumbic electrostatics and Atomic Solvation Parameter (ASP)-based desolvation energy. The scoring function in ICM-DISCO (Fernandez-Recio et al., 2002) takes into consideration the intermolecular grid-based energy terms and the Accessible Surface Area (ASA)-based desolvation energy. RosettaDock program also employs a similar scoring scheme.

Incorporating Protein Flexibility

Currently, all modern docking techniques use different approximations to include protein flexibility within the docking process. This may include rotating the protein side chains and possibly involve simple dynamics of the backbone. Flexibility in general is treated in two different ways: "implicit flexibility" and "explicit flexibility". Rigid-body approaches incorporate protein flexibility in an implicit way, by either using soft docking (surface softening) or through more advanced techniques such as ensemble-based docking. Surface softening techniques include low resolution docking methods, simplified models for the side chains and surface layer thickening (Szilagyi et al., 2005). Rigid-body docking methods show successful results in many cases (Viricel, Ahmed, & Barakat, 2015; Xu et al., 2013). Nevertheless, an accurate and biologically relevant prediction of these protein-protein interactions which involve considerable conformational changes of backbone and/or side chains upon complex formation is merely not possible through rigid-body docking (Grosdidier & Fernández-Recio, 2012; Wang & Schueler-furman, 2005).

Explicit treatment of the protein flexibility is only possible in docking algorithms that involve the atomic coordinates of the different atoms, rather than those that implicitly represent the protein structure on a grid. Each approach treats flexibility to a specific extent in a different way, such as accounting for the dynamic changes of the protein domains, amino acid side-chains and less frequently the backbone of the protein. The different approaches to include protein flexibility are based on energy minimization, atomic-level simulations or optimization of the shape-based characteristics and/or complementarity. Others include considerations related to electrostatic interactions and hydrogen bonding which have been known for a long time. All the mentioned approaches are time-consuming and take several hours to days for an effective treatment in a docking process and this represents the main reason for which flexibility remains a major challenge in the field of protein-protein docking (Ehrlich & Wade, 2001). For example, FiberDock (Mashiach et al., 2010) includes protein flexibility through several energetic calculations and ranking through normal mode analysis (NMA) along with side-chain optimizations (using a rotamer library) and restrained energy minimization with limited degrees of freedom. Another randomized search algorithm, RosettaDock (Gray et al., 2003) that is based on Monte Carlo principles, employs side-chain repacking, followed by optimizing the docked poses using a MC search with rigid-body displacements. Hinge-bending treatment is used in FlexDock (Schneidman-Duhovny, Ruth, & Wolfson, 2007) and FlexDoBi (Guo et al., 2013) programs in which the hinge regions (regions of the protein causing large-scale motions) are specified on the proteins prior to the docking simulation and the docking procedure is then performed, taking these specifications into account. HADDOCK (Dominguez et al., 2003) is regarded as an experimental data-driven program which performs a semi-flexible simulated annealing. Biochemical & biophysical interaction data from NMR experiments, mutagenesis investigations or bioinformatics predictions are used to introduce ambiguous interaction restraints (AIRs). These are then used to control the docking process with allowance for both backbone and side-chain

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

flexibility on the interface. Average interaction energies are then used as a basis for the clustering and ranking of top predictions.

Post Docking Refinement

Docking procedures can be followed by a second ranking/scoring stage to refine the docking results and remove any steric clashes that may emerge form the docking algorithm. This is generally required due to the lack of precision in docking scoring functions. There are many different methods that have been used in the post-docking refinement stage. This includes a biased probability side-chain optimization approach as implemented in the ICM program (Abagyan, Totrov, & Kuznetsov, 1994) or side-chain minimization as employed by Multidock (Multiple copy side-chain refinement Dock) (Jackson, Gabb, & Sternberg, 1998) algorithm. The RosettaDock program (Gray et al., 2003) uses another effective method, which involves the correction of main-chain displacements. In addition, some post-docking algorithms are specialized in refining the results to a higher extent. These include ZRANK (Pierce & Weng, 2007), EMPIRE (Liang, Liu, Zhang, & Zhou, 2007), DARS (Chuang, Kozakov, Brenke, Comeau, & Vajda, 2008), DECK (Liu & Vakser, 2011), RDOCK (Li, Chen, & Weng, 2003), pyDock (Cheng et al., 2007), Eigen-Hex (Venkatraman & Ritchie, 2012), RPScore (Moont, Gabb, & Sternberg, 1999), Multidock (Jackson et al., 1998) among others. DOCKSCORE (Huang et al., 2015) and FiltRest3D (Gajda, Tuszynska, Kaczor, Bakulina, & Bujnicki, 2010) are two of the online webservers which allow ranking of poses from protein-protein docking.

Docking Evaluation

When a new docking technique is developed and is claimed to be good at predicting the structure of a protein-protein complex, it needs to be evaluated to provide reliable data and information to scientists and research groups to obtain the highest quality results from their investigations. The Critical Assessment of Predicted Interactions (CAPRI) experiment (Janin et al., 2003) is created to compare and evaluate the performance of various docking algorithms developed by different groups. CAPRI is modeled after Critical Assessment of Structural Prediction (CASP), which started in 1994 for comparing the performance of protein-folding algorithms (Moult et al., 2014). The way CAPRI aims at evaluating the docking algorithms is through using a set of standard benchmark proteins (unbound pairs), with the correct match known (co-crystallized complex) which is kept confidential. These are assigned to the computational research groups and the results obtained are further assessed and compared. CAPRI has attracted significant attention of the scientific community and the results have led to great improvements to the docking techniques (Vakser, 2014). Furthermore, systematic studies are being constantly conducted to provide up to date insights into different aspects of docking programs (Chen, 2015; Moal et al., 2013).

The variability in the conformational sampling methods and scoring employed by the different docking algorithms, makes selecting a particular docking software a hard task. Each docking tool discussed so far has its own strengths as well as shortcomings. A fair way to compare these different tools is to test them against the same set of data using exactly the same set of parameters with identical amount of elapsed time (Cole, et al., 2005). This has been the case employed by CAPRI evaluations, which provide reliable and periodical comparison among the different groups developing PPI docking software packages and servers.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Table 2 summarizes a comparative overview of protein-protein docking software and/ servers with an emphasis on the most recent CAPRI experimental outcomes. For the complete references for each docking tool, please refer to Table 1. The latest CAPRI experiment (5th Evaluation) which was carried out in 2013 (Bonvin, 2013), reported the ClusPro server as the best in the automatic protein docking server category. In particular, the server's performance was equivalent to the best human predictor group. HADDOCK (De Vries et al., 2010), SwarmDock (Moal et al., 2013) and PIE-DOCK (Ravikant & Elber, 2010) servers were ranked next. In the human predictor category, HADDOCK (Dominguez et al., 2003) was ranked first followed by SwarmDock (Venkatraman & Ritchie, 2012), Vakser group, Vajda/Kozakov group (Camacho & Vajda, 2002; Chuang et al., 2008) and ICM (Fernandez-Recio et al., 2002) in the 2nd to 5th position (Kozakov et al., 2013) (Lensink & Wodak, 2013).

However, it is worth noting that a single docking algorithm cannot provide the ultimate answer for a particular problem and it would be better to combine at least two algorithms for the same research question. This will ensure a high quality of the final results, which should also make use of additional computational tools along with the docking methods to fulfill their gaps and shortcomings. Likewise, other numerical measures such as root-mean-square deviation (RMSD), careful analysis of interaction-based measures and visual examinations may provide additional credibility to the results (Hernández-santoyo et al., 2013).

Furthermore, we carried out a quick citations' survey for the top ranked docking algorithms (using Google Scholar; http://scholar.google.com), which resulted in the pie chart shown in Figure 3. This chart includes the citations of only the software packages. All docking servers were excluded to avoid

Table 2. Comparative overview of different docking software and tools with respect to 2013 CAPRI experiment

Docking Software and /Server	Strength	Weakness
HADDOCK	• Semi-flexible simulated annealing permitting almost full protein flexibility • Allows for ambiguous interaction restraints • Efficient scoring performance •CAPRI 2013: software ranked 1st, server ranked 2nd	•Reduced accuracy without structural information
ClusPro	• Efficient prediction •CAPRI 2013: Server ranked 1st	•Rigid-body docking; no/less inclusion of flexibility
RosettaDock	• Flexible protein docking • Post-docking correction of main-chain displacements.	•Sχορινγ φυνχτιονσ require improvement
ZDOCK	• Efficient scoring through a combination of functions. • Allows for specifying residual restraints.	• Rigid-body docking; no/less inclusion of flexibility • Inaccurate for docking of homology models
SwarmDock	• Εφφιχιεντ πρεδιχτιον using normal modes and flexibility during docking •CAPRI 2013: Server ranked 3rd	•Inconsistency ιν σχορινγ φυνχτιονσ.
PIE-DOCK (software and server	•Εφφιχιεντ πρεδιχτιον •CAPRI 2013: server ranked 4th.	•Poor scoring as indicated by CAPRI 2013
PatchDock	•Scalable ΦΦΤ βασεδ αλγοριτημ •Efficient computer run time	•Poor scoring as indicated by CAPRI 2013 •Takes minimal flexibility into account •Poor refinement

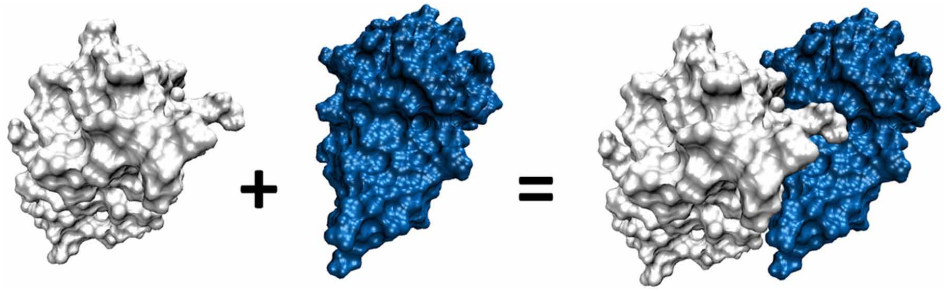
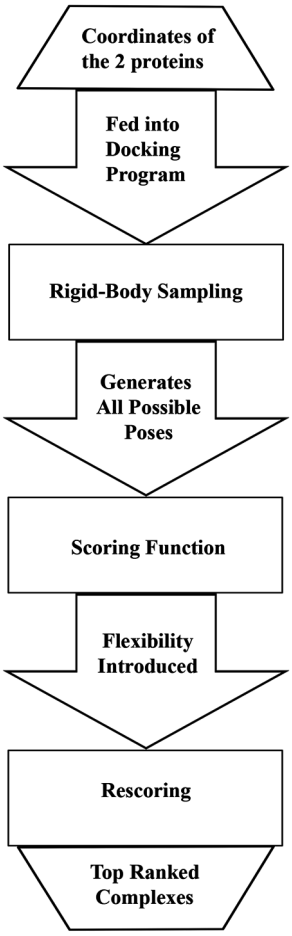
Figure 1. A depiction of two proteins shown individually and when docked together in complex





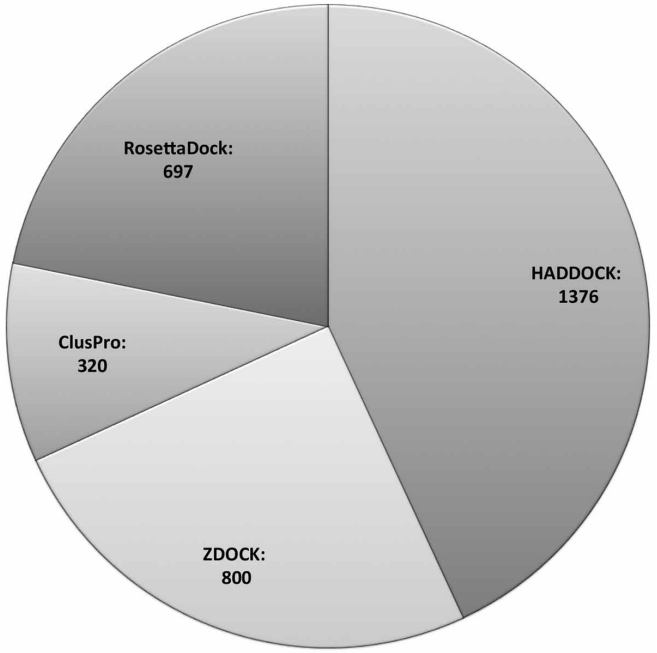


Figure 2. General scheme of docking and the different stages involved. The docking process usually starts with rigid-body docking, covering only the six dimensional space of the two proteins in 3D translational and 3D rotational. This is followed by ranking the generated complexes using a simple scoring function (e.g. shape complementarity). A more complex energy-based scoring method is next employed. Flexibility is then introduced to allow side chains or backbone dynamics. Incorporating protein flexibility usually leads to a more realistic and detailed picture of interaction. Rescoring stage is sometimes implemented for a more sophisticated ranking of poses.

Figure 3. Pie chart presenting the relative number of citations to each docking tool; for the sake of consistency, only the docking software are mentioned and servers are excluded.

discrepancies in the presented data. Accordingly, HADDOCK software was considered to be one of the most popular protein-protein docking tools, which confirms its proven accuracy and credibility amongst scientific groups.

CASE STUDIES

In our recent work (Ahmed & Barakat, 2015; Viricel et al., 2015), we have applied ensemble-based docking technique to understand the interaction between Programmed Death- 1 (PD-1) and PD-Ligand-1 proteins using the ZDOCK software (R. Chen, Li, & Weng, 2003) and the FFT search. These proteins belong to the immune system and play important functions in the T-cell inhibition pathway, leading to immune tolerance and inactivity against cancer and infectious cells. The novel results produced in this study predicted how these proteins interact in human. This interesting modeling approach, which combined molecular dynamics simulations, docking and free energy calculations, provided a good example for how protein-protein docking techniques can help understand complex protein interactions at the atomic level. In another interesting study (Zhang et al., 2005), the ZDOCK server (Pierce et al., 2014) was used for finding the possible protein-protein complex formed between the severe acute respiratory syndrome coronavirus (SARS-CoV) S1 protein and its receptor, human angiotensin-converting enzyme 2 (ACE2). This study illustrates successful identification of the interfacial key residues involved in the process of complex formation and has provided valuable information for further study of the mentioned system.

Protein-protein docking tools are frequently employed for investigating the structural details of various types of ion channels. These multimeric biological complexes are difficult to crystallize and the

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

available literature indicates wide use of computational techniques for their study. A good example of such successful attempts is the work by Smith et al. (2007), who employed Rosetta-based docking for modeling the transmembrane domain of KCNQ1/KCNE1 cardiac ion channel. The docking approach in this study has produced one of the most accurate starting models and has provided significant information on the structural basis for this ion channel.

The HADDOCK software (Dominguez et al., 2003) has been quite successful in resolving a large number of accurate models for protein-protein complexes. One good example is the study of the complex formed between plectasin, a member of the innate immune system and the bacterial cell-wall precursor Lipid II (Schneider et al., 2010). The bacterial cell wall biosynthesis is targeted by plectasin, through complex formation with Lipid II. The study has clearly identified the residues involved at the binding site between the two proteins by using the HADDOCK protein-protein docking tool, providing valuable information for the design of novel antibiotics.

CHALLENGES AND FUTURE DIRECTIONS

Despite the outstanding success of many protein-protein docking algorithms and their application throughout the last decade, there are still a number of challenges that need to be addressed within the next few years to advance the field for more realistic predictions. The initial sampling stage of most of docking algorithms is generally rapid and efficient, however there are certain shortcomings of protein-protein docking approaches, which fall into different categories mainly, related to scoring and flexibility issues.

The scoring functions are regarded as one of the major challenges of docking algorithms and frequently fail to accurately rank the resultant complexes. Even with the considerable improvements so far, detection of correct conformations is still considered to be beyond the scope of current docking algorithms. Using post-docking filtering techniques usually conceals this drawback, although it complicates the overall docking procedure. Accordingly, it is crucial to reach a point where the docking algorithms themselves gain the ability of completely refining the complexes correctly. The scoring functions also need to focus on solvation, entropy and the effects of protonation states of the charged residues. Development of new implicit and explicit models for further investigation of the role of water in the proteins interfaces during protein-protein docking, requires more effort. (Moal et al., 2013)

The treatment of proteins' structural flexibility remains an active area of research and is still lagging behind. The problem is even more puzzling when dealing with the proteins' backbone flexibility and large structural changes as seen in antigen-antibody complexes (Chen & Tou, 2013).

Furthermore, advancements in the structural genomics studies are leading to more number of therapeutically significant 3D structures being determined and thus, opening doors for docking studies to explore such interactions at the atomic level. However, it is predicted that there would be more number of 3D structures obtained by homology modeling rather than experimental techniques. This would produce more controversies and errors in the resulting complexes, due to uncertainties and limitations of homology modeling in correct prediction of 3D structures (Wass, Fuentes, Pons, Pazos, & Valencia, 2011).

The success of the current docking algorithms is largely dependent on the availability of experimental data (such as binding sites, interaction partners and conformational changes), without which there are high chances of obtaining incorrect conformations. This reliance on experimental data would always remain a challenge for many docking studies (Smith & Sternberg, 2002).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Improvements to the docking techniques in general, may include the optimization of existing algorithms or the development of new ones to overcome these limitations. With the aid of community efforts such as CAPRI, docking algorithms are being successfully evaluated to identify the potential limitations and the benchmark testing has led to overcoming a large number of them. The remaining challenges such as flexibility incorporation are still under investigation and with the accelerated pace of research in this area, the problem of flexibility will be soon tackled. Other tricky challenges like the prediction of multi-protein complex structures could be addressed and investigated more in the future (Grimm et al., 2005; Wodak & Méndez, 2004).

CONCLUSION

Understanding protein-protein interactions is an essential step to comprehend many important biological processes and to identify new treatments for many diseases. The huge discrepancy between the amount of genomic data deposited in the literature and the experimentally determined protein structures place a huge pressure on the computational groups to predict the structure of many proteins and understand how they interact. Amongst the current computational tools in use is protein-protein docking. This technique involves several algorithms that have been developed to analyze the protein-protein interactions at the atomic-level. They predict the mode of binding between two interacting proteins and involve two interconnected stages, namely sampling of protein conformations and scoring the docked poses. More advanced algorithms include the proper incorporation of protein flexibility and sophisticated scoring methods, referred to as post-docking refinement.

This chapter briefly introduced the concepts behind protein-protein docking, with an emphasis on the different approaches. It also reviewed the theoretical concepts, principles and specific features of the search strategies and scoring functions implemented in different programs, highlighting their strengths as well as their limitations. The main sampling techniques reviewed here include FFT correlation, direct search in Cartesian space, randomized search and MC algorithm. Scoring of the protein-protein docking solutions span different methods including force field-based methods, empirical scoring, knowledge-based and heuristic scoring functions.

Despite the great efforts of many research groups in this exciting area of research, there are still many challenges that need to be addressed to improve the method. This includes mainly developing more accurate scoring methods and the proper incorporation of protein flexibility. Although many algorithms are on the edge of overcoming these problems, more work need to be done to fully solve these issues. With the accelerated pace of improvements in the field of computational approaches and their successful applications in understanding many biological systems, we believe that the field of protein-protein docking will evolve rapidly towards a more accurate method to predict protein-protein interactions. We hope this chapter provides a brief, yet comprehensive, overview to researchers working in this area.

KEY TERMS AND DEFINITIONS

Docking: The computational task of predicting a biologically relevant and stable complex formed by two individual molecules.

Hot Spot Regions: The critical residues at the interface regions of proteins, where the binding takes place. These are the main components responsible for protein interactions and contribute the most to the binding free energy in bound forms of proteins.

Molecular Dynamic Simulations: Computer simulation techniques for prediction of the dynamic behaviour of molecules based on integration of Newton's equations of motion.

Post-Docking Refinement: A number of methods employed for more accurate ranking of the conformational poses from the docking process. Due to lack of precision in docking scoring functions, this stage is implemented to ensure the correctness of predictions.

Protein Flexibility: Proteins are dynamic entities and continuously undergo deviations from their equilibrium state. This is caused either due to the motion of the protein side-chains or sometimes the backbone structure. The issue of flexibility is often considered a challenge in docking studies and requires special treatments.

Sampling: A set of techniques in docking process for generating a large number of alternative poses for the two molecules (receptor and ligand) by sampling all the possible binding modes.

Scoring: Mathematical methods to rank the poses from docking with different types of scoring functions based on the binding free energy (non-bonded interactions) between the two docked molecules.

This work was previously published in Methods and Algorithms for Molecular Docking-Based Drug Design and Discovery edited by Siavoush Dastmalchi, Maryam Hamzeh-Mivehroud, and Babak Sokouti, pages 173-195, copyright year 2016 by Medical Information Science Reference (an imprint of IGI Global).

Chapter 43
Protein–Protein Interactions (PPIs) as an Alternative to Targeting the ATP Binding Site of Kinase:
In Silico Approach to Identify PPI Inhibitors

Sailu Sarvagalla
Pondicherry University, India

Mohane Selvaraj Coumar
Pondicherry University, India

ABSTRACT

Most of the developed kinase inhibitor drugs are ATP competitive and suffer from drawbacks such as off-target kinase activity, development of resistance due to mutation in the ATP binding pocket and unfavorable intellectual property situations. Besides the ATP binding pocket, protein kinases have binding sites that are involved in Protein-Protein Interactions (PPIs); these PPIs directly or indirectly regulate the protein kinase activity. Of recent, small molecule inhibitors of PPIs are emerging as an alternative to ATP competitive agents. Rational design of inhibitors for kinase PPIs could be carried out using molecular modeling techniques. In silico tools available for the prediction of hot spot residues and cavities at the PPI sites and the means to utilize this information for the identification of inhibitors are discussed. Moreover, in silico studies to target the Aurora B-INCENP PPI sites are discussed in context. Overall, this chapter provides detailed in silico strategies that are available to the researchers for carrying out structure-based drug design of PPI inhibitors.

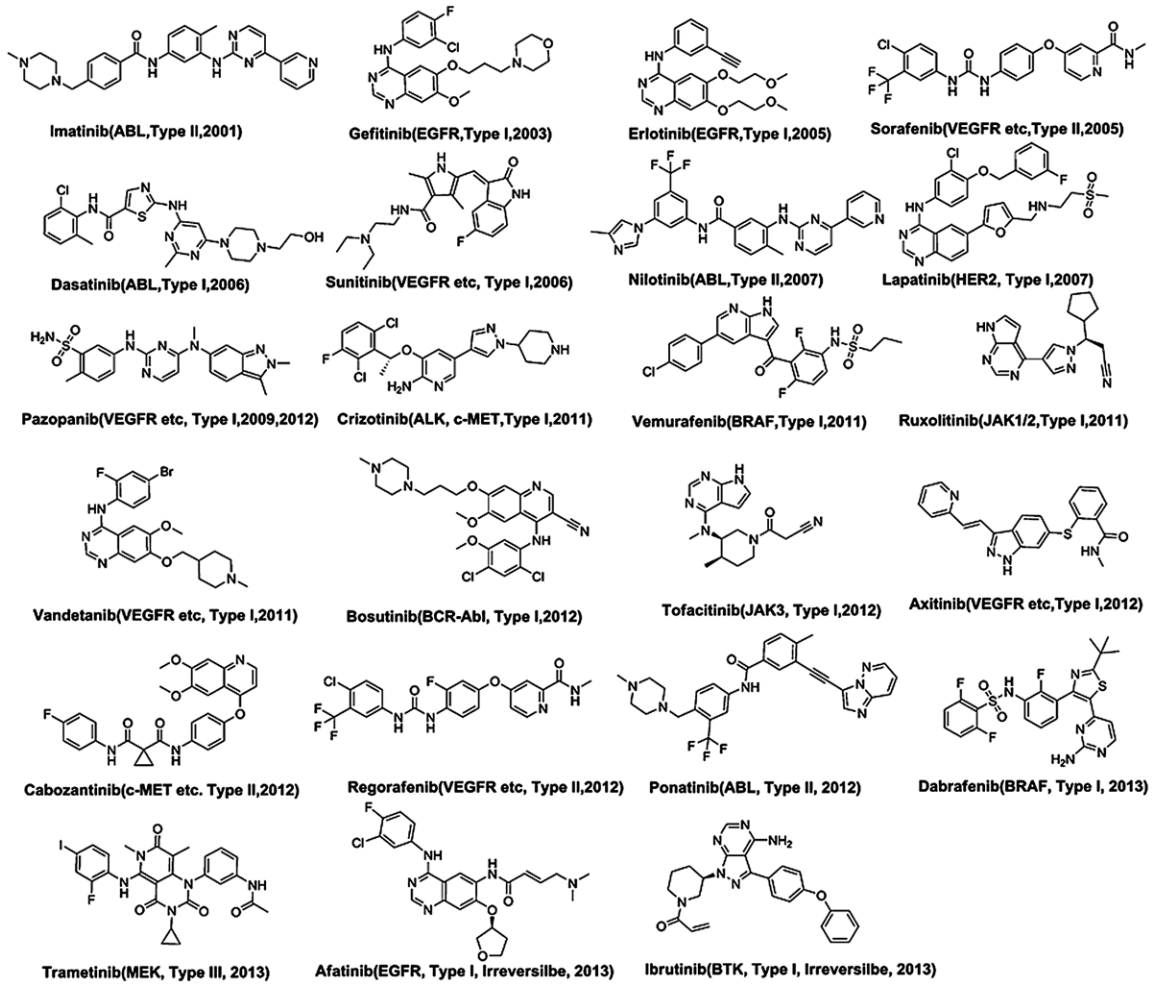
INTRODUCTION

Protein kinase enzymes, also known as phosphotransferases, are the most extensively pursued class of drug targets in current pharmaceutical research. Several kinase inhibitors are registered for pre-clinical & clinical trial evaluation for different ailments, including cancer (O'Brien & Fallah Moghaddam, 2013; Rask-Andersen, Zhang, Fabbro, & Schioth, 2014; J. Zhang, Yang, & Gray, 2009). These enzymes transfers ATP terminal phosphate group to the substrate protein, and thereby regulate various activities including cell proliferation, differentiation, survival, transcription, apoptosis, metabolism, and a wide array of other signal transduction process (Adams, 2001; P. Wu, Nielsen, & Clausen, 2015). The involvement of kinases in various pathological conditions, makes them an attractive drug target for therapeutic intervention in diseases such as cancer (Fabbro, Cowan-Jacob, Mobitz, & Martiny-Baron, 2012), vascular (Abeyrathna & Su, 2015; Kikuchi et al., 2014) & central nervous system (CNS) disorders (Chico, Van Eldik, & Watterson, 2009), inflammatory disease conditions (Barnes, 2013; Rommel, 2010), and diabetes (Banks et al., 2015; Y. Wu & Chakrabarti, 2015). Consequently, for the past one and half decades, pharmaceutical companies and academic researchers are mounting intense efforts to develop small molecule kinase inhibitors. As a result of this, the first successful kinase inhibitor imatinib was approved in 2001 by FDA for the treatment of chronic myeloid leukemia (Gambacorti-Passerini & Piazza, 2015; Wisniewski et al., 2002). Since then, understanding of kinase structural and functional mechanism and their involvement in pathological conditions has significantly improved by the advancement of cell and molecular biology, structural biology, genetics, and associated fields. Concomitantly, the kinase inhibitors approval has also increased, and presently around 28 small molecule kinase inhibitors are approved by the US FDA for therapeutic usage in various cancers (Fabbro, 2015; P. Wu et al., 2015; Z. Zhao et al., 2014). The structures of approved kinase inhibitor drugs are represented in Figure 1.



The entire human genome encodes approximately 518 protein kinases (Manning, Whyte, Martinez, Hunter, & Sudarsanam, 2002), and have conserved kinase domain fold. The 3D structure of kinase contains a helix-dominated conserved C-terminal region, and a β sheet-dominated N-terminal region, which varies in sequence length and amino acid composition. A flexible hinge region connects the N- and C-terminal lobes, and in between these two lobes there exist a conserved ATP binding cleft. Glycine rich loop contains a conserved GXGXXG motif, and acts like a clamp to stabilize the binding of ATP at this cleft. Binding of ATP to the active site is controlled by the activation loop N-terminal starting residues Asp-Phe-Gly, also called DFG motif which adapts "DFG-in" and "DFG-out" conformation according to protein active and inactive state, respectively. The DFG motif residue Asp together with metal ion Mg^{2+} regulates kinase transactivation mechanism during phosphorylation process (Eswaran & Knapp, 2010; Thaimattam, Banerjee, Miglani, & Iqbal, 2007).

KINASE INHIBITORS, THEIR BINDING MECHANISM AND DRAWBACKS

The small molecule kinase inhibitors are useful as therapeutic agents, as well as to understand various cellular functions in normal and disease conditions. To date, most of the discovered kinases inhibitors are ATP competitive in nature; the heterocyclic core group in the inhibitor forms one to three hydrogen bond interactions with the conserved hinge region residues of the kinase (Garuti, Roberti, & Bottegoni, 2010; J. Zhang et al., 2009). Thus, they mimic the typical hydrogen bond interactions of adenine ring of ATP with the kinase. Based on the inhibition mechanism, kinase inhibitors are classified as either reversible

Figure 1. FDA-approved kinase inhibitors with binding modes.
Reproduced from reference Z. Zhao et al. (2014).

or irreversible (P. Wu et al., 2015). The reversible inhibitors are further categorized as Type-I, Type-II, Type-III and Type-IV inhibitors, based on their binding mechanism as well as DFG motif conformation (Z. Zhao et al., 2014). The type-I inhibitors binds to active state of the protein where the DFG motif adapts into "DFG-in" conformation; in this state, the DFG motif residues Asp and Phe are placed inside and outside of the ATP binding pocket, respectively. The type-II inhibitors bind to the inactive state of the protein, where the DFG motif adapts into "DFG-out" conformation; in this conformation, the DFG motif residues Asp and Phe are placed outside of the ATP binding (under αC-helix) pocket. Moreover, in this conformation, the gate keeper residue permits the inhibitors to access the back pocket region. The type-III inhibitors also called allosteric inhibitors which binds exclusively to the ATP adjacent pocket (back pocket), and modulates the ATP binding by allosteric mechanism. While, type-IV inhibitors binds to a distant place from ATP binding site. Both type-III and type-IV inhibitors show highest degree of kinase selectivity because of their allosteric binding mode and regulatory mechanism that are unique to particular kinase enzymes (P. Wu et al., 2015). The irreversible inhibitors of kinases have tendency

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

to bind covalently with ATP binding site residue, most frequently by interacting with nucleophilic Cys residue, which results in irreversible inhibition (Garuti, Roberti, & Bottegoni, 2011).

So far, most of the developed kinase inhibitors are ATP competitive in nature, and have serious drawbacks because of the shared conserved ATP binding site among the human kinome. The primary concerns regarding ATP competitive inhibitors are: off- and on-target toxicity issues (Burtness, 2014; Ho, Yeo, Kang, & Chua, 2014; Liu & Kurzrock, 2014), development of drug resistance (Barouch-Bentov & Sauer, 2011; Murray & Miller, 2015) and unfavorable intellectual property situation. Because of the conserved ATP binding site, development of selective kinase inhibitors is very challenging, and most of the approved and developed kinase inhibitors are also having reasonable multi-kinase activity which ultimately causes serious on- and off-target toxicity. The second major concern about kinase inhibitors is the development of drug resistance because of mutations in the gate keeper residue of the ATP binding site, which eventually causes loss of drug binding and drug efficacy to a particular kinase target. Because, at this particular position (gate keeper residue), the size of amino acid side chain regulates the inhibitors accessibility to the back pocket region or ATP adjacent pocket. As the kinase inhibitors make crucial hydrophobic interactions at the ATP adjacent pocket, loss of these interactions decrease the binding affinity of the inhibitors to the target kinase (J. Zhang et al., 2009).

The most frequently reported gate keeper residue mutations are observed in different kinases, including BCR-ABL1 (T315I), EGFR (T790M), FLT3 (G697R), KIT (T670I), PDGFR (T674I) and BTK (C481S) which results in drug resistance (J. Zhang et al., 2009). For example, gate keeper residue mutation (T315I) of BCR-ABL1 confers drug resistance to imatinib (Gleevec) in chronic myeloid leukemia patients (O'Hare, Eide, & Deininger, 2007). Further, mutation of EGFR gate keeper residue T790M results in drug resistance to geftinib and erlotinib by decreasing inhibitors accessibility to the ATP back pocket region (Godin-Heymann et al., 2008). Moreover, the recently approved Bruton's tyrosine kinase (BTK) inhibitor ibrutinib also showed resistance to gate keeper residue mutation (C481S) (D'Cruz & Uckun, 2013). In addition to these gate keeper mutations, other aberration such as target amplification and up-regulation of alternative kinase pathways also leads to the development of drug resistance to ATP competitive inhibitors (Barouch-Bentov & Sauer, 2011). The third concern regarding kinase inhibitors is the development of diverse set of molecules with favorable IP (intellectual property) situation. Because of the conserved ATP binding pocket, it is very difficult to develop kinase inhibitors with diverse set of functional groups which are protectable by IP laws (Backes, Zech, Felber, Klebl, & Muller, 2008). Thus, there is an urgent need to develop alternative strategies to develop small molecule inhibitors towards these indispensable drug targets.

Beside the ATP binding pocket, protein kinases have other prominent structural features including the binding sites that are involved in protein-protein interactions (PPIs) (Dickson, Wilbur, Reinke, Young, & Vojtek, 2015; Pearson et al., 2001; Rechfeld, Gruber, Hofmann, & Kirchmair, 2011; Rudolph, 2007; White, Westwell, & Brahemi, 2008). These PPIs directly or indirectly monitor the protein kinase activity, and interruption of interaction at these sites (PPI sites) have emerged as an attractive and alternative strategy to develop selective kinase inhibitors with favorable IP situation (Cierpicki & Grembecka, 2015; Jin, Wang, & Fang, 2014). As the activity of different kinases are controlled by numerous protein-protein interactions, and their binding interface significantly varies from one kinase family to other kinase family member proteins, targeting these PPI sites have advantage over targeting the conserved ATP binding site. This might allow higher level of selectivity as compared to the ATP competitive inhibitors. Moreover, development of kinase PPI inhibitors permits for combinatorial treatment with ATP competitive inhibitors which could synergistically block kinase activity as compared to ATP competitive inhibitors

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

alone. However, targeting kinases PPI site is very challenging, because of their flat and featureless large hydrophobic interface region; further, these interactions are transient and are exposed to solvent regions, causing difficulties in PPI inhibitor development. Nevertheless, growing evidence indicates that targeting PPI sites of kinases are emerging as an important therapeutic strategy in drug discovery and development (Corbel et al., 2011; Dickson et al., 2015; Han, Kim, & Yang, 2012; Kaidanovich-Beilin & Eldar-Finkelman, 2006; Rechfeld et al., 2011; B. Zhang et al., 2011).

PROTEIN-PROTEIN INTERACTIONS AS THERAPEUTIC TARGETS

The fundamental functions of living cell such as cell growth, morphology, nutrient uptake, gene expression, signaling network, and apoptosis are accomplished by macromolecular interactions; among them, protein-protein interactions (PPIs) have critical role in various biological and pathological conditions (Ryan & Matthews, 2005). It is reported that a single cell of a human can have around 130,000 to 650,000 PPIs (Stumpf et al., 2008; Venkatesan et al., 2009). Thus, understanding the importance of PPIs in various pathological conditions has wide application in rational drug design and protein engineering. However, previously it was assumed that PPI sites are "undruggable (or) intractable", because of their flat and featureless large hydrophobic region that couldn't accommodate a small molecule inhibitor (Wells & McClendon, 2007). This misconception was assumed due to lack of understanding of these sites, and also, there weren't many known small molecule inhibitors that could bind to PPI sites as compared to the traditional drug targets such as enzymes, receptors and ion channels. Further, lack of experimental assay methods, and small molecule libraries that were suitable for identification of PPI inhibitors were not available in yesteryears. However, recent developments in molecular biology, structural biology, computational chemistry and associated fields have helped in gaining better knowledge of PPIs (Cierpicki & Grembecka, 2015; Kuenemann et al., 2015; Villoutreix et al., 2014; Watkins & Arora, 2015).

Traditional drug targets such as receptors, enzymes and ion channels have served as attractive drug targets for many of the pathological conditions, including cancer. At the same time, toxicity issues and drug resistance development was concurrently observed for many of these drug targets (Barouch-Bentov & Sauer, 2011; Liu & Kurzrock, 2014; Wallace, 2015) Consequent to this, quest for new targets for therapeutic intervention turned the focus on PPIs, because of their importance in various pathologies (Ryan & Matthews, 2005; Wells & McClendon, 2007). Thus, design of small molecule inhibitors that directly block PPIs has become an attractive and an alternative strategy to develop small molecule inhibitors for various diseases. However, structural analysis of PPIs revealed that as compared to traditional drug targets, PPI sites are complex and flexible; they lack cavities that are essential for small molecule binding (Cierpicki & Grembecka, 2015). The interfaces of PPIs are considerably flat, and contain featureless large hydrophobic surface area (around 1200 to 3000 $Å^2$) (Cierpicki & Grembecka, 2015; Lo Conte, Chothia, & Janin, 1999). Further, the intrinsic properties of PPIs such as flexibility and dynamic nature is different in solution as compared to crystal binding mode, and it is very difficult to design small molecule inhibitors for PPIs when structure based drug design methods are applied.

In spite of these challenges, the current body of literature evidences suggest that only few of the clustered residues of PPIs sites contributes to majority of the binding free energy (called as 'hot spots'), and these hot spot residues are critical for protein-protein structure stability and function (Bogan & Thorn, 1998; Clackson & Wells, 1995; Kuttner & Engel, 2012; Moreira, Fernandes, & Ramos, 2007). Thus, targeting PPIs hot spots residues provide an attractive opportunity to explore these drug targets

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

for therapeutic intervention (Cukuroglu, Engin, Gursoy, & Keskin, 2014; Guo, Wisniewski, & Ji, 2014). Further, structural analysis revealed that PPIs sites could be subdivided into three to four sub-pockets (Fuller, Burgoyne, & Jackson, 2009; Jubb, Blundell, & Ascher, 2015) and the binding to these sub-pockets could be explored using natural products and peptidomimetics like compounds. Recently, few small molecule and peptide inhibitors of PPIs are discovered using the above information (Arkin, Tang, & Wells, 2014). The interface residues of PPIs are conserved and are less prone to the development of drug resistance (Kozakov et al., 2011; X. Li, Keskin, Ma, Nussinov, & Liang, 2004; Ma, Elkayam, Wolfson, & Nussinov, 2003). Moreover, growing evidences indicate that PPIs are challenging but tractable drug targets for various diseases. As a proof of concept, few small molecule inhibitors have already entered into clinical trials and a number of small molecule inhibitors are in pre-clinical development (Arkin et al., 2014; Bogoyevitch, Barr, & Ketterman, 2005; Cierpicki & Grembecka, 2015). In the following section, few important PPI drug targets (IAP family proteins, bromodomains, BCL family proteins, MDM2-p53 complex interface, and HIV integrase) and their inhibitors that have progressed towards clinical trials are described in brief. Interested readers may also refer to other review articles for additional information (Arkin et al., 2014; Ivanov, Khuri, & Fu, 2013; Jin et al., 2014; Kuenemann et al., 2015; Laraia, McKenzie, Spring, Venkitaraman, & Huggins, 2015; Sheng, Dong, Miao, Zhang, & Wang, 2015).

IAP Inhibitors

The Inhibitors of Apoptosis Proteins (IAPs), including XIAP, cIAP1, cIAP2, Survivin, and Levivin, play vital role in various biological function including cell division, duplication, cell death, DNA damage, autophagy and immunity (Budhidarmo & Day, 2015; Damgaard & Gyrd-Hansen, 2011). On the other hand, it has been demonstrated that these proteins are over expressed in many of the human solid tumors. Consequently, these proteins have become attractive drug targets for cancer therapy (Dubrez, Berthelet, & Glorian, 2013). These proteins contain at least one conserved BIR domain, and involves in PPIs. IAPs BIR domain directly binds to N-terminal tetra-peptide sequence of caspase-3, caspase-7 and caspase-9 during their proteolytic activation; as a result it inhibits their pro-apoptotic mechanism. However, an endogenous peptide inhibitor of IAPs called Smac (Second mitochondrial activators of caspases) binds to their BIR domain, and activates the apoptosis mechanism. Therefore, developing a small molecule inhibitor of IAPs that mimics the Smac is an attractive approach to inhibit the IAPs protein-protein interaction with caspases. Several Smac mimetics have been developed by many scientific groups; among them, seven compounds have reached clinical trials and five compounds including LCL-161, AT-406, TL-32711, GDC-0152, and GDC-0917 are actively pursued in clinical development for the treatment of cancer (Arkin et al., 2014).

Bromodomain (BRD) Inhibitors

The bromodomain family proteins (BET, BRD2, BRD3, BRD4 and BRDT) are ‘epigenetic readers’, which have significant role in targeting multiple enzymes, protein scaffolds and DNA binding proteins to their specific sites. Usually, these proteins recognize the acetylated lysines (Kacs) on histone tail, and thereby govern chromatin remodeling and gene transcription (Sanchez & Zhou, 2009). However, dysfunctions of these proteins have been reported in various cancers, and targeting these proteins interaction with acetylated lysine peptide has become an attractive approach for the design of small molecule inhibitors for cancer (Muller, Filippakopoulos, & Knapp, 2011). Consequently, the hydrophobic pocket

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

of bromodomains that recognizes acetyl-lysine peptide has been used to design and develop the Kac mimetic inhibitors. Currently, few compounds including I-BET762, CPI-0610, Ten-010 and OTX15 are in clinical development for cancer (Arkin et al., 2014).

BCL Family Protein Inhibitors

BCL family proteins include pro- and anti-apoptotic proteins which regulates cell death mechanism in various biological events (Hardwick & Soane, 2013). The pro-apoptotic proteins BAD and BAK are tightly regulated or inhibited by anti-apoptotic proteins including BCL-2, BCL-xl and MCL1. Over expression or deregulation of anti-apoptotic proteins have been observed in various cancers (Besbes, Mirshahi, Pocard, & Billard, 2015). The anti-apoptotic proteins are helical proteins which forms an open cavity that binds to BH3 domain (single helix) of pro-apoptotic proteins. Hence, disrupting these PPIs using small molecule inhibitors has become an attractive approach for cancer therapy. In the past, several inhibitors were reported to modulate these PPIs; currently, ABT-199 and ABT-263 are in clinical development for cancer (Arkin et al., 2014).

MDM2-p53 PPI Inhibitors

p53 is the principal tumor suppressor protein, also called as "guardian of genome" because of its central role in protecting and stabilizing the human genome from various mutations. It tightly regulates cell-fate decisions including cell cycle arrest, senescence and apoptosis (Surget, Khoury, & Bourdon, 2013). Mouse Double Minute 2 homolog (MDM2), also known as E3 ubiquitin-protein ligase is one of the major regulator of p53 (Momand, Wu, & Dasgupta, 2000). MDM2, constantly ubiquinates p53 leading to degradation by nuclear and cytoplasmic proteasome enzymes, thereby limiting its tumor suppressor function in unstressed cells. However, mutations are reported in p53 and its regulator protein, which results in loss of p53 tumor suppressor function. Thus, disruption of MDM2-p53 PPIs results in p53 activation in tumor cells. The inhibitor nutlin is the first breakthrough that was discovered by large high-throughput screening for disruption of MDM2-p53 PPIs (Shangary & Wang, 2009). Subsequently, several small molecule inhibitors were discovered by many scientific groups. Currently, RG-7112 (Ro5045337), RG-7388 (Ro5503781) and MI-888 are in clinical development for the treatment of cancer (Arkin et al., 2014; Y. Zhao, Aguilar, Bernard, & Wang, 2015).

HIV Integrase Inhibitors

HIV integrase (IN) allows integration of viral genome into host genome by catalyzing 3′ processing and stand transfer. In this process, the human protein - Lens Endothelial Growth Factor (LEDGF) acts as IN cofactor to activate the integration process, and also to protect from proteolytic degradation. Thus, targeting these host-pathogen PPIs (LEDGF-IN) is an alternative and attractive approach for the design of small molecule inhibitors for treating AIDS. Recently, a second class of IN inhibitors that mimics the LEDGF peptide has entered into clinical trials (Engelman, Kessl, & Kvaratskhelia, 2013). Currently, the inhibitor *tert*–Butoxy-(4phenyl-quinolin-3-ly-acetic acid (*t*BPQA) derivative and BI-224436 are in clinical development for the treatment of AIDS (Arkin et al., 2014).

STRUCTURE-BASED DRUG DESIGN OF PPI INHIBITORS USING *IN SILICO* APPROACHES

The arena of structure based drug design (SBDD) has rapidly grown because of the advancements in genomics, proteomics, structural biology and computational chemistry. SBDD has an important role in drug discovery, and many successful lead molecules have been discovered using this approach (Anderson, 2003; Lionta, Spyrou, Vassilatis, & Cournia, 2014). Once the 3D structure of a particular disease target is resolved using experimental (X-ray or NMR) or computational methods (homology modeling and threading), then it could be used for virtual screening or for de-novo design to identify lead molecule inhibitors. In this chapter, the authors describe in a step-wise manner how SBDD methods could be applied to discover small molecule inhibitors of PPIs. Figure 2 summarizes the SBDD approach for the identification of PPIs inhibitors.

Modeling of Protein and PPI Complex Structures

For the rational design of PPI inhibitors using structure-based drug design (SBDD), it is essential to have 3D structures of PPI complexes involved in the particular disease state. However, available 3D structures of protein-protein complexes are very few in Protein Data Bank (PDB), as compared to the traditional drug targets such as enzyme and receptor structures. Resolving the 3D structures of PPIs using X-ray and NMR methods is much more challenging (Widmer & Jahnke, 2004). Due to the experimental limitations, *in silico* methods including comparative modeling (homology modeling), threading and fold recognition and Ab initio methods can be used to build the protein structure. Knowledge of resolved homologue protein structures and physical principles of protein such as that mimic the protein folding

Figure 2. Structure-based drug design (SBDD) approach for the identification of PPI inhibitors

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

or stochastic (global optimization of energy function) methods are used to search the possible solutions. The *in silico* tools or modules that are available for protein 3D structure predictions are listed in Table 1. Among them, MODELLER (Eswar et al., 2006), SWISS-MODEL (Biasini et al., 2014) (for comparative modeling), I-TASSER (Yang et al., 2015) (for threading), ROBETTA server (Kim, Chivian, & Baker, 2004) (combination of comparative and Ab initio methods) are well known modules for protein 3D structure prediction.

Further, in the absence of experimental PPIs complex structures, the available monomer structures (from PDB or modeling) of two individual protein partners could be used to build the PPI complexes using protein-protein docking (Vakser, 2014). The ultimate goal of protein-protein docking is to predict the 3D structure of the macromolecular complexes of interest as they would occur in a living organism.

Thus, execution of protein-protein docking of two interested proteins would produces number of plausible candidate complex structures, and these candidates must be ranked using scoring functions to identify structures that are most likely to occur in the native state. There are a number of algorithms and scoring functions developed to model PPIs complexes with reasonable accuracy (Sable & Jois, 2015). The most commonly used protein-protein docking tools and their algorithms are listed in Table 2.

Table 2. List of available protein-protein docking tools and web servers

Sl. No	Name of the Tool	Applied Methodology	Description and Web Links
1	ZODOCK	It uses Fast Fourier transformation (FFT), shape complementarity, desolvation energy and electrostatic interactions	It is available as a webserver (http://zdock.umassmed.edu/) and also as a standalone tool; implemented in Accelrys software suit (discovery studio).
2	HADDOCK	Data-driven bimolecular docking	It is an information-driven flexible docking program used to model bimolecular complexes (http://haddocking.org/)
3	GRAMM-X	Fast Fourier Transformation	It employs smoothed potentials, refinement and knowledge-based scoring function to find the possible solution. (http://vakser.compbio.ku.edu/resources/gramm/grammx/)
4	ClusPro	Rigid-body docking using the FFT correlation approach and RMSD clustering	Webserver (http://nrc.bu.edu/cluster)
5	Patch dock	Global search	It uses shape complementarity and atomic desolvation energy to search possible solution (http://bioinfo3d.cs.tau.ac.il/PatchDock/)
6	RosettaDock	Rigid body docking (energy based method)	It optimizes the rigid body docked poses and side chains to finds lowest energy conformation (http://rosettadock.graylab.jhu.edu/)
7	GPU.proton. DOCK	Fast Fourier Transform bottleneck and electrostatic fields computation	It is a state of the art server for prediction of protein–protein interactions via rigorous and ultrafast docking code (http://gpudock.orgchm.bas.bg/)
8	HexServer	Fast Fourier transformation	(http://hexserver.loria.fr/)
9	3D-Garden	Marching cubes algorithm	http://www.sbg.bio.ic.ac.uk/~3dgarden/_

Identification of Ligand Binding Cavities and Hot Spot Residues at the PPI Interface

The next step for the identification of inhibitors of PPIs is to identify the cavities and ligand binding hot spot residues in PPIs interface region. It has been demonstrated that PPIs interface are flat and contains featureless large hydrophobic surface region (Cierpicki & Grembecka, 2015). Nevertheless, the large hydrophobic surface area is separated into three to four superficial sub-pockets which could be of 50 $Å^3$ size (Fuller et al., 2009). Moreover, it is also demonstrated that only few clustered residues of each partners of PPIs contributes to the majority of binding free energy (affinity) towards the complex formation. The clustered residues which are mainly contributing to the binding energy are called 'hot spots' (Bogan & Thorn, 1998; Clackson & Wells, 1995). Further, these hot spots of PPIs are conserved throughout evolution and show high propensity for ligand binding. Thus, identification of superficial cavities and ligand binding hot spots are two primary steps that are very critical for the SBDD of PPIs inhibitors. It should also be noted that sometimes it is not possible to get both these structural features at the same site. The ligand binding cavity may exists at one site and the hot spot residues exist at other site or the hot spot residues may be projected into the ligand binding cavity. Therefore, the integrated knowledge that is derived from both the cavity and hot spots detection can be used for SBDD of PPI inhibitors (Kuenemann et al., 2015; Laraia et al., 2015; Watkins & Arora, 2015).

Ligand binding pockets or cavities on the protein surface can be identified using various *in silico* tools which are mentioned in the virtual ligand screening website (http://www.vls3d.com/links/bioinformatics/binding-pockets). Generally, these tools are classified into three categories: (1) protein geometry based methods; (2) energy based methods and (3) combination of above two methods (H. Li, Kasam, Tautermann, Seeliger, & Vaidehi, 2014; Zheng, Gan, Wang, & Wang, 2013). Most of the tools using these methods are also suitable for detecting the cavities in traditional drug targets. More specifically, few energy based methods such as FTMap server (Ngan et al., 2012) and FindBindSite (H. Li et al., 2014) were specifically developed to detect the ligand binding cavities at PPIs interface. These methods use molecular docking approach to map the whole protein surface using small probes or fragments. Consequently, mapping small molecule fragment on protein surface by docking effectively identifies the superficial cavities at PPIs.

The PPIs hot spots can be identified using either experimental or computational methods. Among these methods, experimental alanine scanning mutagenesis is well known and is widely employed in the literature to study the structural and functional aspects of the protein (Lefevre, Remy, & Masson, 1997). Moreover, it exactly identifies the hot spots by substituting the selected residue with alanine. Upon substitution (mutation) it estimates binding free energy by means of thermodynamic properties. After alanine scanning mutagenesis, if the total binding free energy of mutant protein drops more than 1-2 kcal/mol, as compared to the native protein then the mutated amino acid is considered as hot spot residue. However, identification of hot spots using experimental alanine scanning mutagenesis is very expensive and time consuming. On the other hand, various *in silico* methods such as Robetta server (Kim et al., 2004), DrugScorePPI server (Kruger & Gohlke, 2010), HotRegion database (Cukuroglu, Gursoy, & Keskin, 2012), KFC server (Darnell, LeGault, & Mitchell, 2008) and PocketQuery server (Koes & Camacho, 2012a) could be used to detect the hot spot residues in PPIs interface region. These methods use different algorithms, energy functions and parameters to optimize and to correlate with the experimental results. These methods are classified into three categories: (1) simple free energy function based methods, (2) molecular dynamics simulation based methods and (3) machine learning based

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

methods. In fact, all the developed methods have their own advantages and limitation and are widely used by various scientific groups in their research. Moreover, these are very fast, reliable and also correlate with experimental results. Thus, along with the superficial cavities that are identified by cavity detection methods, hot spots knowledge could be used to define the ligand binding sites or to derive the pharmacophore features and used for screening the small molecule databases. Some of the hot spot and ligand binding cavity detection methods and tools that are specially developed for PPIs are listed in Table 3.

Virtual Screening for the Identification of PPI Inhibitors

After the identification of ligand binding sites of PPIs using the cavity detection methods and the detection of hot spots, small molecule inhibitors or initial hits for PPIs can be identified using virtual screening (VS) methods (Reddy, Pati, Kumar, Pradeep, & Sastry, 2007). It is a common practice in the drug discovery project to search the libraries of small molecules to identify molecules that are most likely to bind to a drug target. VS can be carried out using either molecular docking or pharmacophore based methods.

Molecular docking (Ferreira, Dos Santos, Oliva, & Andricopulo, 2015) is a computational technique, used in drug design projects to predict the binding orientation of small molecule inhibitors in their target proteins. Thus, the knowledge derived from binding orientation could be used to predict the binding affinity or activity of the small molecules using scoring functions. Hence, docking has become a powerful *in silico* tool in various pharmaceutical industries. Some of the well-known docking programs that are

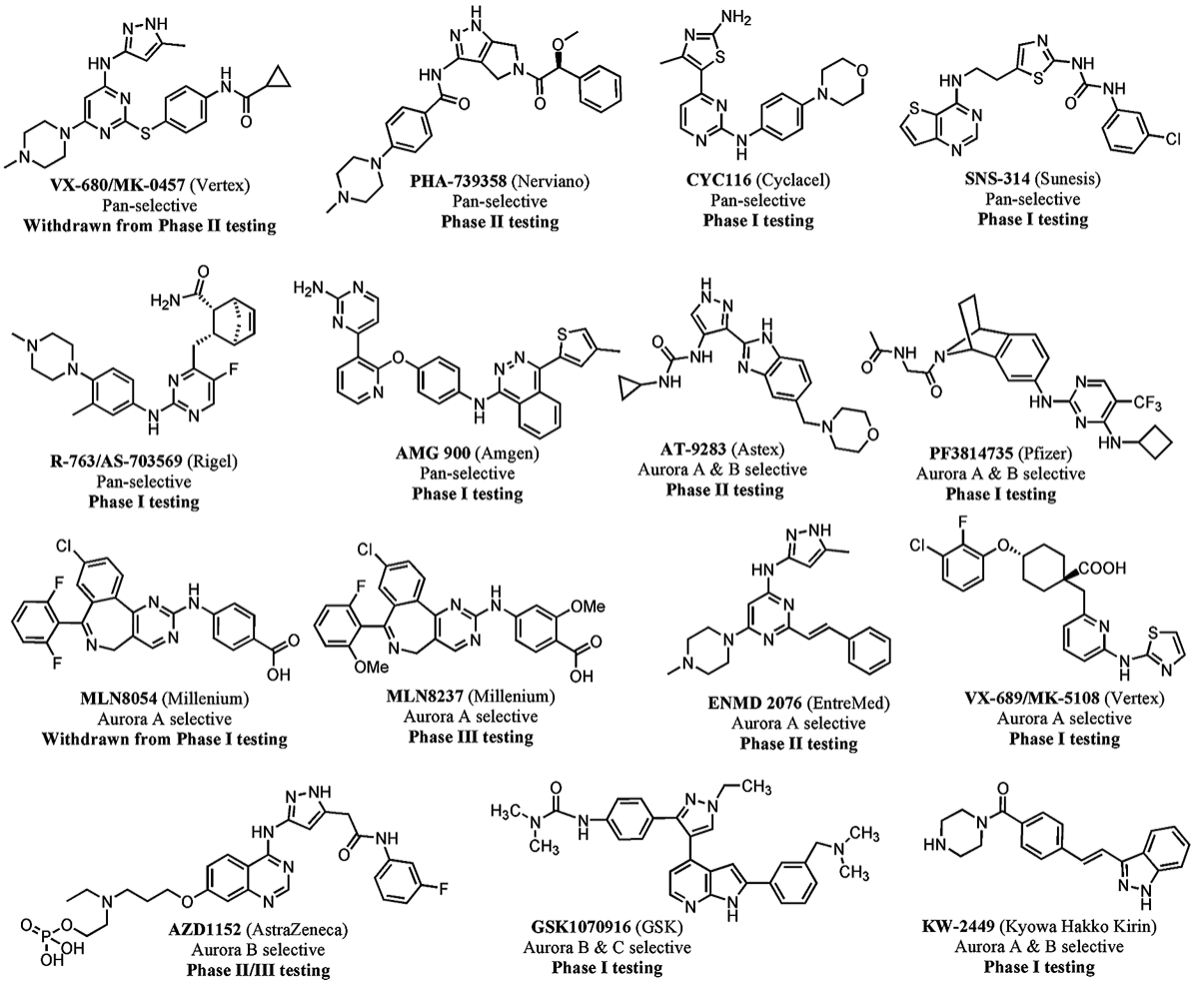
commonly used by scientific communities are: AutoDock (Morris et al., 2009), GOLD (Jones, Willett, Glen, Leach, & Taylor, 1997), DOCK (Ewing, Makino, Skillman, & Kuntz, 2001), Glide-XP (Friesner et al., 2006), LibDock (Diller & Merz, 2001), CDOCKER (G. Wu, Robertson, Brooks, & Vieth, 2003), FlexX (Rarey, Kramer, Lengauer, & Klebe, 1996), LigandFit (Venkatachalam, Jiang, Oldfield, & Waldman, 2003), etc. All these programs use different algorithms and parameters, and these could be classified broadly as shape based (e.g. LibDock) and energy based (e.g. Glide XP) methods.

Virtual screening using structure based pharmacophore (SBP) is an important and an alternative method to docking (Pirhadi, Shiri, & Ghasemi, 2013). SBP method uses a set of essential features (steric and electrostatic interactions) that are necessary to maintain the optimal intermolecular interactions with a specific biological target to activate or block its biological response. Generally, pharmacophore features include hydrogen bond acceptor, hydrogen bond donor, hydrophobic, aromatic, positive and negative ionizable groups. Earlier, only ligand based pharmacophore hypothesis were usually employed to screen the small molecule databases in the absence of the protein structure. But, advancement of structural biology and computational chemistry greatly helped to derive the pharmacophore features from protein or protein-ligand complex structures. Thus, several tools are developed to derive the pharmacophore features using protein or protein-ligand structural information. Among them, Catalyst (Discovery Studio 3.1), Phase and E-pharmacophore (Schrödinger Suite 9.2 software package), Ligand and Structure-Based Query Editor (MOE), LiganScout (Wolber & Langer, 2005), and ZINCPharmer (Koes & Camacho, 2012b) are few routinely employed tools in drug discovery projects. Using these tools, the pharmacophore features could be derived from the known protein-ligand crystal structure or exclusively from the identified binding sites or from the identified hot spot residues of the given target PPIs. Moreover, the pharmacophore features can be derived from docking the fragments at the defined binding site of protein using E-pharmacophore module (Schrödinger software suit), which takes the advantages of both ligand and structure based methodologies to generate an energetically optimized pharmacophore hypothesis that can be used to screen the small molecule databases. Interested readers may refer to Clik2Drug website (http://www.click2drug.org/directory_Docking.html) for an exhaustive list of tools available for SBDD.

The PPIs inhibitors identified by VS could be further evaluated using various computational methods. One approach is, assessing the binding stability of the compound with the target protein using molecular dynamics simulation (Mortier et al., 2015). Using this, the dynamic behavior of the compounds with the target protein in the presence solvent molecules could be studied. The second approach is to assess the drug-like properties of the identified hits, using Lipinski's rule of five (Lipinski, Lombardo, Dominy, & Feeney, 2001). Based on the favorable results from the above *in silico* investigations, the identified inhibitors could be subjected to *in vitro* testing and further optimization to identify PPIs inhibitors.

An *In Silico* Approach for the Identification of PPI Inhibitors: Aurora B-INCENP PPI as a Case Study



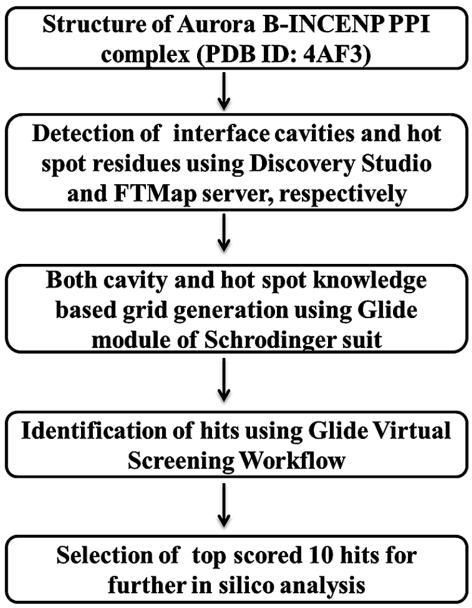
Aurora kinases are a subclass of protein kinase that plays a crucial role in mitosis through phosphorylation of serine/threonine residues of the substrate protein. There are three isoforms of Aurora kinases (Aurora-A, B and C) which share a conserved ATP binding site. Among these three isoforms, Aurora A and B are over expressed in many of the human solid tumors (Fu, Bian, Jiang, & Zhang, 2007). Consequently, scientific communities are developing Aurora kinase inhibitors for cancer therapy. Presently, over a dozen Aurora kinase inhibitors that target the ATP binding site are in various phases of clinical

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

development (Figure 3) (Cheung, Coumar, Chang, & Hsieh, 2011; Cheung, Coumar, Hsieh, & Chang, 2009; Cheung, Sarvagalla, Lee, Huang, & Coumar, 2014). Most of the developed Aurora kinase inhibitors are pan-selective (Aurora A, B and C selective), and few of them are isoform selective (Aurora A or B selective); but none of them have been approved for clinical use so far. The major reasons for the failure is due to on- and off-target toxicity problems associated with the administration of non-selective Aurora kinase inhibitors (Sarvagalla & Coumar, 2015).

As Aurora kinase family shares a conserved ATP binding site, developing isoform selective inhibitors is very difficult. Hence, most of the developed Aurora kinase inhibitors are pan-selective, and evaluation of these inhibitors in the clinical trials reported on- and off-target toxicity (Kollareddy et al., 2012; Sarvagalla & Coumar, 2015). The major on-target toxicities that are reported in clinics are: neutropenia, leukopenia, myelosuppression, septicemia, pneumonia and thrombocytopenia. In addition to this, several off-target problems including mucositis, proctalgia, hypertension, somnolence, stomatitis, grade 3 increases in aspartate aminotransferase and grade 2 ventricular dysfunctions have been reported. Drug resistance, is another major problem that need to be addressed for Aurora kinase inhibitors (Girdler et al.,

Figure 3. Chemical structures of Aurora kinase inhibitors in clinical development



EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

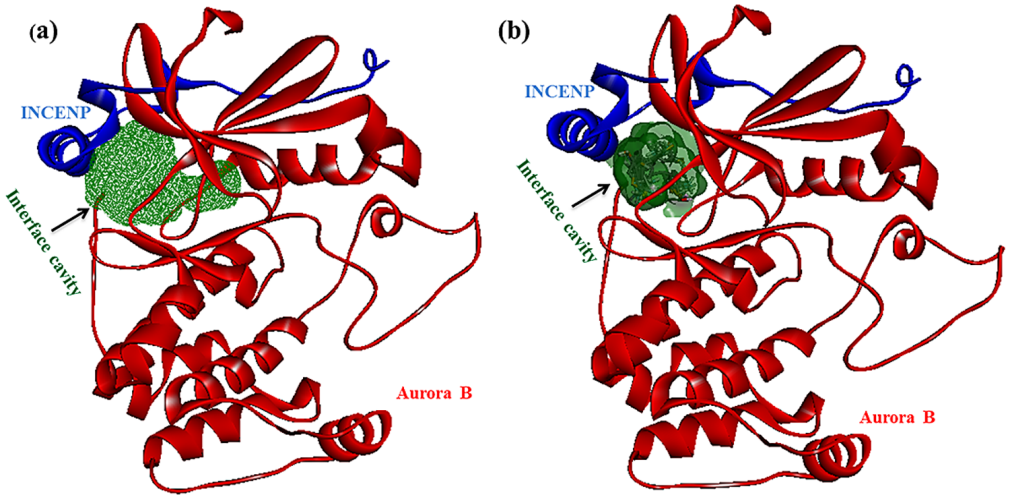
2008). Because of the development of drug resistance, drug efficacy and affinity is greatly affected. It is also reported that various types of cancer cell lines develop resistance to many Aurora kinase inhibitors. Another drawback of Aurora kinase inhibitors is the lack of chemical diversity, because of the conserved ATP binding site, resulting in difficulties in IP protection (Backes et al., 2008).

The above reported problems could be overcome by targeting the PPI sites of Aurora kinases. Aurora kinase A interacts with TPX2 (Bayliss, Sardon, Vernos, & Conti, 2003); whereas Aurora B interacts with INCENP protein (Sessa et al., 2005). The interactions of TPX2 and INCENP with their respective Aurora kinase isoform are very specific and essential for the full activation of the kinase. Thus, inhibiting these PPIs would be very specific and serves as an alternative strategy to target the Aurora kinase for cancer treatment with reduced toxicity profile. Recent evidence also indicates that the design of isoform selective Aurora kinase inhibitor has advantage over the pan-selective Aurora inhibitors (Sarvagalla & Coumar, 2015). This could be achieved by targeting PPI sites of Aurora enzymes (Gohard, St-Cyr, Tyers, & Earnshaw, 2014). To this end, to design isoform selective small molecule inhibitors of Aurora kinase B, here the authors have applied the cavity and hot spot detection techniques discussed above to identify ligand binding PPIs sites in the interface of Aurora B-INCENP. Further, molecular docking was carried out to identify PPI inhibitors by screening approved drugs (http://www.drugbank.ca/). The methodology applied for the identification of Aurora B-INCENP PPIs inhibitors is depicted in Figure 4.

For this process, first the Aurora B-INCENP protein crystal structure (PDB ID: 4AF3) was downloaded from PDB, and was processed for docking as reported earlier (Sarvagalla et al., 2015). Then, the prepared protein was used to identify the ligand binding cavities using two different methods: The first one is shape based method (Define Site- discovery studio module) and the second one is based on the energy based method (FTMap server). These two methods identified a common ligand binding cavity at the interface of Aurora B-INCENP complex. Further, comparison of the results from both the

Figure 4. Schematic representation of the workflow used to identify PPI inhibitors of Aurora B-INCENP complex

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



method revealed that most of the residues identified in the cavity are common. The residues involved in the cavity are shown in Table 4, and the location of the cavity that was identified by discovery studio and FTMap are shown in Figure 5.

Further, the hot spot residues of both the proteins (Aurora B and INCENP) were identified by mutating the interface residue to alanine using discovery studio module and Robetta web-server. Results from both the methods are shown in Table 5. Analysis of the results revealed that four hot spots residues (Phe101, Ile102, Tyr141 and Leu210) from Aurora B and six hot spot residues (Ile855, Gln858, Tyr859, Leu865, Leu868 and Phe869) from INCENP protein are projected into the identified cavity. Next, the integrated knowledge derived from the cavity and hot spot detection was used to define the ligand binding site using 'Receptor Grid Generation' option of glide module; this was followed by Virtual Screening of approved drug bank compounds. For VS, Glide module 'Virtual Screening Workflow' was employed; this module provides three stages of screening: first HTVS (high-throughput virtual screening) mode, then SP (standard precision) mode and the final XP (extra precision) mode. The VS workflow, enriches

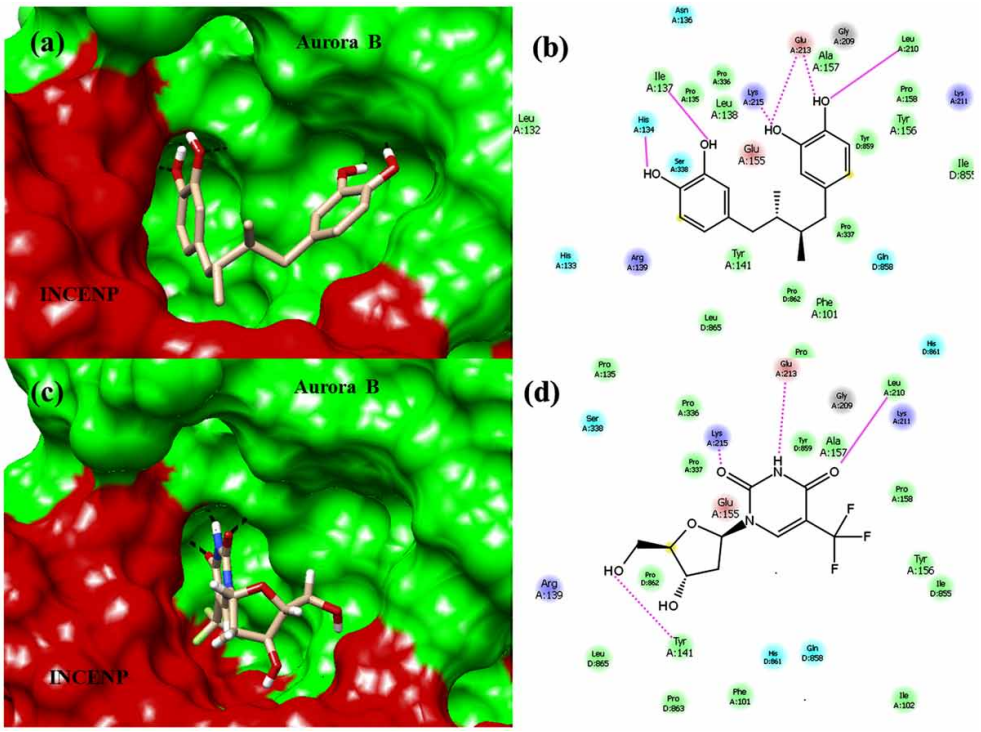
12	Tyr143	H (2.88)	H (2.48)	28	Ile880	H (1.35)	H (1.30)
13	Tyr145	H (1.87)	H (1.40)	28	Phe881	H (2.99)	H (2.76)
14	Ile150	NH (0.0)	H (1.03)	30	Lys882	NH (0.0)	H (0.94)
15	Tyr156	NH (0.0)	H (0.73)				
16	Leu210	H (1.89)	H (0.95)				

the data in every step by eliminating false positives by applying more extensive sampling and scoring methods. After screening, top scored 10 compounds were selected as initial hits for Aurora B-INCENP PPI inhibition. The selected 10 compounds, Glide XP docking scores and the hot spot residues involved in non-bonded interaction are listed in Table 6. Analysis of these hits in the PPI binding site shows that few hot spot residues of Aurora B (Phe101, Tyr141 and Leu210) and INCENP (Ile855, Gln858, Tys859 and Leu865) are consistently making hydrogen bonds as well as hydrophobic interactions with the identified hits. Thus, the selected hits might disrupt the PPI of Aurora B-INCENP complex by interacting with the important hot spot residues. For illustration, top scored two compounds 3D and 2D binding mode in the Aurora B-INCENP complex is shown in Figure 6. As a next step, the identified hits need to be tested in *in vitro* assay, to confirm their ability to interfere in Aurora B-INCENP PPI.

CONCLUSION AND FUTURE DIRECTIONS



Most of the kinase inhibitors in the market or those under development act by interacting with the ATP binding site of the kinase. Due to the conserved nature of the ATP binding site of the kinase, existing kinase inhibitors are burdened with drawbacks including off- and on-target toxicity and development of drug resistance. These drawbacks could be overcome by targeting the protein-protein interactions (PPIs) of kinase, instead of targeting the ATP binding site. Though targeting the PPIs is a difficult task

and success in the form of a marketed drug is yet to come, it is worthwhile exploring these targets, as they are very selective in nature and provides distinct advantages. Moreover, if the PPIs are considered as potential drug targets, then the number of targets would exceed the druggable human kinome; because large numbers of PPIs exist in a living cell as compared to human kinome, and many of them are involved in disease conditions.

Towards this end, here the authors have provided an *in silico* framework for the identification of kinase PPI inhibitors. By utilizing the structural knowledge (cavities and hot spots) of kinase PPI interfaces, structure-based drug design could be carried out. As a case study, Aurora B-INCENP PPI inhibitor identification using the *in silico* framework is discussed. In the future, availability of 3D protein-protein interaction complex, advancement in protein-protein docking algorithms and reliable *in silico* tools for the detection of hot spots, could greatly enhance the speed at which PPI inhibitors could be reliably identified.

KEY TERMS AND DEFINITIONS

Aurora Kinases: Human genome encodes three members of Auora kinases: Aurora A, Aurora B, and Auora C. These members belong to serine/threonine kinase families that are essential for cell division and duplication.

Docking: Docking is a computation tool which predicts predominant binding mode of biomolecule interactions including protein-ligand, protein-protein, protein-DNA, protein-RNA and protein-carbohydrate.

Drug Target: Drug target is a biomolecule within the living organism to which an endogenous ligand or drug molecule binds to produce the therapeutic effect.

Hot Spots: In the protein-protein interaction interface region, a residue or cluster of residues that contributes to the majority of binding free energy for the complex formation is called hot spots.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

INCENP: The human gene *INCENP* encodes a protein known as - Inner Centromere Protein, which is essential for the full activation of Aurora B kinase.

Kinase: Kinase is an enzyme which catalyzes the transfer of an ATP terminal phosphate group to a specific substrate protein; the process is called phosphorylation.

Pharmacophore: Pharmacophore is a 3D hypothetical model of molecular features which are essential for the molecular recognition of a ligand by a drug target.

Protein-Protein Interactions: Protein-protein interactions (PPIs) refer to a physical contact that is formed between two or more proteins. As a result of PPIs, a wide array of biological functions including cell division, cell growth, signal transductions, metabolic reactions, and transportation of molecules from one location to another will occur within the living organism.

Chapter 44
Rational Drug Design
Rational Drug Design: One Target, Many Paths to It

ABSTRACT

For the past three decades rationale drug design (RDD) has been developing as an innovative, rapid and successful way to discover new drug candidates. Many strategies have been followed and several targets with diverse structures and different biological roles have been investigated. Despite the variety of computational tools available, one can broadly divide them into two major classes that can be adopted either separately or in combination. The first class involves structure-based drug design, when the target's 3-dimensional structure is available or it can be computationally generated using homology modeling. On the other hand, when only a set of active molecules is available, and the structure of the target is unknown, ligand-based drug design tools are usually used. This review describes some recent advances in rational drug design, summarizes a number of their practical applications, and discusses both the advantages and shortcomings of the various techniques used.

INTRODUCTION

Once, a US General summarized his philosophy on warfare in just four concise statements, "The art of war is simple enough. Find out where your enemy is. Get at him as soon as you can. Strike him as hard as you can, and keep moving." Although these overarching statements formed the basic premise of modern war strategies, the same concepts have been applied in designing new drugs aimed at combating a broad range of diseases. In this context, rational drug design (Hao, Yang, & Zhan, 2012; Hedvat et al., 2012; Mandal, Moudgil, & Mandal, 2009) has been established as an exciting research approach

aimed at developing safer and more efficacious drugs using modern computational tools which are fast and inexpensive compared to traditional methods. The ultimate goal of this research is to design small organic non-peptidic compounds that bind to a specific molecular target, and result in the inhibition (or less frequently, activation) of a particular protein or enzyme involved in a given cellular pathway, i.e. a blockage of a specific protein-protein interaction. The development of such drugs has been recognized early on by the pharmaceutical industry as a principal foundation that provides it with the necessary return on investment to fuel further research and development (Szymkowski, 2005) leading to a discovery and development cycle.

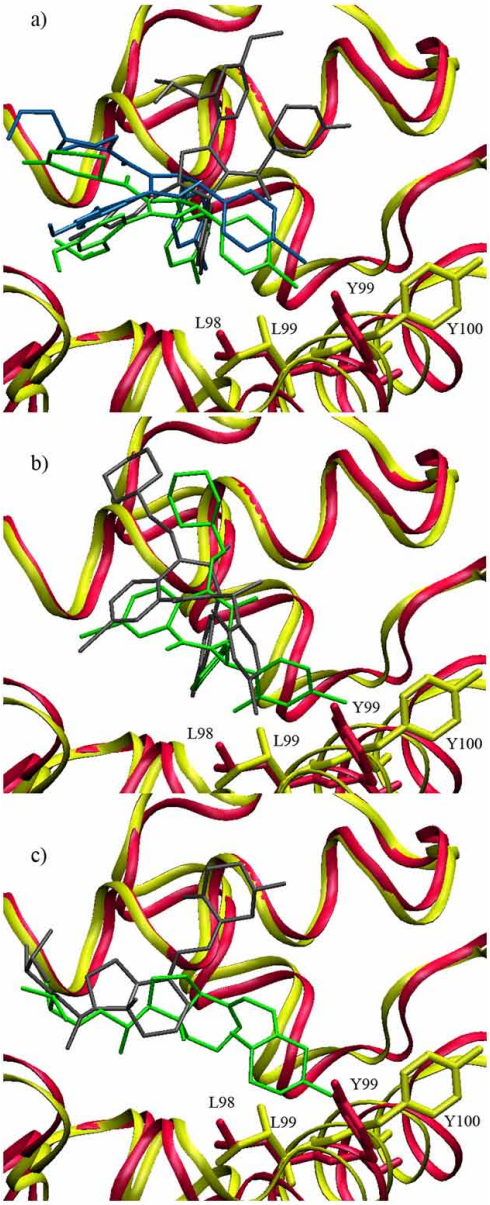
Our understanding of cell mechanisms and pathways at a molecular level becomes deeper and clearer every day. This is largely due to the great efforts and hard work of genomic and proteomic research groups who add novel targets for drug intervention on a regular basis (Drews, 2000; Fishman & Porter, 2005; Hopkins & Groom, 2002). Thus far, several hundred proteins have been synthetically expressed and many of them are currently evaluated for their druggability (Hopkins & Groom, 2002). These targets involve several families comprised of G-protein coupled receptors (GPCRs), ligand-gated ion channels (LGICs), cytoskeleton proteins, phosphatases, kinases, nuclear receptors (NRs) and DNA repair proteins. The growing list of potential drug targets encourages a bold question if it is in principle possible to restore any diseased cell to a healthy state by uncovering a drug for every potential druggable target? Certainly, if this dream is ever realized, many diseases will be cured and relegated to the dustbin of history in a manner similar to the effect of the discovery of vaccines in the 19th and early 20th century. We think this is most definitely achievable as a result of rapid progress made in the computational drug discovery area.

A typical rational drug design effort involves many tools that can be used either separately or in combination depending on the available structural and kinetic data. Once the structure of a target (typically a protein) is available, docking algorithms can be used to place each ligand (i.e. a molecule or a molecular fragment included in a typical library of compounds) and predict its most probable binding mode within the binding site of the target (Abagyan & Totrov, 2001; Schneider & Bohm, 2002). Moreover, most docking programs can rank the predicted activity of each compound by analyzing the different ligand-target interactions in terms of the estimated binding affinity of the complex. In addition to docking techniques, one can define the essential interactions between the ligand and the binding site of the receptor and translate this information into the formulation of binding-site pharmacophore models (Good, Krystek, & Mason, 2000). These models can be used to search the available chemical space for compounds that can complement the physicochemical features of the receptor. As these two procedures require a comprehensive understanding of the structural arrangement of the target, they have been commonly termed as structure-based drug design (SBDD). On the other hand, and for most of the cases, the three-dimensional structure of the target, the binding site or even the target itself are not accurately known, although there may be a number of known active compounds that have been identified experimentally. In this case, data mining algorithms can be used to screen for compounds that are structurally similar to the known actives (similarity search) (Willett, 2006) or that comprise the chemical features of these compounds (pharmacophore search) (Krovat, Fruhwirth, & Langer, 2005), in what is called ligand-based drug design (LBDD). Thus, these two fundamental procedures, SBDD and LBDD, form the general layout of present-day rational drug design protocols. This review summarizes the recent advances in rational drug design, focusing on the methods and their successful applications in drug discovery. Moreover, we will summarize the shortcomings of the various techniques used, pointing out to future directions of the field.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

STRUCTURE-BASED DRUG DESIGN (SBDD)

SBDD requires the knowledge of the three-dimensional structure of the target protein (Hedvat et al., 2012; Heikamp & Bajorath, 2013; Lyne, 2002; Schneider & Bohm, 2002; Shoichet, Stroud, Santi, Kuntz, & Perry, 1993). Therefore, an essential step prior to the actual screening procedure is to generate or predict the structure of the target protein. The target structure can be obtained by experimental techniques such as NMR, X-ray crystallography, electron crystallography or it can be predicted computationally using homology modeling (Levit, Barak, Behrens, Meyerhof, & Niv, 2012). In addition to the 3D-structure, it is also important to identify the relevant binding site(s) within the protein, which is (are) deemed responsible for its biological activity. In general, the binding site is a pocket, a groove or a protrusion having an assortment of apparent hydrogen bond donors and acceptors, hydrophobic features and it can be associated with molecular adherence surfaces (Berezovsky, 2013; Nussinov & Tsai, 2013). There may be a number of metal ions or water molecules as part of the active site that are essential for the activity of the protein and they must be considered during the screening procedure in order to produce a correct result. There are two basic approaches for SBDD namely, docking (Abagyan & Totrov, 2001) and receptor-based pharmacophore modeling (Good et al., 2000).



Docking

Molecular docking is a standard constituent of many SBDD studies described in the literature (Abagyan & Totrov, 2001; Halperin, Ma, Wolfson, & Nussinov, 2002; Mihasan, 2012). The idea of docking and scoring as a virtual screening tool has been proposed since the birth of docking methods (DesJarlais et al., 1990; Kuntz, 1992; Kuntz, Blaney, Oatley, Langridge, & Ferrin, 1982). The main problem which all docking algorithms try to solve can be stated as follows: given two interacting molecular structures, what is the most probable binding configuration to form a stable three-dimensional protein-ligand complex? In order to address this problem, docking procedures can be divided into two major steps. First, explore the conformational space of the ligand within the binding site of the target. At this stage, numerous conformations are generated for the ligand. Second, select the optimal target-ligand alignment by scoring their interactions and ranking the docking results (poses) according to their predicted binding affinity. Today, there are at least 30 docking programs commercially (or publicly) available with different conformational sampling algorithms and a variety of scoring functions (Bissantz, Folkers, & Rognan, 2000). The most commonly used programs are AUTODOCK (Goodsell & Olson, 1990), GOLD (Jones, Willett, & Glen, 1995b), GLIDE (Friesner et al., 2004), DOCK (Kuntz et al., 1982), ICM (Totrov & Abagyan, 1997), IFREDA (McGann, Almond, Nicholls, Grant, & Brown, 2003) and FlexX (Rarey, Kramer, Lengauer, & Klebe, 1996). These programs differ mostly in the way they deal with protein-ligand flexibility or their scoring and ranking methods.

Regardless of the poor representation of the receptor flexibility during docking, most docking methods can handle the flexibility of ligands efficiently (Bissantz et al., 2000). In other words, for most of the cases, docking algorithms can reproduce the protein-ligand binding modes that have been observed experimentally using X-ray crystallography. As an example, Figure 1a shows the successful docking of nutlin, a well-known p53-MDM2 inhibitor, to the p53-binding site within MDM2 using AUTODOCK 4.0. In general, the degree of success for docking methods can be measured by comparing the predicted binding mode to the experimental conformation (the native binding mode) (Goodsell & Olson, 1990; Jones et al., 1995b; McGann et al., 2003). This assessment can be evaluated quantitatively by calculat-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 1. Structural variations between MDM2 (yellow) and MDMX (red) and their effect on the binding modes of nutlin-3 (a) and two selected hits form the predicted MDM2/MDMX inhibitors (b and c). Tyr100 and Leu99 of MDM2 and the same residues in MDMX are shown in Licorice representations with the same color as that of the two proteins. For each compound, the binding mode within MDM2 is shown in green and within MDMX is shown in gray. Tyr99 and Leu98 prevent nutlin-3 from binding to MDMX with the same binding conformation adopted by nutlin-2 within the MDM2-pocket (blue). The conformation of nutlin-2 was extracted from the MDM2-nutlin crystal structure 1RV1. On the other hand, compounds Pub#11952782 (b) and ZINC04629876 (c) from the suggested MDM2/MDMX inhibitor list can tolerate the structural variations in the two binding sites in order to maximize their interactions with the proteins.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

ing the root-mean-square deviation (RMSD) between the two structures. However, in certain systems, where unexpected flexibility of the receptor is crucial for the binding reaction or the interaction of the ligand and protein is mediated by water molecules or metal ions, docking may fail to predict the correct binding conformation of the complex, leading to improper and unrealistic interactions.

Ligand Flexibility

The binding reaction between a ligand and a particular target involves numerous conformational changes in the two molecules as well as water molecules and ions located in their interface. Each entity in this reaction adapts its shape and distribution in order to maximize its interactions with the other entities, forcing the whole system to reach the global minimum. This binding interaction is somehow similar to a folding problem of a protein, comprising a huge number of degrees of freedom. Consequently, the majority of docking programs avoid this combinatorial explosion problem by implementing almost full-flexibility for the ligands while keeping the target completely rigid with no flexibility allowed (Abagyan & Totrov, 2001; Bissantz et al., 2000). According to the nature of the search method, the conformational sampling techniques that have been adopted by all docking programs to introduce ligand flexibility can be classified into three main categories: (1) systematic search routines, (2) stochastic exploration, and (3) simulation techniques.

Systematic Search

In a typical systematic search, all rotatable bonds in the ligand are gradually rotated in order to cover all possible combinations among the dihedral angles. Evidently, the number of generated structures using this method increases dramatically with the number of rotatable bonds involved, leading to the problem of combinatorial explosion. In this way, applying a standard systematic search to explore the entire conformational space of a ligand requires massive calculations and considerable computational time. Although, a number of docking programs such as FLOG (Miller, Kearsley, Underwood, & Sheridan, 1994) get around this obstacle by limiting the created structures to a pre-generated set of conformations recorded in structural databases, other docking algorithms adopt an incremental procedure to reconstruct the ligand within the binding site of the target. The main objective of these methods is to limit the number of degrees of freedom for the ligand, allowing for a less-expensive and rapid conformational search.

Essentially, there are two main approaches for the incremental reconstruction methods. First is the one that has been employed by LUDI (Bohm, 1992), FlexX (Rarey et al., 1996), DOCK (Kuntz et al., 1982), ADAM (Mizutani, Tomioka, & Itai, 1994) and Hammerhead (Welch, Ruppert, & Jain, 1996), where the ligand is split into a rigid core fragment that is docked first and a number of flexible regions that are subsequently and successfully added. This method is commonly referred to as the "incremental approach". The other method, known as "place and join", is to break the ligand into several fragments, dock them within the binding site of the target and finally connect them together in order to rebuild the final ligand conformation.

Stochastic Exploration

Stochastic exploration samples the conformational space of a ligand by generating random variations in the orientation of all rotatable bonds and in some cases random translations for the whole ligand within

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

the binding site. This is done mainly to enable crossing the energy barriers and searching for local minima enclosed by the rugged energy surface of the ligand. This procedure can be applied to a single ligand or a population of conformations derived from the same molecular structure of the ligand. Each resultant conformation is then evaluated according to a probability distribution or by estimating its binding affinity with respect to the target. In fact, there are three methods that are derived from this technique, namely: Monte Carlo simulations, Genetic Algorithms and Tabu Search methods (Schneider & Bohm, 2002).

The Monte Carlo (MC) method of simulations is one of the most powerful techniques ever developed to allow crossing potential energy barriers and sampling the conformational space of a complex system. Since this method has been successfully implemented to solve several molecular modeling problems, it was regarded as one of the natural options to explore ligand flexibility in docking. The method starts with a randomly generated conformation for the ligand by randomly changing one or more dihedral angles or even the whole orientation or position of the ligand with respect to the target. This new conformation (pose) is accepted or rejected according to a Metropolis algorithm that follows the Boltzmann probability distribution. Programs like ICM (Totrov & Abagyan, 1997), MCDOCK (Liu & Wang, 1999) and DockVision (Hart & Read, 1992) employ this approach in exploring the flexibility of ligands during docking.

Genetic algorithms (GA) exploit the biological concepts of natural selection introduced by Darwin in order to explore all possible conformations of the ligand and predict its native structure. In contrast to MC-based algorithms, instead of manipulating a single ligand, GA generates a random population of the same molecular structure of the ligand (Goodsell & Olson, 1990; Jones et al., 1995b). Each member of this population is unique in terms of the internal orientation and the global placement and alignment within the binding site of the target. This random population forms the initial generation (seed) of a set of non-interacting ligand species. These poses are further subjected to a number of biological operators that add up more diversity to the generated structures. Among these operators the most important ones are the mutation operator (generates new ligands from earlier ones by altering a rotatable bond or moving the whole ligand to a new position), and the crossover operator (merges two ligands in order to create a new structure comprising their common features). The fitness of each newly generated structure is evaluated by calculating its binding affinity to the target. The pose, which retains the most predominant interactions with the binding site survives and becomes the parent of the new generation. This iterative procedure terminates after reaching a predefined number of generations or energy evaluations, or if no more improvement to the binding affinity has been observed (converged solution). Examples of programs that incorporate genetic algorithms in conformational sampling include AUTODOCK, GOLD and DARWIN (Taylor & Burnett, 2000).

As a memory-based stochastic exploration method, Tabu Search (TS) prevents the searching machinery from revisiting the same conformation more than once. PRO_LEADS is one of the most popular programs that employ this searching technique (Baxter, Murray, Clark, Westhead, & Eldridge, 1998). This is generally achieved by creating a list that records all previously visited solutions, which acts as a memory for the algorithm. A decision to accept or reject a new conformation is made after comparing its RMSD to the other recorded conformations in order to ensure that no conformation is visited twice.

Simulation Techniques

Simulation techniques employ a deterministic approach that either: (1) passes through both time and space giving rise to an evolving trajectory describing the biological behavior of a typical system, or (2)

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

reconfigures the system by rearranging its particle composition towards a more stable state. Molecular dynamics (MD) simulations and energy minimization methods are the most widely used techniques in a number of docking programs. Although the two approaches can handle the full-flexibility of both the ligand and target, their foremost disadvantage is that they can be readily trapped within a local energy minimum, which in turn precludes them from efficiently sampling the conformational space of the complex. Therefore, simulation techniques are usually used as complementary methods and a refining step subsequent to GA or MC simulations (Bissantz et al., 2000).

Protein Flexibility

Docking a ligand against a crystal or relaxed receptor structure is a commonly used approach in structure-based drug design (Abagyan & Totrov, 2001). However, in many cases, the degree of success that may be achieved in a typical docking experiment depends on the characteristics of the target and how important the protein flexibility is in the simulation. Most of the successful cases reported in the literature were either related to nearly rigid proteins or proteins having a real binding mode of their respective ligands, or complexes whose structure was determined experimentally (Reddy, Pati, Kumar, Pradeep, & Sastry, 2007). In spite of these studies, there are cases where the binding interaction has been shown to induce significant conformational changes in the target protein, ranging from local reorganization of side-chains to hinge movement of domains. Sampling these conformational changes during docking is impractical, as they involve too large a number of degrees of freedom. To address such problems, a number of docking packages like AUTODOCK, GOLD, FlexE and IFREDA, manage to include a modest amount of flexibility in the target during the docking simulations. These approaches include soft docking (Osterberg, Morris, Sanner, Olson, & Goodsell, 2002), sidechain flexibility (Schneider & Bohm, 2002), combined protein grid and united descriptors of the target (Knegtel, Kuntz, & Oshiro, 1997).

Soft docking algorithms allow the ligand to penetrate through the surface of the protein in order to approximate and predict the dynamical changes that may take place within the active site as a result of ligand binding. This is generally achieved by attenuating Lennard-Jones repulsive parameters in the potential energy function that describes the system (Osterberg et al., 2002). Another commonly used technique to introduce active site dynamics in the context of docking is to allow key side chains that have been shown to mediate the interactions with the ligand to rotate freely and search for their preferred conformation. These side chain rotations are usually restricted to a number of pre-defined experimental conformations stored in rotamer libraries or predicted from a prior MD simulation. While this method reduces the risks associated with the lack of flexibility to some extent, it neglects backbone dynamics, which may affect the ultimate docking results (Reddy et al., 2007).

In order to account for a larger degree of receptor flexibility at a reasonable computational cost, a number of dominant protein conformations can be combined simultaneously to generate a comprehensive model that describes the essential dynamics of the binding site (Knegtel et al., 1997). This approach is generally termed as “combined protein grid” and is usually implemented in two steps. First, for each conformation, all possible protein-ligand atomic interactions are calculated and recorded in what is called a docking grid. Second, a combined grid is created by applying a weighted average for all the resulting grids that represent various conformations. Alternatively, the averaging procedure may be applied to the atomic coordinates to generate an average structure for the protein.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Scoring Methods

As scoring of the poses is crucial in prioritizing and ranking of the compounds, it is important to use sensitive and accurate scoring functions that can not only reproduce but also predict experimental results. This is normally achieved using an objective scoring function that directs the conformational search algorithm in predicting the native conformation and ultimately estimates the binding affinity of the protein-ligand complex. Nevertheless, it has been broadly demonstrated that docking scoring functions are less successful at predicting the actual binding affinities and at discriminating true binders from inactive (decoy) compounds (Abagyan & Totrov, 2001; Schneider & Bohm, 2002; Shoichet et al., 1993). These puzzling results are direct outcomes of many factors that have been mistreated while analyzing the binding interactions of the resulting poses as a compromise to achieve a speed-up of the docking process. These factors mostly comprise the lack of proper solvation, the neglect of protein flexibility and the bias toward the training set of structures that have been used in optimizing the scoring process (Reddy et al., 2007). In fact, developing new scoring functions and innovative ranking schemes is a widely open area of research in the field of docking. Although a more precise scoring method can be practically implemented within docking, a large computational cost that is associated with such a function will be the actual barrier to using it. In this way, many assumptions have been proposed in the currently used docking scoring functions in order to reduce the complexity and computational time required to evaluate a particular pose. Overall, a typical scoring function includes among its ingredients at least the following ones: a descriptor of the hydrophobic effects, van de Waals dispersion interactions, hydrogen bonding, electrostatic interactions, and solvation effects. Based on their scoring functions, all docking programs that are in use today (Bissantz et al., 2000; Kitchen, Decornez, Furr, & Bajorath, 2004; Reddy et al., 2007) can be divided into four major categories: force field-based, empirical, knowledge-based and consensus methods.

According to the energy landscape theory, the native conformation for a ligand within the binding site of its target is correlated with a pronounced deep minimum on the energy surface. Therefore, potential energy (force-field) functions have been used to describe protein-ligand interactions and assess their binding affinity by exploring the energy surface and locating these minima. As docking algorithms usually deal with a single target conformation, the internal protein interactions are typically neglected. Accordingly, force field methods approximate the ligand-protein binding interactions by adding the interaction energy between the protein and the ligand to the ligand internal energy. These internal interactions are approximated by harmonic springs that describe the vibrations and rotations of the different bonds forming the ligands. The non-bonded interactions between the ligand and its target are estimated by van de Waals, hydrogen bonding, and electrostatic terms. Consequently, the major drawback of standard force field scoring functions is the lack of solvation and entropy contributions to the binding energy. Examples of force-field-based scoring functions include D-Score (B. Kramer, Rarey, & Lengauer, 1999) and GoldScore (Verdonk, Cole, Hartshorn, Murray, & Taylor, 2003).

Another widely used scoring approach is to hypothesize an empirical scoring function that has been optimized to reproduce a collection of experimental data (Bohm, 1992). These data may include binding affinities or native conformations for known active compounds. Notable examples include F-Score (Rarey et al., 1996), ChemScore (Eldridge, Murray, Auton, Paolini, & Mee, 1997), SCORE (Tao & Lai, 2001) and Fresno (Rognan, Lauemoller, Holm, Buus, & Tschinke, 1999). The basic concept behind this type of scoring functions is that the binding energies can be approximated by a summation of unrelated contributions. Each element of this summation describes a certain binding interaction such as hydrophobic,

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

hydrogen bonding, electrostatic or solvation effects. Some functions may comprise an approximation for the loss of entropy due to binding, which is proportional to the number of rotatable bonds included in the ligand. Overall, the terms that build up a typical empirical scoring scheme are simple enough to be rapidly evaluated in order to speed up the docking process. A fairly accurate estimate for the coefficients pre-multiplying these terms can be obtained by performing regression analysis and fitting the whole function against the set of experimental data. Although several empirical functions have been successfully used in many cases, they are generally biased toward the experimental data that have been used in their optimization (Bissantz et al., 2000; Reddy et al., 2007).

Similar to empirical scoring functions, knowledge-based scoring methods attempt to reproduce experimentally determined structures using simpler atomic interaction-pair potentials. These potentials are based on the frequency of occurrence of all possible interactions between the ligand and its target. Using statistical analysis, knowledge-based models implicitly describe binding effects that are hard to represent explicitly during docking. Therefore, the accuracy of these methods depends on the extent of the manipulated protein-ligand data set and the diversity of atomic interactions included in these complexes. An example of such functions is DrugScore (Gohlke, Hendlich, & Klebe, 2000).

A more recent scoring technique, consensus scoring collects assessments from several scoring functions in order to evaluate a particular docking result (Charifson, Corkery, Murcko, & Walters, 1999). Hence, the method is expected to reduce the errors that result from the individual scoring functions and to improve the probability of selecting true binders. Nevertheless, it has been recommended to use different and uncorrelated scoring functions in constructing a successful consensus scheme. This is because correlated functions tend to produce similar results leading to error amplification and misleading results. Despite these constraints, several studies have pointed to the success of a number of consensus scoring functions when compared to using a single scoring method (Terp, Johansen, Christensen, & Jorgensen, 2001). These methods include X-CSORE (Wang, Lai, & Wang, 2002) and FlexX (Rarey et al., 1996) scoring functions.

Structure-Based Pharmacophore Modeling (SBPM)

In spite of the great efforts of many research groups in both the pharmaceutical industry and academia, there still exist several barriers that prevent the use of docking methods as a leading approach to drug discovery (Abagyan & Totrov, 2001; Ou-Yang et al., 2012; Zoete, Grosdidier, & Michielin, 2009). These barriers include the following: (1) the inclusion of sufficient target flexibility and the simulation of the induced fit mechanism; (2) the druggability of the target; (3) the modeling of water-mediated interactions at the interface of the target-ligand complex; (4) the effect of metal ions located within the binding site of interest, and; (5) the fine-tuning of the protonation states of both the receptor and the ligand. Consequently, these difficulties motivated researchers to develop novel rational drug design approaches that are far removed from standard docking methods. In this context, structure-based pharmacophore modeling (SBPM) originated as an alternative SBDD technique that can describe the essential interactions behind the binding of a ligand to its target (Z. Chen et al., 2009; Kim, Lee, Kang, Kim, & Lee, 2006; Leach, Gillet, Lewis, & Taylor, 2009; Sun, 2008).

It is important to keep in mind that the concepts of pharmacophore modeling have a long history and date back to their introduction by Ehrlich as early as in 1909 as "a molecular framework that carries (*phoros*) the essential features responsible for a drug's (*pharmacon's*) biological activity". These features are generally classified into two major categories, namely, chemical-based and shape-based features.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

The former include hydrogen bond acceptors or donors, charge centers, metal binding regions, aromatic rings and hydrophobic regions, while the latter mainly include volume-excluded regions and geometrical constraints like distances, angles and dihedral angles. By allocating the different features and including their three-dimensional distributions within the binding site, one can understand the essential properties required for bioactivity of known true binders (Sun, 2008).

Currently, there are two approaches to generate a pharmacophore model depending on the accessibility of the target structure. If the structure of the target is available, one can build a pharmacophore hypothesis that would complement the chemical features within the binding site of the target (Krovat et al., 2005). These pharmacophore models can be further improved if there is any active compound that has been co-crystallized with the target. This approach is called "binding site-based pharmacophore models" or "structure-based pharmacophore models". The second approach, that is more widely used, relies only on the known active compounds and no information about the target is required. This technique is commonly referred to as "ligand-based pharmacophore modeling" and will be explained in detail below. In this section, we focus on the "structure-based pharmacophore models".

The most straight-forward approach in designing a SBPM is to analyze the experimentally determined crystal structures of protein-ligand complexes. The program LigandScout (Wolber & Langer, 2005) introduced by Wolber and co-workers is very effective at manipulating these structures and automatically interpreting the various interactions between a particular macromolecule and its co-crystallized ligands into functional pharmacophore models. The program starts by cleaning up the structures of the ligands by assigning hybridization states and bond characteristics that are missing in the crystal structure. This is accomplished by using an extended heuristic approach combined with template-based numeric analysis. Following this step, pharmacophore models are created by analyzing the atomic interactions between the ligand and all residues located within the binding site of the target. These interactions are classified into complementing groups in terms of hydrogen bonding, electrostatic charges and hydrophobic contacts. Moreover, the flexibility of both the target and ligand can be incorporated by aligning several models in order to generate a common-feature pharmacophore model.

When only the structure of the active site is available, programs such as structure-based focusing (SPF) aid in building up complementing pharmacophore hypotheses (Hoffren, Murray, & Hoffmann, 2001). The process starts by mapping favorable regions or "hot spots" for protein-ligand interactions within the binding site of the target. These regions are then clustered into hydrogen bond donating and hydrogen bond accepting vectors and hydrophobic interaction sites. The clustered groups are then used to build the pharmacophore model. Other algorithms that can construct SBPMs in addition to LBPMs are Unity (Tripos. http://www.tripos.com/) and MOE (Molecular Operating Environment; http://www.chemcomp.com/). Once a pharmacophore hypothesis is created, the model can be converted to a query that is used to screen chemical databases for molecules that satisfy these proposed hypotheses.

CASE STUDIES FOR SBDD

Condensing all the great discoveries and outstanding developments that took place in the last twenty years of SBDD studies is an unattainable task for the purpose of this review. However, here we will try to summarize the most important studies that helped to advance the field and guide the drug discovery community towards the highest impact techniques. These studies were not only centered on uncovering

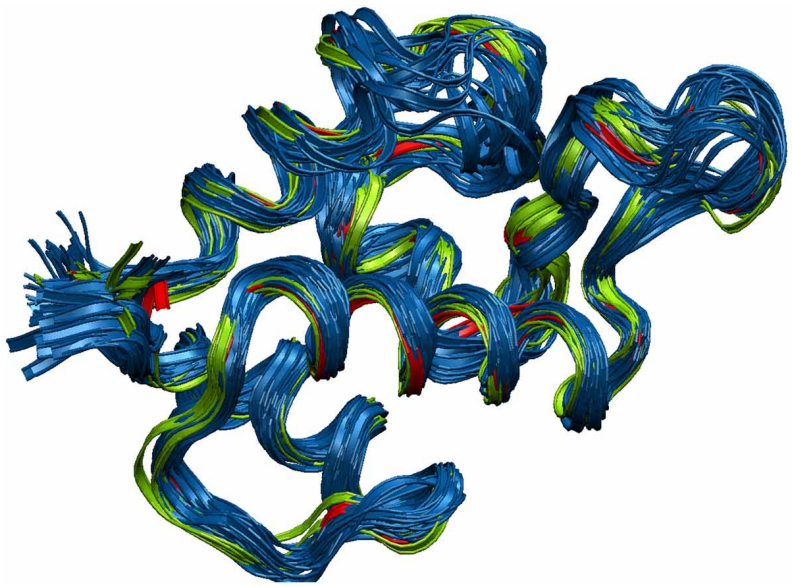
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

new drug entities but also directed towards validating the methods developed, reducing their shortcomings and adding new approaches to the computational arsenal.

The initial evaluations of docking programs were focused on their ability to reproduce the native structures of co-crystallized ligands (Jones, Willett, Glen, Leach, & Taylor, 1997; Verdonk et al., 2003; Warren et al., 2006). It is only during the last 10 years that this focus has shifted towards determining the ability of docking techniques to filter chemical databases as a VS tool (Chen, Lyne, Giordanetto, Lovell, & Li, 2006; Z. Zhou, Felts, Friesner, & Levy, 2007). Nevertheless, even with the many studies published in the literature that ranked and benchmarked docking programs, there are still many practical problems preventing the robust and fair assessment of these programs (Chen et al., 2006; Cole, Murray, Nissink, Taylor, & Taylor, 2005). Warren and Chen carried out two independent studies to assess different docking programs considering a number of crucial factors. These factors included the variety of the screened compounds, the diversity of the targets and the effect of intrinsic docking parameters on the outcome of the VS protocol. The docking algorithms that were tested in these studies comprised Glide, GOLD, ICM, FlexX, DOCK, Dockit, Flo, Fred, LigFit, MOE and MVB. As a principal conclusion resulting from these two studies, there is no universal docking algorithm or scoring function that can work well for every target (Chen et al., 2006; Warren et al., 2006). In particular, most used scoring functions were inaccurate in predicting the actual binding affinities for a number of ligands. Unsurprisingly, recent studies suggested that consensus scoring might form a successful approach in reducing the imprecision of single scoring methods (Feher, 2006). However, this statement still requires more validation (Oda, Tsuchida, Takakura, Yamaotsu, & Hirono, 2006). On the other hand, it is worth mentioning that many improvements have been implemented for a number of well-established scoring functions. Relevant examples include potential of mean force (PMF) (Muegge, 2006), DrugScore (Velec, Gohlke, & Klebe, 2005) and Glide XP (Friesner et al., 2006).

Above and beyond scoring functions, protein flexibility and its effect on hit ranking is the other most important factor in SBVS (C, Subramanian, & Sharma, 2009; Mishra et al., 2009; Nettles et al., 2007). The importance of protein flexibility has been demonstrated in many studies and shown to have a remarkable influence on the final results. Bouzida et al. (1999) investigated the docking of sb203386 and skf107457 inhibitors to HIV-1 protease using MC simulated. These authors compared docking against a single protein conformation to using an ensemble of structures. Their recommendation was to use different protein structures in order to improve the docking results and enhance the final protein-ligand conformation. In another study by Murray et al. (1999) only 49% of the ligands were cross-docked correctly to another target that was co-crystallized with a different ligand. On the other hand, this showed that inducing small movements of the side chains in the binding site resulted in large variations in the predicted binding affinities. These early studies have drawn the attention to the importance of target flexibility and provided a motivation to implement various techniques to include this factor in the context of docking.

One way to accommodate receptor flexibility with more accurate scoring techniques is to implement a hybrid between docking and MD simulations. Originally, the use of MD simulations in VS studies was intended to create a set of receptor conformations (Broughton, 2000; Carlson et al., 2000). However, it was always debatable whether to use structures derived from MD simulations or NMR data. For example, Philippopoulos et al. suggested NMR structures as the most effective source for protein conformations (Philippopoulos & Lim, 1999). A set of 15 NMR conformations for ribonuclease HI was compared to a trajectory obtained in a 1.7 ns MD simulation. The NMR data explored the conformational space of the protein more efficiently than the conventional MD simulation. In spite of their findings, it should



EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

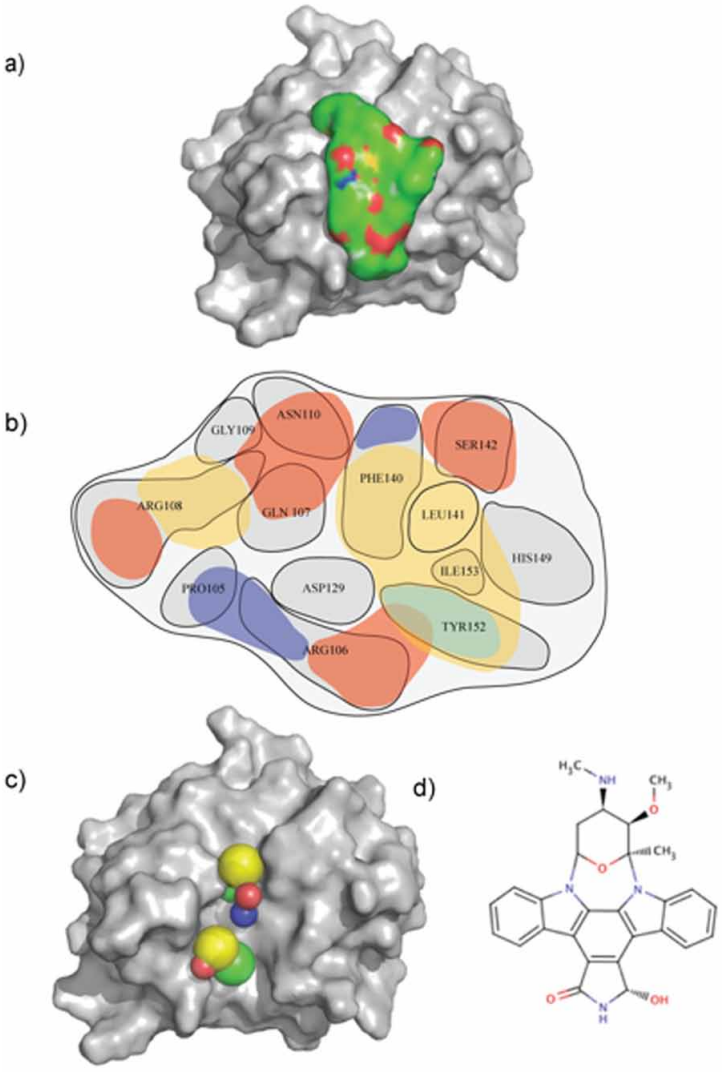
be noted that Philippopoulos et al. used standard single trajectory MD simulations for a relatively short simulation time. In generating such ensembles, one should employ multiple trajectory MD simulations, commonly termed the replica exchange molecular dynamics (REMD), or run the simulation over longer times. For example, Figure 2 shows 28 dominant conformations representing the major backbone dynamics of the MDM2 target as extracted from ~100 ns of an MD simulation. Another benefit of incorporating MD simulations with docking is to use more accurate scoring functions like molecular mechanics/ Poisson-Boltzmann surface area (MMPBSA) (Thompson, Humblet, & Joseph-McCarthy, 2008) or linear interaction (Aqvist, Medina, & Samuelsson, 1994) methods to re-rank the docking results.

In this context, a successful approach reported by Perryman and McCammon et. al.(Lin, Perryman, Schames, & McCammon, 2002) is the relaxed complex scheme (RCS). MD simulations are applied to explore the conformational space of the protein receptor, while docking is subsequently used for the fast screening of drug libraries against an ensemble of receptor conformations. This methodology has been successfully applied to a number of cases (Lin et al., 2002). An excellent example of such a case is an HIV inhibitor, raltegravir (Markowitz et al., 2006), which became the first FDA approved drug targeting HIV integrase. MD simulations played a significant role in discovering a novel binding site, and compounds that can exchange between the two binding sites have formed a new generation of HIV integrase inhibitors.

In our recent work, we have applied an improved RCS to uncover dual-inhibitors for the MDM2/ MDMX- p53 protein-protein interactions (Barakat, Mane, Friesen, & Tuszynski, 2009). In this study we first filtered a set of ~6000 different ligands against 28 distinct MD-based conformations for the p53-binding site within MDM2 using AUTODOCK 4.0. Top 300 hits were redocked to the same binding site within MDMX. We finally rescored the top hits from both of the two screening experiments using MMPBSA. In this study, although the binding sites were fairly similar (see Figure 1), the MDMX pocket

Figure 2. Twenty-eight dominant conformations for MDM2. This ensemble comprised the crystal structure (red), five structures extracted from the holo (p53-bound)-trajectory (green) and twenty-two structures extracted from the apo (p53-free)-trajectory (blue).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



seemed to be more compact than that of MDM2. This is mainly due to the three residues Pro95, Ser96 and Pro97 in MDMX that have been replaced by His96, Arg97 and Lys98 in MDM2. These substitutions shifted a helical domain in MDMX relative to MDM2 and caused Lys98 and Tyr99 to protrude into the p53-binding cleft within MDMX, making it shallower and less accessible to many of the MDM2 top hits we found. This observation is clear when comparing the binding modes of nutlin within the two pockets (see Figure 1a). While Tyr100 and Leu99 of MDM2 extend the binding site allowing nutlin to intimately bind to MDM2, while the same residues in MDMX clash with the drug preventing it from taking the normal conformation that was adopted within MDM2. On the other hand, Figure 1b-c show how two compounds from the list of proposed MDM2/MDMX inhibitors were able to tolerate the structural variations between the two binding sites. This is apparent in Figure 1, where the compounds took on different conformations within the two binding pockets in order to maximize their interactions with the proteins. Recently, we used similar approaches to identify inhibitors for the XPA-ERCC1 (see Figure 3) (Jordheim et al., 2013) and XPF-ERCC1(K. H. Barakat et al., 2012) protein-protein interactions (Barakat, Gajewski, & Tuszynski, 2012).

In another interesting study, Doman *et al.* examined protein tyrosine phosphatase-1B (PTP1B) using both docking-based VS and HTS. In the course of the HTS run (Doman et al., 2002), approximately 400,000 compounds were screened against the target and only 85 compounds resulted in IC_{50} values less than 100 μM. Applying the docking-based protocol against the X-ray crystal structure and using 165,581 compounds, the top 350 hits were tested which resulted in 127 compounds with IC_{50} values less than 100 μM. While docking based VS yielded better results than HTS, it should be mentioned that the screened libraries and assay conditions were different in the two approaches. In a more difficult study, Vangrevelinghe et al. (2003) carried out a VS experiment using DOCK 4.0 in discovering the most potent inhibitor for human casein kinase II (CK2). This work started by building a homology model using a crystal structure template that shared 85% similarity with the human protein (Vangrevelinghe et al., 2003). Then, 400,000 different compounds were screened against the target followed by post-processing of the 12,428 top hits. The processing procedure followed two levels of iterations. Since the interaction with the hinge domain of the binding site was determined to be crucial for any potential activity, the top ranked compounds were first filtered for molecules that have at least two hydrogen bonds with this hinge structure. The second filter employed a more sophisticated scoring function that included an additional solvation term. This two-step filtering scheme revealed 1592 promising compounds. Only 12 compounds were finally tested experimentally and resulted in 4 hits that inhibited more than 50% of the enzyme activity. The most potent compound exhibited an IC_{50} of 80 nM and it turned out to be the best CK2 inhibitor discovered so far.

Using the induced-fit conformation for aspartic protease renin protein, Krovat et al. (2004) employed shape-based VS using the docking program LigandFit/Cerius to uncover novel renin-inhibitors and test a number of scoring schemes. Seven different scoring functions (LigScore1, LigScore2, PLP1, PLP2, JAIN, PMF, LUDI) were used to rank the compounds (Krovat & Langer, 2004). A collection of 990 diverse and drug-like compounds was used along with 10 known active renin inhibitors. Individually, all seven scoring functions that were used recovered at least 50% of the active compounds within the first 20% of the entire database. Using a consensus scoring that incorporated only four scoring functions (LigScore2, PLP1, PLP2, and JAIN), a hit rate of 90% in the top 1.4% was recorded. Finally, a more focused database was created and these compounds were docked to the binding site of the protein. A hit rate of 100% in the top 8.4% resulted from the use of the triple consensus scoring of PLP1, PLP2, and PMF.

*Figure 3. ERCC1-XPA-inhibitor pharmacophore determination. (a) The equilibrated ERCC1 (grey surface) showing the excluded volume occupied by atoms from ligands obtained in the virtual screening experiments (green surface). Atoms included in this image were obtained by clustering the top ligands, from virtual screening experiments, and omitting those that were outside of a 90% RMSD cutoff. (b) Pharmacophores from each of the top 30 ligands were created with their interactions in the ERCC1 binding site. The type of pharmacophore interactions, with each residue were scored and are represented schematically. Yellow patches indicate hydrophobic interactions with the pocket, red and blue patches represent hydrogen bond acceptor and donors respectively, while green patches indicate aromatic interactions. Orientation of the binding site is the same as in panel a. Tyr145 and His149 (indicated by an asterisk *) do not lie on the bottom of the pocket but are observed within a lip that overhangs the pocket (see panel a). (c) The averaged pharmacophore model obtained from the docked poses from virtual screening. Each sphere represents a specific chemical entity with the size being representative of the overall contribution at each position. Coloring is identical to that described for panel a. (d) The chemical structure of UCN-01, a weak ERCC1-XPA small molecule inhibitor.*

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Although the above-mentioned success cases integrated docking as the key and principal ingredient of the VS protocol, other studies employed pharmacophore search techniques to reduce the size of the chemical database and extract a more focused library of compounds (Brenk et al., 2003; Cavasotto & Phatak, 2009; Rollinger, Haupt, Stuppner, & Langer, 2004; Rollinger, Hornick, Langer, Stuppner, & Prast, 2004; Sirois, Wei, Du, & Chou, 2004; Varady et al., 2003; Westerfors et al., 2003). Varady et al. introduced an exciting example of the method in their screening of 250,251 compounds for dopamine 3 (D_3) inhibitors (Varady et al., 2003). Similar to the Vangrevelinghe approach mentioned above, Varady et al. started by building up a homology model for D_3 followed by applying a hybrid, stepwise computational screening approach. Then, a pharmacophore model was developed and used to identify promising compounds from a chemical database of approximately 250, 000 synthetic compounds and natural products. As a result, 6,727 molecules were identified which satisfied the pharmacophore hypotheses. These molecules were further screened through structure-based searching using multiple receptor models obtained from MD simulations via computational docking and scoring. Top-ranked potential D_3 inhibitors were further subjected to structural novelty screening by comparing them to the known D_3 ligands. Finally, the most promising 20 potential D_3 ligands were tested for their D_3 binding affinities. As a result, 11 of these 20 compounds showed IC_{50} values greater than 3 μM and 8 compounds showed a nanomolar affinity.

In contrast to Varady's case, instead of initially filtering the database for potential hits, a pharmacophore model was used as a post-docking filter to validate the results and reduce the number of hits submitted to experimental verification (Betzi et al., 2007). Betzi used this technique to identify the first set of drug-like ligands that bind to the HIV-1 Nef SH3 surface. To accomplish this, the whole chemical database was filtered for drug-likeness properties which reduced the set of compounds to ~1,400 molecules. These structures were then docked to the binding interface between Nef and SH3 proteins. Top 335 hits were then filtered using a structure-based pharmacophore model derived from the binding site within the SH3 domain. This post-filtering procedure yielded 33 compounds that were visually inspected and reduced to 10 hits for experimental validation. Out of the final 10 tested compounds, one molecule resulted in a dissociation constant, K_D, of 1.8 μM.

Rollinger et al.(2004) used structure-based pharmacophore screening for the discovery of novel inhibitors for acetylcholinesterase (AChE). This study generated a pharmacophore model using the protein and one of the known inhibitors. Then, the in-house 3D database was screened which included about 110, 000 natural products within a molecular mass of 140−700 Da (Rollinger, Hornick, et al., 2004). Finally, two compounds from the top VS hits were subjected to experimental validation and progressed to *in vitro* and *in vivo* testing. On another large scale SBVS study and using a pharmacophore searching strategy (Sirois et al., 2004), Sirois et al. screened over 3.6 million compounds against SARS (severe acute respiratory syndrome). About 0.07% of the initial database of compounds satisfied at least five of the original six pharmacophoric points. Furthermore, a subsequent evaluation for the druggability of the top ranked compounds retrieved 17% that had a perfect score of 1.0.

LIGAND BASED DRUG DESIGN (LBDD)

Despite the advances in macromolecular structure prediction methods, the number of protein structures that have been determined experimentally is still lagging compared to that of their sequenced counterparts. In this case, homology modeling may play a major role in understanding and predicting

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

the three-dimensional structure of the target (Bordner, 2012; Levit et al., 2012; Ravna & Sylte, 2012). However, homology modeling has its own limitations and the degree of success of incorporating the method within the context of VS depends mainly on the quality of the predicted structure (Cavasotto & Phatak, 2009). Therefore, it is important to seek alternative routes that depend merely on known active compounds and in which no information about the target is required (Speck-Planche, Luan, & Cordeiro, 2012; Wilson & Lill, 2011). These ligand-based filtering techniques have played a significant role in discovering potent inhibitors for many targets. In fact, ligand-based screening methods use known active and inactive compounds as templates and employ comparative algorithms to identify new compounds that are similar to the templates. Overall, one can classify the different LBDD methods into two main approaches, namely, similarity search (Willett, 2006) and pharmacophore search (Sun, 2008).

Similarity Search

The fundamental theory behind this approach is Maggiora's "similar property principle" (Johnson & Maggiora,1999), which states that similar molecules are more than likely to have similar properties. While not universally correct (Kubinyi, 1998), there are many cases where this simple idea showed great success and helped in the discovery of novel active molecules (Martin et al., 1993; Patterson, Cramer, Ferguson, Clark, & Weinberger, 1996). According to this concept, one can use known active compounds as reference structures and filter a given chemical library for ligands that are structurally similar to the active molecules. The filtered compounds are expected to display some activity that in some cases could be greater than the original reference structures. In fact, there are mainly two ways to assess the similarity between two molecular structures. These methods comprise molecular alignment and molecular descriptor algorithms (Lemmen & Lengauer, 2000).

Molecular alignment algorithms such as FlexS (Lemmen, Lengauer, & Klebe, 1998) or GASP (Jones, Willett, & Glen, 1995a) typically align the filtered compounds with the reference structure and rank them according to their degree of similarity. During this superposing process, the two aligned molecules can be treated either as rigid or flexible. Similar to docking methods, flexibility can be introduced by employing an incremental construction approach (FlexS) or a genetic algorithm procedure (GASP). Other algorithms like Fflash (A. Kramer, Horn, & Rice, 2003; Pitman et al., 2001) apply fragment-based techniques to incorporate ligand flexibility during the filtering process. Other algorithms adopted more complicated approaches to carry out more accurate molecular alignment. These methods include incorporation of Gaussian functions as in the program MIMIC (Mestres, Rohrer, & Maggiora, 1997) or constructing interaction potential grids around molecules (Goodford, 1985).

A major drawback of molecular alignment techniques is that the time required for a single molecule comparison is long enough to discourage a user from employing the method in screening large databases (Willett, 2006). As a result, more efficient and accurate techniques have been developed to describe the information inherited in the molecular structure of a given ligand along with its physiochemical and topological properties. These molecular descriptors are generated on-the-fly and compared to the reference structure very rapidly. Based on the dimension of the information that is used, molecular descriptors can be classified into 1D-, or 2D-descriptors. Evidently, the higher the dimension of the descriptor approach, the lower its computational time will be and the higher the accuracy one can expect from the searching protocol. Generally speaking, bulk properties like molecular weight, molar refractivity or log P values are adequate to construct a 1D-molecular descriptor (Lipinski, Lombardo, Dominy, & Feeney, 2001). However, since there is no information about the structural properties or chemical features of

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

the ligand, it is impossible to only rely on such descriptors in filtering a typical chemical library for active molecules. Consequently, one should draw on a higher level of information and include structural properties as an additional descriptor in order to increase the accuracy of the method. This introduced molecular fingerprints as the most successful and widely used similarity search approach in LBVS.

Molecular fingerprint is a bit-string representation that reflects structural features and other properties of a molecule given its chemical structure (Willett, 2006). Key advantages of this approach over direct comparisons of molecules are that it is very simple to implement, remarkably fast to be calculated and the final outcome is expressed as a single number that quantifies the degree of similarity. According to the complexity level and designing scheme, one can recognize two basic approaches in generating a molecular fingerprint for a specified structure. The first approach is what is known as "keyed" representation (McGregor & Pallai, 1997). In this case, an individual bit within the string can be set as "on" or "off" reflecting the presence or absence of a pre-defined functional group (pattern) in the sub-structural space of the ligand. While the order of the bit-string map is the same for each molecule, the individual bits are turned on or off if their representative substructure exists or not. A widely used VS algorithm that employs this procedure is MACCS (McGregor & Pallai, 1997) whose bit-strings may include up to 166 bits representing commonly known fragments. The second approach is known as the "hashed" representation (James & Weininger, 1995). This method resembles human fingerprints by not restricting the definition of bits to describe a pre-specified set of patterns. That is, similarly to human fingerprints, which are very characteristic of individuals, a pattern's fingerprint characterizes the pattern, but the meaning of any particular bit is not well defined. To do so, a typical hashed representation algorithm starts by generating a pattern for each atom. Then it creates a pattern representing each atom and its nearest neighbors in addition to the bonds that join them. This hierarchal construction evolves to include higher order nearest neighbors until the complete structure is recovered.

At the heart of these similarity-based VS techniques lays a similarity measure, usually termed a similarity coefficient that is used to quantify the degree of resemblance between two molecules. In fact, the most commonly used parameter is the Tanimoto (Jaccard) coefficient (defined in equation 1) (Willett, 2006) To understand the concept behind this parameter, let us consider the case of 2D fingerprints representing two molecules A and B that have a and b bits that are set as true, respectively. Now, if there are c common bits that are mutually set as true in the two molecules, where c is the intersection subset of a and b, one defines their Tanimoto coefficient as:

$$T = \frac{c}{a + b - c} \tag{1}$$

The Tanimoto coefficient gives values between zero (no similarity) and one (completely similar structure). Although this coefficient is the most popular choice for both in-house and commercial screening packages, a number of studies have indicated that it is dependent on the size of the fingerprint of the reference structure and on how many bits are set in its bit-string representation (Flower, 1988). However, other studies suggested that 85% of compounds that have a Tanimoto coefficient value of 0.85 or greater relative to an active compound are predicted to be active as well (Patterson et al., 1996).

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Pharmacophore Search

While the basic concepts behind the pharmacophore search approach have been introduced in previous sections, here we focus on pharmacophore modeling techniques that have been broadly followed in the literature when no target structure is available (Barnum, Greene, Smellie, & Sprague, 1996; Z. Chen et al., 2009; Ou-Yang et al., 2012; Sun, 2008; Z. L. Zhou et al., 2013). In this case, the only information that can be exploited is a set of known active compounds that are recognized experimentally and the general procedure can be summarized in two fundamental steps. First, this set of molecules is analyzed in order to identify all chemical features within their structures. Then, for each molecule an ensemble of different conformations is generated and used to produce the best alignment between the different compounds to overlay their corresponding features. Although the main approach seems feasible and simple to implement, searching the conformational space is the most important and most difficult part of the method. This is because it is hard to predict the active conformer of a given ligand without understanding how it interacts with the target, with the solvent molecules and other elements of the binding environment. Nevertheless, there are several programs that have been successfully used in building ligand-based pharmacophore models for many targets. These programs differ mostly in the way they handle ligand flexibility and in the method of searching a typical chemical database for promising hits. The most popular programs are Catalyst (Barnum et al., 1996), DiscoTech (Martin et al., 1993) and GASP (Jones et al., 1995a).

Catalyst introduces ligand flexibility very efficiently and additionally is extremely fast in searching 3D chemical databases (Barnum et al., 1996). In brief, the program extensively explores the conformational space of a ligand by using a random search algorithm along with a poling function, which creates a large number of low-energy conformations. Catalyst follows two alternative algorithms in building up pharmacophore models. The first algorithm, HypoGen, is a quantitative approach in which each chemical feature allocated to the ligand structure is associated with a particular weighting factor that is related to its relative importance in describing the bioactivity of the molecule. Following this procedure, the algorithm builds up a number of pharmacophore hypotheses and ranks them based on their ability to explain available experimental data. In the other approach, Catalyst follows a qualitative procedure that is termed the HipHop algorithm. In this process, for each ligand, the algorithm checks for the surface accessibility for receptor interactions. Then, chemical features are defined based on their absolute coordinates in the different conformations of the molecule rather than by their inter-feature distances. This procedure usually starts with the most active compounds in the training set followed by highlighting their matching features from other less-important molecules. This results in a considerable number of proposed pharmacophore hypotheses that is significantly reduced by rejecting models that cannot explain the bioactivity of these molecules. Regardless of which approach is used, Catalyst can merge different models in order to generate a more comprehensive pharmacophore hypotheses.

Disco not only suggests pharmacophore models that demonstrate the important features in a ligand, but it also predicts their potential complementary regions that should be located within the binding site (Martin et al., 1993). This is accomplished by breaking up a pharmacophore to groups of ligand points and binding pocket interaction sites. Ligand points include atoms with hydrogen bonding properties, charge centers and hydrophobic characteristics. Binding pocket interaction sites are predicted to be complementary regions within the target and are calculated using the coordinates of the heavy atoms of the ligand. Similarly to Catalyst, the conformational flexibility of the ligands is explored using a set of pre-calculated conformations for each ligand in the training set. However, one pitfall of using Disco

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

is that all chemical features that make up the final pharmacophore model must be identified in every molecule, which may result in the exclusion of talented models.

In contrast to both Catalyst and Disco, the program GASP (Jones et al., 1995a) handles the ligand conformational flexibility in a very sophisticated manner. Instead of using a pre-calculated set of ligand conformations, the program uses a genetic algorithm to explore the conformational space of the ligand during the pharmacophore generation process. GASP algorithm starts by detecting all possible chemical features in the structure of each ligand. The molecule with the least number of features is selected as a reference structure. Every structure in the training set is then fitted to the reference structure using a genetic algorithm that is similar to its counterparts in docking programs (see above). However, in this case, the fitness of a particular model is measured based on a combination of similarity, the number of overlaid features and the volume integral of the overlay. One more advantage for GASP over DISCO and Catalyst is that, models generated by GASP account for the steric clashes between the ligands in generating the final pharmacophore model. On the other hand, the other two programs propose their models by only matching the chemical features of the ligands without taking their overall shape into account.

Regardless of which approach is used to generate a pharmacophore model, which includes SBPM, there are two main ways to screen chemical libraries for compounds that satisfy the constraints of the pharmacophore hypotheses (Z. Chen et al., 2009; Sun, 2008). First, one can use a database file format that includes a set of pre-defined conformers for each compound in the database. Although this approach remarkably speeds up the search process, it requires massive storage of the different conformations. Alternatively, a single conformation can be used as a precursor for generating an ensemble of conformations followed by fitting these structures to the pharmacophore query during the screening process. While this procedure eliminates the need for substantial storage, it is much slower than the former method.

Case Studies for LBDD

Similar to SBDD, a plethora of LBDD studies has been published in the literature in the past few years including methodology-development papers focused on enhancing the accuracy of current models or devising new methods (Bender et al., 2009; Hert et al., 2004; Selvaraj & Singh, 2013; Speck-Planche et al., 2012). Others represent pure applications for the various techniques attempting to recognize bioactive molecules or identifying new scaffolds by screening chemical databases.

In an important assessment study Bender et al. (2009) compared the performance of 37 different molecular descriptors. The judgment was based on the ability of the different descriptors to rank active compounds from a database using a number of randomly selected query molecular structures. The basic question in this study was which descriptors contain independent (orthogonal) information and which descriptors are redundant because they are correlated with each other. Consequently, Bender et al. identified four independent broad descriptor classes: (1) circular fingerprints; (2) circular fingerprints considering counts; (3) path-based and keyed fingerprints and; (4) pharmacophoric descriptors. In 2004, Hert et al. (2004)investigated the performance of a new similarity searching methodology, known as data fusion. This technique is similar to the consensus scoring approach that is widely used in current docking protocols. However, similarly to consensus scoring, data fusion is mainly dependent on the combination(s) of similarity measures that are used to rank the compounds, which, if selected properly, will lead to a significant enhancement in searching performance. In another interesting study, Tresadern et al. (2009) compared a number of LBVS methods with a careful application to corticotropin releasing factor 1 receptor (CRF1). This list of assessment and development studies continues to grow and includes

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

many entries that are committed to improve the LBVS techniques and increase their accuracy (Burton, Ijjaali, Petitet, Michel, & Vercauteren, 2009; Neves, Dinis, Colombo, & Sa e Melo, 2009).

In addition to the aforementioned evaluation studies, there have been many successful applications of the methods. For example, following a two-step ligand-based approach, Franke *et al.* filtered a database of natural product and natural-product-derived compounds for potential inhibitors of human 5-lipoxygenase (5-LO) activity (Franke et al., 2007). In the first step, a similarity searching was performed using a topological pharmacophore model constructed from 43 known inhibitors. Out of the 430 top hits, 18 compounds were selected that satisfied the pharmacophore features of the original reference inhibitors. Experimental investigation of these compounds retrieved two novel structures that showed significant activity. Using these two molecules a second round of virtual screening was performed through different ligand-based virtual screening methods. The top ranked molecules from the final set of screening potently inhibited 5-LO activity in intact cells representing a novel class of 5-LO inhibitors. Using a similar approach, Carosati *et al.* used LBDD to identify novel activators for Kir6.2/SUR1 K_{ATP} channels (Carosati et al., 2007). Firstly, using pharmacokinetic filtering via the VolSurf program, a set of 65,208 commercially available compounds was reduced to 1,913 compounds. Subsequently, six molecules were selected to serve as reference structures in a similarity search procedure using different scoring methods. As a result, 32 hit candidates were identified and tested for their biological activity. This procedure resulted in the discovery of 3 novel compounds that were able to inhibit insulin release with micromolar potency.

In order to identify compounds that can block NAADP (nicotinic acid adenine dinucleotide phosphate) signaling, Naylor *et al.* used NAADP as the query ligand to screen the chemical library ZINC for compounds with its 3D-shape and electrostatic similarity (Naylor et al., 2009). By testing the top-ranking hits in a sea urchin egg bioassay it was found that one hit, Ned-19, blocked NAADP signaling at nanomolar concentrations.

Sciabola *et al.* developed a new 3D pharmacophore fingerprinting approach (TOPP, Triplets Of Pharmacophore Points) to identify inhibitors for a specific P450 target, polymorphic CYP2D6 (Sciabola, Morao, & de Groot, 2007). Their new 3D pharmacophoric fingerprints were as accurate as other 3D descriptors and 2D features. Interestingly, it was found in the 3D models that the use of more realistic substrate conformations, and by an additional docking step using GOLD on a homology model structure, did not significantly improve the statistical results. Using a hybrid between LBPM and docking-based screening, Li *et al.* screened for inhibitors against Raf-1 kinase (Li et al., 2009). First, a 3D pharmacophore model was developed from a training set of structurally diverse ligand structures. Then a virtual database searching was performed with the pharmacophore model as a 3D query. Subsequently, molecular docking was carried out on the selected hits whose estimated IC_{50} was less than 1 μM, which yielded 29 hits that were identified as potential leads against the Raf-1 kinase target. In another study, Neves *et al.* developed a new ligand-based strategy combining important pharmacophoric and structural features based on a known an aromatase-inhibitor (Neves et al., 2009). The NCI database was screened and new potent aromatase inhibitors were found to be active in the low nanomolar range. Interestingly, all the molecules found exhibited a common binding mode.

Chen and co-workers carried out a very exciting study to look for dual inhibitors for both neuraminidase (NA) type 1 (N1) and haemagglutinin type 1 (H1) (C. Y. Chen et al., 2009). An N1- pharmacophore model was constructed and used to screen the NCI database for N1-inhibtors. Top hits resulted from the initial screening were docked into haemagglutinin type 1 (H1) in order to find out dual-inhibitors for both N1 and H1. It was suggested that the compound NCI0353858 could be effective in curing the worldwide disease N1H1 influenza.

CONCLUSION

Under a growing social and economic pressure directed at discovering new and improved drugs and lowering the cost of current brand names, the pharmaceutical industry is struggling to develop innovative, fast and economical drug discovery techniques. Although HTS still remains the main approach driving the identification of new lead compounds, the overall methodology is still largely phenomenological and technology driven (Lahana, 1999). Moreover, the basic cost of a typical HTS laboratory includes collecting and maintaining screening libraries of thousands, if not millions, of compounds. In contrast, using rational drug design methods for drug discovery, the compounds that are tested need not physically exist or be chemically synthesized as long as they can be synthesizable in principle. In addition, experimental difficulties that are associated with HTS such as limited solubility or aggregate formation are not relevant to these tools and do not need to be considered (Stahura & Bajorath, 2004; Zoete et al., 2009).

Even when used perfectly, no computational method developed thus far can predict all possible solutions. It is important to use a combination of all possible approaches in order to substitute a weakness of one technique with strengths in the others (Muegge, 2006). Although SBDD is more computationally demanding than LBDD (Reddy et al., 2007), it is easier to rationalize and to aid in designing more specific drugs by targeting a precise domain or binding pocket within a particular target. Additionally, recent advances in crystallography allowed the automation of structure prediction for parallel crystallization of different protein targets. These new rapid techniques introduce protein crystallography as a powerful high throughput approach in reducing the gap between sequenced and structured proteins (Sharff & Jhoti, 2003). Moreover, new co-crystallized ligands, binding affinity assays and high performance computing facilities add more promise for improving and validating SBDD protocols. Nevertheless, as the majority of potential therapeutic targets, especially membrane proteins, continue to be hard to crystallize (Drews, 2000), LBVS will remain a dominant alternative means in identifying new lead compounds and designing new drugs. On the other hand, SBDD on its own cannot elucidate the functional activity of a typical ligand. Examples of such problems include agonism, antagonism (Mailman & Murthy, 2009) and side effects, which are hard to capture and are difficult to model. Hence, in our opinion both SBDD and LBDD taken together will remain strongly positioned as two optional and complementary methods in drug discovery and development. However, based on the discussion presented here, rational drug design as a whole is still under development, and far from forming a mature of field of science. This is apparent in the fact that the number of strategies followed in the field is nearly as considerable as the number of reported screening campaigns.

ABSTRACT

Smart and intelligent computational methods are essential nowadays for designing, manufacturing and optimizing new drugs. New and innovative computational tools and algorithms are consistently developed and applied for the development of novel therapeutic compounds in many research projects. Rapid developments in the architecture of computers have also provided complex calculations to be performed in a smart, intelligent and timely manner for desired quality outputs. Research groups worldwide are developing drug discovery platforms and innovative tools following smart manufacturing ideas using highly advanced biophysical, statistical and mathematical methods for accelerated discovery and analysis of smaller molecules. This chapter discusses novel innovative applications in drug discovery involving use of structure-based drug design which utilizes geometrical knowledge of the three-dimensional protein structures. It discusses statistical and physics based methods such as quantum mechanics and classical molecular dynamics which can also play a major role in improving the performance and in prediction of computational drug discovery. Lastly, the authors provide insights on recent developments in cloud computing with significant increase in smart and intelligent computational power thus allowing larger data sets to be analyzed simultaneously on multi processor cloud systems. Future directions for the research are outlined.

INTRODUCTION

Rapid and steady growth of low-cost computer power in discovering and designing new drugs has become a central topic in modern biology and medical chemistry. These includes methods and techniques ranging from high-throughput screening of compounds in databases to protein inhibition through molecular dynamic and thermodynamic approaches using distributed and cloud computing. Computational drug design approaches can be divided into structure and ligand-based approaches (Reddy et al., 2007). Former approach focuses on available X-ray crystallographic protein structure, NMR-based structure or homology model obtained from known template from protein databank. Once a rigid structure of the target is available, ligand-based virtual screening identifies novel ligands by three-dimensional (3D) similarity searching or by pharmacophore protein matching (Reddy et al., 2007). Ligand based virtual screening detects compounds that are similar to the active known compounds. Next, the target compounds are identified through virtual screening following which the docking algorithms are applied to position the available compounds in the binding sites derived from several biochemical studies (Reddy et al., 2007). These compounds are then ranked according to their steric and electrostatic interactions between the receptor and ligand (Reddy et al., 2007). On the other hand, ligand-based approach is useful in absence of experimental 3D structure. Under such circumstances, known ligands are explored to understand the basic structural and chemical properties correlating with specific pharmacological properties. Design of new ligands is performed in several steps mostly by manual inspection and qualitative interpretation of ligand-binding site interactions. Ligand-based approaches use Quantitative Structure Activity Relationship (QSAR) method and pharmacophore modeling. The QSAR is a computational methodology for quantifying correlation between structures of chemical compounds and chemical/biological process (Acharya et al., 2011).

The QSAR model is applied to optimize active compounds to increase their relevant biological activities to the maximum possible level. The success of this model is closely related to the selection of appropriate molecular descriptors and its ability to generate mathematical relationships between the molecular descriptor and biological activity (Acharya et al., 2011). Some of the major statistical methods used to select molecular features are multivariate linear regression analysis (MLA), Principle Component Analysis (PCA) and Partial Least Square Analysis (PLS), all of which will be discussed in this chapter review (Acharya et al., 2011). Structure-based approaches also involve virtual screening of compound libraries which can be manifested using molecular docking approach and Molecular Dynamics (MD) simulations (Okimoto et al., 2009; Durrant & McCammon, 2011). Molecular docking allows prediction of different complex protein-ligand conformations and estimation of binding affinity using mathematical algorithms for faster conformational search of ligands. MD simulations allow the estimation of the effect of explicit and implicit water molecules around the binding site of ligand and calculation of binding free energy. The techniques involved are thermodynamic integration (TI), free energy perturbation (FEP) and molecular mechanics/Poisson-Boltzmann surface area (MM/PBSA) (Okimoto et al., 2009; Durrant & McCammon, 2011).

One of the robust methodologies currently being developed and extensively used is cloud computing in computational drug discovery. Cloud computing is a term which involves services provided over the Internet. This idea has been implemented from distributed/grid computing that integrates several individual computers to generate a super computer system of superior computational abilities (Shudong et al., 2004). Cloud computing utilizes computing resources allocated on-demand over the Internet. Use

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

of massive computational power can thus be applied for virtual screening of principal compounds and undergoing complex calculations within a very short time span.

In this chapter we will discuss all the computational methods developed and currently used in drug discovery and design. We will focus on the ability of these smart, intelligent and innovative methods and approaches for identifying novel drug candidates and latest advances in intelligent computing power and their interconnection and smart manufacturing applications in computational biochemistry.

Computational Drug Design Strategies

Application of computational tools in drug discovery has grown steadily over the past several years and there have been significant improvements over the methods. A number of computational techniques are used to resolve complex chemical and biological problems including statistical analysis of large datasets, structure-based drug designs, computational genomics, molecular simulations and pharmacophore based molecular library designing. Computational chemistry tools are regularly employed to resolve detailed atomic structures of different ligand-receptor complexes; and for evaluating small-molecule drug characters. Statistical and information sciences are being increasingly used nowadays to generate and manage chemical and biological activity databases. With the aid of computers, new techniques have been developed for automated derivation of drug derivatives. Libraries of compound derivatives can be assembled by targeted structure-based combinatorial chemistry. Improved methods have developed for rapid generation and prediction of potential drug binding to proteins. In addition, refinement of drug candidates can also be performed in most effective manner. Therefore, use of computers has become an important asset for development of new therapeutics for most common and complex diseases.

Structure-Based Drug Designing

SBDD is one of the powerful approaches in drug discovery as it combines both combinatorial chemistry and high-throughput screening for synthesis of potential drug candidates. First step in drug development is to find small molecule which can bind to target proteins and alter its biological function by increasing or inhibiting its activity (Wilson & Muftuoglu, 2012). Development of small molecule drug candidate against a given disease requires proper understanding of metabolic pathways. Therefore, first step in drug designing is identification of potential biological target from the given metabolic pathway. Therefore, identification and development of potential ligands specific to the biological target is the second step in Structure-Based Drug Design (SBDD) (Reddy et al., 2007). There are many automated screening tools and software that allow screening, testing and selection of large number of compounds from online Web databases which is based on their ability for interaction with biological targets. Some of the tools such as PyRx developed by The Scripps Research Institute allow screening libraries of compounds against potential drug targets (http://mgltools.scripps.edu/documentation/links/pyrx-virtual-screening-tool). The VSDocker is an important tool allowing parallel high-throughput virtual screening on windows based computer cluster systems (Prakhov, Chernorudskiy, & Gainullin, 2010).

The biological target has pocket where the ligand binds and alters the activity of the target. The pocket comprises of different types of possible hydrogen bond donors and acceptors and hydrophobic characteristics (Reddy et al., 2007). Compounds (or fragments of compounds) from the available databases are then positioned over a selected region or in other words, the active site of the structure. These are

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

next scored and ranked depending on the steric and electrostatic interactions with the target site. Top selected compounds are next screened using biochemical assays (Anderson, 2003).

Molecular Docking Approach from Virtual Screening of Lead Compounds

Structure-based computational methodology involves computational screening of compounds which can be performed by molecular docking. It is often useful when the 3D structure of the biological target is available. Molecular docking involves knowledge of putative binding sites where the ligand can bind and initiate a biological response. The knowledge can either be acquired from biochemical studies or obtained from co-crystallizing the target protein with a ligand. Once the target binding sites are known, correct binding modes (binding pose) of a ligand molecule is conducted by running number of trials by searching different translational as well as rotational degrees of freedom. The ligand-receptor interaction energy is calculated for each binding pose and a '**score**' is assigned for each pose. Score is calculated mainly by three scoring function techniques: force-field, knowledge and empirical based scoring functions (Kroemer, 2007; Cheng et al., 2010).

Force field based functions employ a force-field to compute non-covalent ligand-receptor interactions in an implicit solvent. Generalized Born (GB/SA) or Poisson-Boltzmann (PB/SA) methods are used for computing the interactions. Knowledge-based scoring functions are generated from the inter-atomic distances available in the protein-ligand complex structures databases. Frequency distributions are computed from the distances and the distribution is converted to potential of mean force or knowledge-based potentials. Empirical based method is based on the principle that free energy change upon ligand binding (ΔG_{bind}) can be decomposed into the summation of the internal energy (ΔG_{int}), the solvation energy (ΔG_{solv}), the conformational energy (ΔG_{conf}) and the free energy of motion (ΔG_{motion}).

Virtual Screening

Small-molecule compound library is prepared. Table 1 illustrates a list of databases which can be used for library preparation. Both the biological target and the compound library require preprocessing such

Table 1. Number of compounds (entries) in the commonly screened databases (Note: All are approximate figures)

Databases	Number of compounds
PubChem	30 million
ChEMBL	1 million
NCI (National Chemical Institute)	250,000
ChemSpider	26 million
ACX	140,000
ASINEX	140,000
ChemBridge	900,000
ChemDiv	1.2 million
ChemNavigator	55 million

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

as assigning proper tautumeric, stereoisomeric, and protonation states (Cheng et al., 2010). Each compound in the library is docked to the biological target molecule using a docking program or tool which models the ligand-receptor interactions for achieving optimal complimentarity between the active site of target and the compound. Scoring function evaluates the fitness between the target and compound and calculates a score for each binding pose. Binding poses are ranked based on their scores. Lee et al. (2010) performed virtual screening for determining vascular endothelial growth factor receptor (VEGFR)-2 kinase inhibitors using pharmacophore modeling and docking studies.

Recent Advances in Docking

4D Docking

Giovanni et al. utilized a novel procedure of ligand docking by exploiting the receptor flexibility (Bottegoni et al., 2009). In four dimensional (4D) docking procedure, an ensemble of receptor conformers are generated. Generated structures are converted to conformational stack and matching structure with complete sequence in Uniprot database is selected as reference structure. All the other structures are superimposed to the reference structure by an iterative weighted process. This procedure of making a conformational stack with one reference molecule is called 4D grid. Ligands are placed in the 4D plane and allowed to move from one 4D plane to another allowing transfer between the different receptor conformations. Receptor-ligand poses with lowest energy conformation then undergoes all atom scoring procedures. This approach was tested on 99 therapeutically relevant proteins and 300 diverse ligands. The approach reproduced correct ligand-binding geometry matching the success rate of the traditional process.

Drug Repositioning by Structure-Based Virtual Screening and Molecular Docking

Drug repositioning is a strategy which involves generation of new or additional value from drug by targeting diseases. In this approach, candidate compounds are screened against the biological targets for higher potency and selectivity against the targets. Combination of structure-based virtual screening and drug repositioning represents highly efficient approach for development of novel medicines. For drug repositioning, specialized virtual libraries are available through databases which contain information about existing drugs and compounds which have made through later stages of clinical trials and commercialization (Ma et al., 2013). When potential compounds are identified by virtual screening, molecular docking can be performed using "single target" approach which identifies potential interactions between the drug candidates and biological target. Molecular docking involves three main steps: (1) generation of molecular model of the biological target and pre-treatment of ligands, (2) conformational sampling of the ligands on the biological target binding site, (3) Assignment of score for the poses of the ligand-receptor complexes. Docking can be performed by various algorithms. Some of the commonly used algorithms are Monte Carlo (MC) or Genetic Algorithms (GA) (Hart & Read, 1992; Morris et al., 1998). Drug repositioning has been applied in several applications. A well-known example is its use in discovery of sildenafil for the treatment of erectile dysfunction in human males (Ashburn & Thor, 2004). Sildenafil was originally known for its anti-anginal activity for inhibition of phosphodiesterase family of proteins. By performing drug repositioning, male erectile dysfunction was treated in phase I clinical trials.

Drug Docking via Systems Theorem

Computational docking of drug candidates is performed by various docking approaches in which the flexible drug compound is docked to the rigid receptor and various receptor-drug conformational poses are generated. Score is calculated for each pose of the complex. However the docking algorithms considers receptor structures as rigid which does not provide accurate docking scores. Flexible protein and ligand motions are required for efficient docking at the docking site. The Lyapunov approach provides focused stability during protein folding for drug docking calculations (Sung & Chen, 2012). Applying the Lyapunov equation and the molecular dynamics approaches, lowest energy protein structure can be determined. Ligand-receptor docking procedure consists of 3 major steps, namely, (1) creation of docking box around the receptor binding site, (2) placement of ligands in the docking box, (3) generate various poses and score the poses based on various interacting energy terms. The Lyapunov function provides dynamic stability in both linear and non-linear systems which are based on Hess's law by which free energy of binding of ligand and receptor is calculated in solvent system. Lyapunov stability function illustrates relationship between minimum energy and modeling. Reaction coordinates are generated and stability basins of the energy landscape for system of interest are characterized using biomolecular simulations. This approach is based on stability theory which decomposes the molecular systems into subsystems. Then it constructs a suitable vector Lyapunov function. Authors have tried this approach on Cyclooxygenase-2 protein by docking with Flurbiprofen. However, practical application of the approach remains unexplored.

Molecular Dynamics Approach

Macromolecular structures (target biological receptors) play a vital role in drug discovery. For novel drug discovery prediction, virtual screening of the compounds is performed using drug database. This is followed by selection of potential compounds and docking to the receptor active site. However, the docking algorithms were unable to take into consideration the role of protein flexibility in ligand binding involving complex calculations essential for describing quantum-mechanical motions and chemical interactions of large molecular systems. MD simulations were able to remove this problem by applying approximations based on Newtonian physics for simulating atomic motions. By undertaking such approach, computational complexity can be further reduced. First, a crystal structure or homology model of the receptor is taken and forces acting on each atom are calculated from the equation (Durrant, & McCammon, 2011):

$$E_{Total} = \sum_{bonds} K_r (r - r_{eq})^2 + \sum_{angles} K_\theta (\theta - \theta_{eq})^2 + \sum_{dihedrals} \frac{V_n}{2}[1 + \cos(n\varphi - \gamma)] + \sum_{i<j} \left[\frac{A_{ij}}{R_{ij}^{12}} - \frac{B_{ij}}{R_{ij}^{6}} + \frac{q_i q_j}{\epsilon R_{ij}} \right]$$

Forces are calculated from contributions from bonded and non-bonded atom types. Bonded atom contribution is composed of chemical bonds and atomic angles from virtual springs and dihedral angles generated from rotations around the bonds. However, the non-bonded contribution is estimated from Van der Waals interactions that are modeled applying the Lennard-Jones potential and the electrostatic

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

interactions based on the Coulomb's law (Leonnard-Jones, 1924). For reproducing the behavior of the target molecule in motion, the energy terms are derived from experimental and quantum-mechanical data. To perform MD simulations, force fields from CHARMM (Brooks et al., 1983), GROMACS (Christensen et al., 2009) and AMBER (Wang et al., 2009) are generally used. Once the forces on each are calculated, each atom is moved to different position according to Newton's laws of motion. Simulation is advanced by a femtosecond and is repeated till the simulation time specified by the user, usually 40-50 nanoseconds. Results from MD simulations explain various conformational changes of protein and ligands. Experimental studies involving protein and ligand have shown good agreement between the experimental and computational measurements using MD simulations (Markwick et al., 2009; Showalter, & Brüschweiler, 2007).

MD simulations provide structural insights into the identification of drug binding sites of the β-adrenergic receptors. MD simulations were performed for 0.5 microseconds which produced distinct conformational changes. MD simulations revealed binding pockets at both the solvent and lipid-exposed areas which serves for undertaking various structure-based approaches for designing new compounds (Ivetac & McCammon, 2010). Using β-adrenergic receptor protein, MD simulations were performed for testing the association of several ligands such as alprenolol and propranolol (Dror et al., 2011). The long MD simulations performed for ~20 microseconds revealed the entire process of association of drug molecules to the GPCR binding site. The process of drug binding explained the energetic barriers required for drug binding and unbinding kinetics.

Statistical Mechanics and Thermodynamic Approaches

The MD calculations utilize virtual screening of ligands for a receptor protein by screening drug databases for available compounds/libraries. However, docking fails to perform in certain cases which limit its use in drug designing. Methods like MM/PBSA and MM/GBSA are applied for calculating binding free energies using molecular mechanics and implicit solvation models. Several thermodynamic approaches have been identified recently which can be used for calculating binding free energy of ligands. Pathway method employs a technique which transforms the system from one state (complex) to another state (unbound) (Shirts, Mobley, & Chodera, 2007). Using FEP method, the system is transformed from one thermodynamic state to another. The two states (A and B) can be characterized by potential energy functions where state A corresponds to unbound ligand state and state B corresponds to complex state. The free energy difference between the two states is calculated by:

$U_{AB} = U_A - U_B$ (Shirts, Mobley, & Chodera, 2007)

where U_{AB} is the free energy difference between the two states. By solving the above equation, we obtain the final *free energy perturbation (FEP) formula* (Shirts, Mobley, & Chodera, 2007):

$$U_{AB} = -kT \ln \left\langle e^{-\beta(U_B - U_A)} \right\rangle$$

where β is the Boltzmann constant and free energy difference between states A and B needs to be calculated by natural log of average Boltzmann factor of potential energy difference between states A and B over equilibrium configurations from the state A. Such a transformation between two end states is

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

termed as *alchemical free energy calculation*. A recent application of the approach was demonstrated the use of FEP coupled with MD and MC used for developing and optimizing lead compounds for HIV-1 protease and non-nucleoside reverse transcriptase inhibitors (Acevedo et al., 2012).

Another widely used approach for binding energy calculation are the MM/PBSA or MM/GBSA methods (Kaukonen et al., 2008). Free energy calculations using MM/PBSA or MM/GBSA methodology are conducted on collective assemblage of structures that are sampled during MD simulations using implicit solvent. By the application of energy minimized structure of receptor; the ligand binding free energies can be estimated. Implicit solvation approximations speed up the calculations, reduce overall completion time and utilize lower computational power in comparison to conventional MD simulation. The free energy is calculated applying PB implicit solvent technique based on SASA using thermodynamic variables based on experimental conditions for regulating specific parameters (for *e.g.* ionic strength, external and internal dielectric constants) (Suenaga et al., 2012; Miller et al., 2012). Free energies calculated using GB also uses implicit solvent method based on SASA. GB method controls other variables such as salt concentration. The biding free energies between the ligand and receptor are calculated as (Hou et al., 2012):

$$\Delta G_{bind} = \Delta H - T\Delta S \approx \Delta E_{MM} + \Delta G_{sol} - T\Delta S$$

where (Hou et al., 2012),

$$\Delta E_{MM} = \Delta E_{internal} + \Delta E_{electrostatic} + \Delta E_{vdw}$$

and (Hou et al., 2012),

$$\Delta G_{sol} = \Delta G_{\frac{PB}{GB}} + \Delta G_{SA}$$

where ΔG_{sol}, ΔE_{MM} and $-T\Delta S$ are solvation energy, change in gas phase molecular mechanical energy and conformational entropy upon binding of ligand. The ΔE_{MM} is calculated as sum of internal energy, electrostatic solvation energy and Van der Waals energy. The ΔG_{sol} is calculated as contribution of polar (PB/GB) and non-polar (surface area) components (Hou et al., 2012).

PBSA and GBSA methods are integrated in MD simulation software suites such as GROMACS (Brooks et al., 1983), CHARMM (Christensen et al., 2009) and AMBER (Wang et al., 2009). Both the methods have been successfully applied for drug binding to the receptor where 59 ligands were tested for binding to 6 different proteins (Hou et al., 2012). The sensitivity of these approaches was evaluated by applying MD simulations for a timescale of 400-4800 picoseconds. The simulation results demonstrated that the length of the simulations did not impact the binding energies seriously. However the solute dielectric constant impacted protein-ligand binding more significantly. The results clearly showed that PBSA and GBSA are important tools in drug designing that can carefully estimate energies and rank inhibitors depending on interactions within the targeted biomolecules.

Ligand-Based Drug Design

Ligand-based drug designing is an indirect method for generating of pharmacologically active compounds interacting with target biological compounds. The first step in drug development will be proper identification of the target molecule associated with a disease present in the biochemical pathway. In the absence of experimental structure or homology model, ligand molecules are analyzed to comprehend the structural and physico-chemical characteristics of the ligand that correlates with targeted pharmacological activity of the ligand.

Ligand-based drug design is generally performed using QSAR and pharmacophore modeling. QSAR is an approach for correlating structures of chemical compounds and biological activities. The first step of QSAR involves identification of the active ligands. The ligands are screened from the drug databases such as PubChem, ChEMBL, NCI, etc by a process called "virtual screening." Next suitable molecular descriptors are identified for the ligand. The molecular descriptors can be characterized into 1D, 2D, 3D or 4D that comprises of the description of shape, volume, density, dipole moment, solvation energy, water accessible surface area, potential energy, torsion energy, electronic energy, electrostatic energy, Van der Waals energy, etc. describing the general characteristics of the ligand.

In the following step a mathematical expression is written for correlating the molecular descriptors and the biological activity. Finally, the QSAR model is constructed and validated for its statistical and predictive abilities (Acharya et al., 2011). The application of QSAR using HypoGen/Discovery Studio softwares for constructing pharmacophore models with hydrophobic and hydrogen bond acceptor features for cathepsin D inhibitors for prevention of various degenerative diseases such as Alzheimer's disease and neuronal ceroid lipofuscinosis (Sakkiah, Thangapandian, & Lee, 2012). Fischer's randomization method was used for identifying correlation between experimental and predicted activity. They obtained 49 compounds as potent cathepsin D inhibitors based on consensus scoring values (Sakkiah, Thangapandian & Lee, 2012).

QSAR approach can be performed using three major statistical methods, namely: MLR, PCA and PLS. The MLR is performed using stepwise regression for finding the best model. MLR has also been used in developing Web-based software (PreADME) which performs *in silico* ADMET (Absorption, Distribution, Metabolism and Toxicity) predictions which is dependent on relationship between molecular descriptors and activity profiles of the compounds (Khan, Mahmud, & Ingebrigt, 2009). One such study using MLR analysis was performed on thermolysin protein responsible for several bacterial infections such as cholera, gastritis and peptic ulcer (Jin et al., 1996; Winfield, Inniss, & Smith, 2009). Thermolysin inhibitors were constructed applying ADMET parameters using QSAR models derived from MLR analysis. This was performed using a Web-based tool called PreADME (http://www.bmdrc.org/04_product/01_preadme.asp). The MLR has also been used successfully in prediction of lead compounds in the development of anti-proliferative agents (Winfield, Inniss, & Smith, 2009). Celecoxib, an FDA approved drug used for treatment of colon cancer was used for development of pyrazole-based molecules as celecoxib was found to cause cardiovascular and cerebral vascular diseases.

There are various steps required for QSAR analysis using MLR. In the *first step*, database of molecules is built and the initial conformations of molecules are energy minimized using a force field. Then molecules are aligned using an alignment tool. In the *second step*, relationship between anti-proliferative activity and structure of compounds is calculated which can include several 2D and 3D molecular descriptors such as *pKa, protein binding, volume of distribution, etc*. From a subset of descriptors, those compounds are selected which shows significant association with anti-cancer activity performed using

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Contingency coefficient, Cramer's V, uncertainty coefficient and correlation coefficient (Winfield, Inniss, & Smith, 2009). In the *third step*, selected compounds are subjected to conformational analysis and alignment. Alignment generates an overlap score and the compounds with highest overlap score are selected. Compounds which best fits the pharmacophore are separated into training and test sets. In the *fourth step*, multiple linear regression equation is determined using statistical software such as SAS for anti-cancer activity prediction. Then, stepwise regression is performed in which descriptors are added or removed based on p-values of F-statistics. Those descriptors which satisfy the minimum significance criteria are considered as 'predictors'. PCA on the other hand generate data from multiple redundant variables into smaller uncorrelated variables (Wold, 1987). This method is used to find collinearities and multicollinearities in multiple and multivariate QSAR. This has been used previously for finding trimethoprim derivatives (Mager, 1982). PLS is an improvised technique which uses combination of MLR and PCA techniques. An improved method of PLS called the non-linear PLS (NPLS) overcomes the inability of PLS for obtaining nonlinear model between principle component of dependent and independent variables (2; Tang & Li, 2008).

QSAR

2D-QSAR

In the QSAR method, several hydrophobic, electronic and steric features are correlated with the biological activities represented by (Acharya et al., 2011):

$$\log\left(\frac{1}{c}\right) = k_1\pi - k_2\pi^2 + k_3\sigma + k_4E_s + k_s$$

C is the concentration of compound needed for biological activity, π is partition coefficient, σ is Hammett electronic substituent constant and E_s is the steric substituent constant. Different chemical groups of the compound mediate specific biological activity. When the chemical group is substituted, the specific biological activity of the substituted compound is evaluated by the summation of parent molecule activity and individual substituent contribution. The molecular descriptors used (for correlation with the biological activity) represent fragments of the parent molecule. The advantages of using fragment-based descriptors include computational ease, diversity of available substituents and their convenient mathematical implementations (Acharya et al., 2011).

3D-QSAR

3D-QSAR uses 3D properties of ligands for correlating and predicting the biological activity. This can be performed using several statistical approaches such as PLS and MLR described above. Several 3D-QSAR techniques such as CoMFA and CoMSA methods have been developed which utilizes the data from the compounds stored in drug databases and derive correlation between the activity of a ligand and its 3D features.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

CoMFA

CoMFA (Comparative Molecular Field Analysis) is a technique for developing correlation between 3D properties of ligands and biological activities. Several optimized conformations of a ligand are generated. The optimized conformations of a ligand are placed in 3D grid and a probe atom is used for calculation of steric, electrostatic, potential and Van der Waals energies (Kubinyi, 2008) A cutoff value for the energies is specified and the conformations which exceed the cutoff values are rejected. Probe atom not only helps in determining the energies but it also helps in determining the activity of the ligand using PLS method (Acharya et al., 2011). Result of the analysis is represented by contour maps which show favorable and unfavorable steric regions around the molecules. The CoMFA has been successfully applied in the development of novel N1-amino-acid substituted 2,4,5-triphenyl imidazoline derivatives for inhibition of p53-MDM2 binding which is responsible for malignant tumor growth in humans (Hu et al., 2012).

CoMSA

CoMSA (Comparative Molecular Surface Analysis) is a method similar to CoMFA (Acharya et al., 2011) and calculates similarity indices by comparison between individual ligand molecule with a common probe having charge, radius, hydrophobicity and hydrogen bond properties similar to (Reddy et al., 2007).. The similarity indices describe receptor-ligand binding interaction energy. CoMSA has also been successfully used for designing molecules for synthesis of new HIV-1 integrase inhibitors which uses Kohonen Self-Organizing Maps (SOM) which allows projection of 3D molecular data into 2D maps (Niedbala et al., 2006).

Cloud Computing Advances in Drug Discovery

Cloud computing is a technology for delivering computational resources using Web technology. Molecular docking and MD simulations require extensive computational power and time for performing high throughput analysis. Cloud computing technology reduces the huge investment in computer power and time by providing same resources over the Internet. The end user can utilize such resources on-demand which means that user can demand amount of computational power for performing high throughput analysis. Such technology has been recently incorporated by InhibOx (http://www.inhibox.com). It has developed next generation drug discovery platform and delivers cloud-based drug development services. Virtual screening of active site of biological receptor protein has been performed by molecular docking tools such as AutoDock (Morris et al., 2009). It applies distributed/grid computing technology that integrates several individual computers generating a super computer with huge computational power (Shudong et al., 2004). Similar research has been performed by cloud computing using Internet version of AutoDock. Using 100 million compound databases of 3D candidate compounds with pre-calculated shape, charge and stereochemistry can be used to guide the process of virtual screening. Using such massively computer intensive and rigorous approach, cloud computing makes the whole approach flexible.

CONCLUSION

In this review, we discussed various computational approaches for drug design from virtual screening of ligands from drug databases to computation of ligand binding free energies using statistical and thermodynamic methods. We clearly outlined both the structure and ligand-based approaches requiring known target 3D structure or clear description of 3D features of the ligand for optimal binding to the receptor for QSAR approach, respectively. Ligand binding to the receptor active site can be performed using long MD simulations, however it requires the extensive processing and graphical power which states current limitation of the approach for larger macromolecules. However, by employing certain molecular mechanics approaches such as PBSA or GBSA can speed up the computation otherwise done for classical all-atom MD approach. Development of cloud-based technology can also help drug discovery projects with higher computational power delivered at a reduced cost.

FUTURE DIRECTIONS

Advances in computational techniques and resources have led to the development of smart and innovative methods in drug designing. However, current research and developments are targeted mostly towards a single receptor protein responsible for causing disease. This approach however creates a targeted drug but neglects the potential effects caused due to various interactions with other proteins and biomolecules which creates a plethora of potential side effects. Current approaches outlined can only be used for designing derivatives of known compounds by various statistical and thermodynamic approaches which completely fail to consider several design parameters aimed at targeting causal biomolecule at targeted site. Certain design parameters and smarter algorithms which can consider the toxicological and other side effects of the compounds during pharmacophore modeling can be manufactured which can specifically target the protein of interest. Also, development of nanoparticles can also enhance the specificity of the ligand by allowing the nanoparticle to carry the drug concentration to the specific target site. Such smarter approaches and innovative thinking can help in the development of novel therapeutic compounds for combating target diseases such as cancer.

KEY TERMS AND DEFINITIONS

Cloud Computing: A term that involves services provided over the Internet. This idea has been implemented from distributed/grid computing that integrates several individual computers to generate a super computer system of superior computational abilities utilizing computing resources allocated on-demand over the Internet.

Computational Drug Design: Drug designs using highly specialized and sophisticated software.

Drug: Chemical substance(s) that can have either medicinal, hallucinogenic or performance improving properties administered as an external/foreign agent to either humans or animals.

Ligands: Small molecules forming complexes with other complex biomolecules such as nucleic acids and proteins to perform highly specialized biochemical reactions and/or transformations.

Molecular Docking: Molecular docking involves knowledge of putative binding sites where the ligand can bind and initiate a biological response.

Molecular Dynamics: Specialized software used for simulating physical movements of atoms and molecules.

Pharmacophore: Molecular characteristics of ligands for identifying specific target biomolecuels.

Chapter 46
Hybrid Plasmonic Nanostructures:
Environmental Impact and Applications

Ahmed Nabile Emam

ABSTRACT

Plasmonic hybrid nanostructure including Semiconductor-metallic nanoparticles, and graphene-plasmonic nanocomposites have great potential to be used as photocatalyst for hydrogen production and for photodegradation of organic waste. Also, they are potential candidate as active materials in photovoltaic devices. Plasmonic-magnetic nanocomposites could be used in photothermal therapy and biomedical imaging. This chapter will focus on the environmental impact of these materials and their in-vitro and in-vivo toxicity. In addition, the applications of these hybrid nanostructures in energy and environment will be discussed in details.

1. INTRODUCTION

Recently, population growth and fast urbanization and industrialization have been increased dramatically. Therefore, several serious environmental issues such as; climate changes, global warming and pollution of water resources were still a main challenge for the whole world. These issues may become even worse if no efficient/sustainable solutions has been developed to reduce their reasons.(Li et al. (2015)) Due to these tremendous advances, the search for the suitable platforms, and materials to be used in wide-variety of environmental applications became the main target for several research groups.

Plasmonic materials and their hybrid nanostructures have unique and intriguing physico-chemical and biological properties compared to their bulk counterparts. This is attributed to their high *surface-to-volume* ratio, shape and size dependent optical properties and their localized surface Plasmon.(Li et al. (2001), Sharma et al. (2008), Iglesias-Silva et al. (2007), Huang and Yang (2008) and El-Nour et al.

(2010)) Additionally, the ease of surface modification functionalization to be utilized in different applications.(Qu et al. (2013), Cuenya (2010), and Zhang et al. (2010)) Therefore, plasmonic nanomaterials and their hybrid nanocomposites represent new class of materials which could be good candidates to provide promising solutions for the most environmental issues.(Guo and Wang (2011), Cao et al. (2013), and Corma and Serna (2006)) These possible applications can varies either from their catalytic and photocatalytic applications, light harvesting, sensing, and antimicrobial applications (Figure 1). (Li et al. (2015))

2. ENVIROMENTAL APPLICATIONS OF PLASMONIC NANOPARTICLES

a. Silver Nanoparticles

Silver nanoparticles exhibit unique optical, catalytic, sensing and antimicrobial characteristics which made them have huge industrial demands, pegged at 16,000 to 24,000 tons per year. As an antimicrobial agent, silver nanoparticles are expected to have annual demand of 2800 tons/year in the fields of 'food, hygiene and water purification, in addition to 3125 tons/year for medicine. Only 36% of the silver consumed in these industrial processes is being recycled and the rest is let out to the environment. The widespread

Figure 1. Schematic illustration of the possible applications od plasmonic nanoparticles in the environmental field. Reproduced from[Li, J., Zhao, T., Chen, T., Liu, Y., Ong, C.N. and Xie, J., 2015. Engineering noble metal nanomaterials for environmental applications. Nanoscale, 7(17), pp.7502-7519] Published by The Royal Society of Chemistry

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

application of Ag NPs in our daily life will unavoidably increase the human and ecosystem exposure. Furthermore, during their production, transport, erosion, washing or disposal of Ag NP containing products, results in their release to the environment. Though the long historical use of silver has not shown obvious adverse effects, there is concern about the potential risks of Ag NPs in the environment.(Lima et al. (2012) and Yu et al. (2013))

i. Antimicrobial Applications

Ag NPs could be used as antimicrobial agents in the health industry, food storage, textile coatings, cosmetics and a large number of environmental applications. Silver nanoparticles were applied in a wide range of applications from disinfecting medical devices and home appliances to water treatment (Bosetti et al. (2002), Cho et al. (2005), Jain and Pradeep (2005), and Li et al. (2008)) Textile industry use Ag NPs in different textile fabrics. In this direction, silver nanocomposite fibers were prepared containing silver nanoparticles incorporated inside the fabric.(Montazer et al. (2012), Xue et al. (2012), Khalil-Abad et al. (2010)), In addition, Ag NPs might be used as surface disinfection agent.(Kumar et al. (2008), Roe et al. (2008), Jain et al. (2009), Gottesman et al. (2011), and Freeman et al. (2012)) This property can be achieved through different ways, such as embedding into bactericidal coating,(Kumar et al. (2008)), surface functionalization of plastic catheters and other medical devices,(Roe et al. (2008)), gel formulation for topical use,(Jain et al. (2009)) coating of packing papers to be used in food preservation,(Gottesman et al. (2011)), or by impregnating fabrics for clinical clothing.(Freeman et al. (2012)).

The mechanism of silver nanoparticles as antimicrobial has been studies against many types of bacteria and biofilms. Table 1 summarizes the mechanism of action and Figure (2) describes how silver nanoparticles can be toxic to bacteria.

Table 1. Details of Ag NPs and their mechanisms of action against bacteria and biofilms

Bacterial Strain	Mechanism of Action
Acinetobacterbaumannii	Alteration of cell wall and cytoplasm
Escherichia coli	Alteration of membrane permeability and respiration
Enterococcus faecalis	Alteration of cell wall and cytoplasm
Klebsiellapneumonia	Alteration of membrane
Listeria monocytogenes	Morphological changes, separation of the cytoplasmic membrane from the cell wall, plasmolysis
Micrococcus luteus	Alteration of membrane
Nitrifying bacteria	Inhibits respiratory activity
Pseudomonas aeruginosa	Irreversible damage on bacterial cells; Alteration of membrane permeability and respiration
Proteus mirabilis	Alteration of cell wall and cytoplasm
Staphylococcus aureus	Irreversible damage on bacterial cells
Staphylococcus epidermidis	Inhibition of bacterial DNA replication, bacterial cytoplasm membranes damage, modification of intracellular ATP levels
Salmonella typhi	Inhibition of bacterial DNA replication, bacterial cytoplasm membranes damage, modification of intracellular ATP levels
Vibrio cholera	Alteration of membrane permeability and respiration

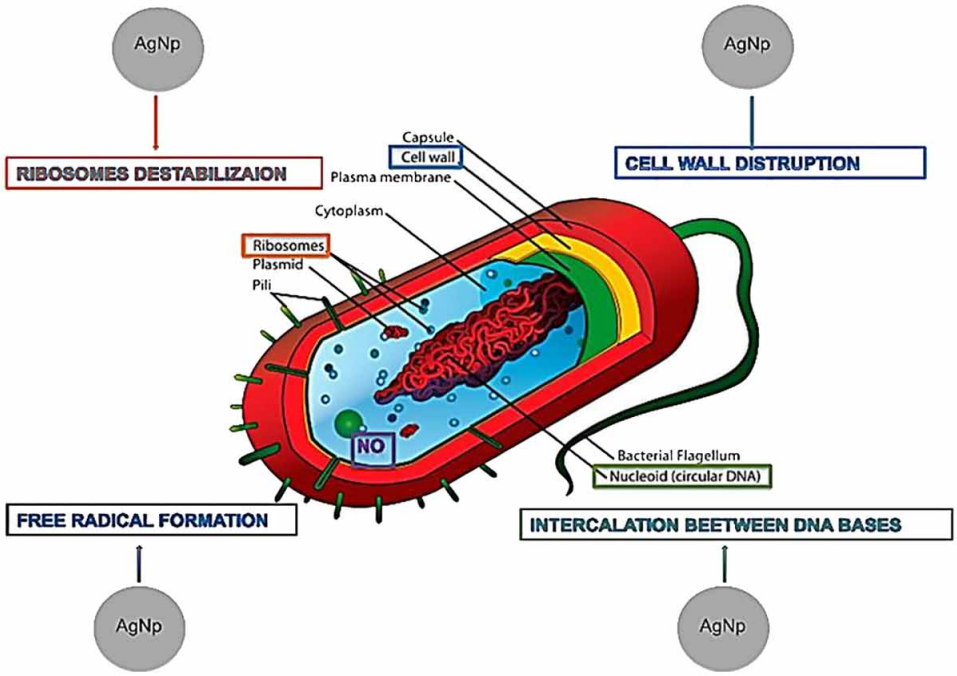
EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



Several products include containing Ag NPs have been approved by a range of accredited authorities such as, FDA, EPA, and SIAA of Japan.(Azonano, El-Nour et al. (2010), Jia et al.(2008) and Bhattacharya and Mukherjee(2008))

For these purpose, the toxicity of silver nanoparticles has been studied in different mammalian cell systems, including rat and human cells. (i.e. rat liver cells, (Hussain et al. (2005)) human keratinocytes and fibroblasts cultures,(Burd et al. (2007)) and human spermatogonial stem cells.(Braydich-Stolle et al. (2005)) *In vitro* studies shows that an elevated dose of nano silver induces oxidative stress (liberation of reactive oxygen species) as a mechanism of cytotoxicity.(Arora et al. (2008)) At the safe concentration range, silver nanoparticles have been described to cause an exert anti-inflammatory effects as: acceleration of wound healing,(Tian et al. (2007)), inhibition of allergic contact dermatitis in mice, suppression of the expression of TNF-α and IL-12, and induction of apoptosis of inflammatory cells.(Bhol and Schechter (2005)), modulation of cytokine production and induction of peripheral blood mononuclear cells proliferation (Figure 2),(Shin et al. (2007)).

ii. Water Purification and Disinfictents

Water is one of the most important substances on Earth and is essential to all living things. Although 70% of the Earth is covered with water, only 0.6% is suitable for human uses. According to the WHO, at least 1 billion people do not have access to safe drinking water. Contamination of drinking water are the leading cause of death in many developing nations.(Pradeep (2009), Tran et al. (2013) and Gusseme et al. (2010))

Figure 2. Mechanisms of Ag NPs' toxic action
Reprinted from [Franci, G., Falanga, A., Galdiero, S., Palomba, L., Rai, M., Morelli, G. and Galdiero, M., 2015. Silver nanoparticles as potential antibacterial agents. Molecules, 20(5), pp.8856-8874].Published by MDPI AG, Basel, Switzerland

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Complexity of contaminants, population growth, presence of resistive pathogens and their impact on the environment create a demand for advanced technologies for clean and safe drinking water. Several chlorine and halo-compounds such as tri-halo methanes, halo-acetic acids, halo-acetonitrile, halo-ketones and other DBPs were found to cause colon, rectal and bladder cancers and adverse reproductive disorders. Ag NPs are very ideal to be used in water disinfection. It could be easily incorporated to polymeric membranes to disinfect the water contaminated from bacteria and viruses.(Gusseme et al. (2010 and 2011), Lv et al. (2009), Yakub and Soboyejo (2012), Jain and Pradeep (2005), Gangadharan et al. (2010), Zhang et al. (2012), and Sheng and Liu (2011)) Moreover, the addition of silver-based NPs could prevent bacterial/viral attachment and biofilm formation in filtration medium.(Sintubin et al. (2011) and Fernández et al. (2015)). The application of silver-based NPs is of utmost importance to prevent outbreaks of waterborne diseases related to poor treatment of drinking water.

b. Gold Nanoparticles

Gold nanoparticles have unique optical and electronic properties due to their surface Plasmon resonance. Thus, many researchers developed the use of gold nanoparticles and their composites in many areas such as biological tagging, chemical and biological sensing, optoelectronics, photo thermal therapy, biomedical imaging, DNA labeling, microscopy and photo-acoustic imaging, drug delivery, surface-enhanced Raman spectroscopy, tracking and drug delivery, catalysis and cancer therapy and imaging.(Kim and Jon (2012), Khlebtsov and Dykman (2010), and Tedsco et al. (2010))

Environmental applications of gold nanoparticles has been limited to fabrication of gold nanoparticles based sensors to detect various metal ions by working on the principle of colour change due to the aggregation of gold nanoparticles. Such types of sensors have been widely used for the detection of copper, mercury lead and arsenic in water (Nalawade et al. (2012)). Another very promising application is using them in catalysis to convert harmful gasses into less toxic or environmental friendly gasses. In particular, using gold nanoparticles, or nanoalloy of gold and another metal loaded into metal oxides are catalytically very active for a wide range of reactions, (Kim et al (2004)) including CO oxidation,(Yoon et al. (2005) and Gluhoi and Nieuwenhuys (2004)) water gas shift reaction,(Liu et al. (2005)) NO_x reduction, CO and CO_2 hydrogenation, NO oxidation, alkene epoxidation and selective oxidation of hydrocarbons. (Hughes et al. (2005))

c. Enviromental Appliations of Plasmonic Hybrid Nanocomposites

Magnetic nanoparticles, especially iron (Fe^0), magnetite (Fe_3O_4) and maghemite (γ-Fe_2O_3) nanoparticles, have sparked an enormous interest in applications for treatment of polluted water or subsurface environments.(Yantasee et al. (2007), Shen et al. (2009 and 2011), Tang and Lo (2013)). Magneto-plasmonic nanostructures open an opportunity for some many environmental applications, such as sunlight photocatalytic inactivation of Bacteria (Zhai et al. (2011)). Zhai and co-workers illustrated a convenient method to fabricate noble metals based super-paramagnetic nano hybrid hetero-structures (i.e. Ag-Fe_3O_4 and Au-AgCl@Fe_3O_4). They reported in their study that Au-AgCl@Fe_3O_4 nanotubes was an excellent candidate for photocatalytic inactivation of bacteria upon irradiation with sunlight (Figure 3). (Zhai et al. (2011))

Sun and co-worker (Sun et al. (2015)) developed another system based on dumbbell-like structure α-Fe_2O_3/Ag/AgX heterostructures via *in-situ* oxidation reaction. In such system showed a higher photocatalytic activity than both of α-Fe_2O_3 and α-Fe_2O_3/Ag systems as shown Figure (4).

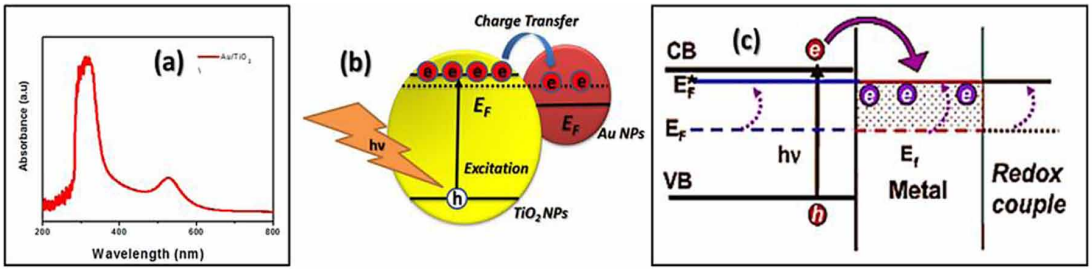
Metal oxide semiconductors nanoparticles hold great promise for wide range applications, such as energy conversion and storage, environmental remediation, and etc... However, critical factors including the high charge – carrier recombination rate and narrow light absorption have restricted more practical and viable applications. ((Pelaez et al. (2012)) Particularly, TiO_2 is one of the most candidates which got a lot of interests from several research groups, due to its low cost and high stability. (Fang et al. and Pelaez et al. (2012), Chehadi et al. (2016)). However, TiO_2 has large energy band-gap of 3.2 eV and only absorbs solar radiations in the ultraviolet (UV) region, while the UV lights only contribute to less than

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



10% of total solar radiations; the visible lights. On the other hand, contribute to 50% of the solar radiations.(Pelaez et al. (2012)) Furthermore, the photo-catalytic activity of TiO_2 decreases substantially with prolonging the service time; and the deactivation of TiO_2 – based photo-catalysts is a crucial drawback for the application.(Wang et al. (2012)) There have been many research efforts devoted to improve the photocatalytic activity by incorporating metals or ions (i.e. Ag, and Au NPs),(Arunachalam et al. (2012) and Suvith and Philip (2014), Bhakya et al. (2015)) to broaden the absorption of solar radiations and to re-activate and regenerate TiO_2-based photocatalysts.(Sangpour et al. (2010), Wu et al. (2010), Linic et al. (2011), Kochuveedu et al. (2013))

Over the past decade, the idea of fabricating hybrid nano-objects that composed of plasmonic metals and semiconductors was emerged, due to their localized surface Plasmon resonance and the formation of effective Schottky junctions.(Subramanian et al. (2003 and 2004), Hirakawa and Kamat (2005)). In such nano-hybrid system; plasmonic nanoparticles are able to absorb visible light intensely due to the surface plasmon resonance (SPR) effect. Through the SPR effect, the electromagnetic field of incident light couples with the oscillations of conduction electrons in the plasmonic nanoparticles, resulting in surface plasmon absorption and an enhancement of the local electromagnetic fields close to the surface of plasmonic nanoparticles. Therefore, plasmonic nanostructures of noble metals in combination with semiconductors offer a promising future for the next generation of energy and environmental needs (Figure 5).(Subramanian et al. (2003 and 2004), Sangpour et al. (2010), Wu et al. (2010), Linic et al. (2011), Kochuveedu et al. (2013))

Contamination of waste water with organic compounds (i.e. dyes, pesticides, drugs, phenolic compounds and polymers) has huge hazardous effect in the environment and spontaneously affects human health. Conventional treatment method of organic pollutant is based upon removing large amounts of organic compounds from waste water streams by adsorption. The disadvantage of this method is that it is non-destructive for the organic pollutants, which simply transfers the pollutants from one phase/substance to another. Photocatalytic degradation of organic pollutants using UV or sun light in presence of nano-catalyst has been a great interest because it has the capability of converting these organic hazards into

Figure 5. (a) Absorption Spectra of Au-TiO_2 Hybrid Nanocomposites. non-toxic compounds. In the recent years, numerous metal oxides, plasmonic and plasmonic graphene hybrid nanocomposites have attracted growing attentions for photo-degradation of organic pollutants. (Wu et al. (2010), Linic et al. (2011), Pelaez et al. (2012), Wang et al. (2012), Kochuveedu et al. (2013))

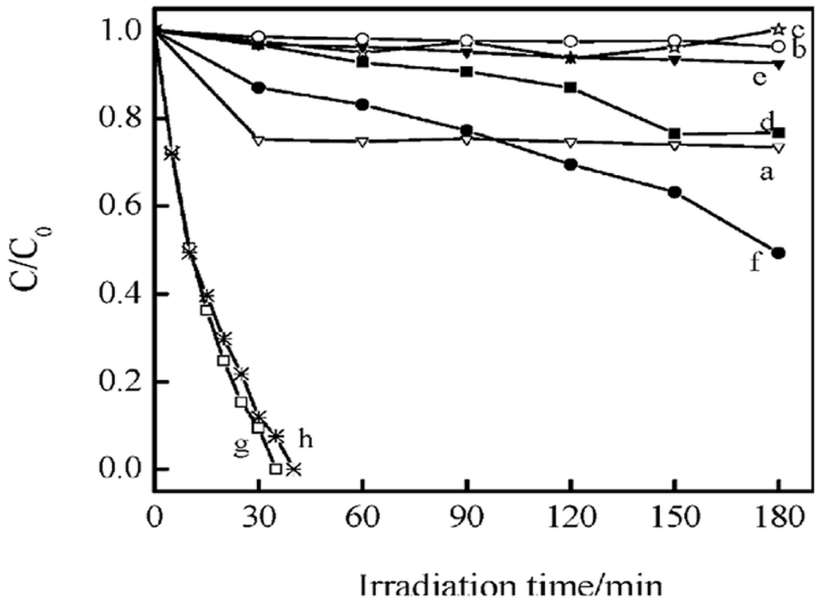
Phenolic based – organic hazardous compounds are considered one of the most and highly spread highly toxic wastes. This is due to the difficulty of their biological degradation, leading to a setting up of restricted level of phenol in the environment.(Hu et al. (2009)) Phenolic based water pollutant compounds, include 2-chlorophenol (2-CP), 2,4-dichlorophenol (2,4- DCP), and trichlorophenol (TCP) have been used in photo-catalytic activity assessment, upon irradiation via sunlight.(Hu et al. (2009)) Several reports has been devoted to use a hybrid nano-objects based on combination between plasmonic nanostructures and metal oxide as a catalyst supports.(Hu et al. (2009) and Chehadi et al. (2016)) Chehadi and co-worker demonstrated the influence of Au NPs as an example of the plasmonic nanostructure on the photocatalytic efficacy of various metal oxide (i.e. TiO_2, ZnO, and Al_2O_3) as a catalyst supports on the photo-degradation of Bisphenol A (BSA) upon laser irradiation. In addition, investigate the effect of different parameter such as, irradiation time, laser power, and catalyst type. They reported that Au/TiO_2 showed a fastest degradation rate than other composite systems. (Chehadi et al. (2016)) Another study has been illustrated by Hu et al. (Hu et al. (2009)). They developed metal-semiconductor nanocomposites base on coupling between plasmonic nanostructures Ag-AgI with mesoporous alumina using deposition-precipitation, and photo-reduction techniques.(Hu et al. (2009)) They reported that their configuration showed higher photo- sensitivity, stability and catalytic activity for the degradation and mineralization of toxic persistent organic pollutants especially Phenolic based organic pollutants upon irradiation using simulated sun light.(Hu et al. (2009)) in addition the capability to be used not only as a photo-catalyst, but also photovoltaic fuel cells (Figure 6).(Hu et al. (2009))



Different shapes of hybrid CdSe/Au penta-pods and nano-dumbblls shows photocatalytic activity for the photo-degradation of organic dyes by irradiation using UV light. Presence of plasmonic at the interface of CdSe Semiconductor nanoparticles enhances the photocatalytic activity three times more (Figures 7 and 8). This is due to the electron transfer from CdSe to Au Fermi level. (Costi et al. (2008), Gao et al. (2011), Tongying et al. (2012) and Haldar et al. (2012))

Recently, Zhou et al. (Zhou et al. (2015)) developed a ternary hybrid nanocomposites of semiconductor-plasmonic hetero-nanostructures loaded into graphene has been developed and display extraordinary photocatalytic efficiency induced by the plasmonic energy that operates in the Ag@CdSe-rGO hybrid ternary composites. The obtained plasmonic photo-catalysts in nanoscale were fabricated by using a one-step hydrothermal method, during which the in situ nucleation of Ag@CdSe core−shell nanoparticles and the reduction of GO to rGO occurred simultaneously. The enhanced photocatalytic and optical properties toward photo-degrading of organic pollutant under visible light irradiation can be ascribed to plasmonic enhancement of Ag by charge and energy transfer and to the carrier rGO further enhancing the separation of photo-generated e^-/h^+ pairs. Three major roles of Ag core, electronic acceptor by the Schottky barrier formed in Ag@CdSe hetero-structure and induced by the local Plasmon resonance of Ag, have facilitated the separation of photo-generated e^-/h^+ in CdSe QDs, and the plasmonic energy transfer from Ag to CdSe has strengthened the excitation and charge separation of CdSe QDs. The introduction of rGO carrier in the Ag@CdSe-rGO system has enhanced the photocatalytic activity for its high charge carrier mobility and ambipolar field effect Figure (9).

3. CONCLUSION

Plasmonic nanoparticles such as Ag NPs and Au NPs have unique optical, catalytic and electronic properties which made their uses in industrial applications grow tremendously in the last few years. The super-antiseptic and antimicrobial effect of silver nanoparticles lead to new generation of disinfectant, infection control and antibiotics based nano-silver products. The catalytic and photothermal properties of gold nanoparticles developed several based applications in medicine and environment such as drug delivery, cancer therapy and imaging, sensors for detection of heavy metals and bacteria in environment Plasmonic-hybrid nanocomposites including magnetic-plasmonic, metal oxide-plasmonic, or quantum dots/plasmonic opens a new class of photo-catalysts used for the photo-degradation of organic pollutant and waste water purifications, light harvesting and hydrogen productions. Extraordinary photocatalytic activity had been achieved via loading these plasmonic hybrid nanostructures on graphene sheets.

Chapter 47
Implementation of Nanoparticles in Cancer Therapy

Ece Bayir
Ege University, Turkey

Eyup Bilgi

Aylin Sendemir Urkmez
Ege University, Turkey

ABSTRACT

Cancer is a wide group of diseases and generally characterized by uncontrolled proliferation of cells whose metabolic activities are disrupted. Conventionally, chemotherapy, radiotherapy, and surgery are used in the treatment of cancer. However, in theory, even a single cancer cell may trigger recurrence. Therefore, these treatments cannot provide high survival rate for deadly types. Identification of alternative methods in treatment of cancers is inevitable because of adverse effects of conventional methods. In the last few decades, nanotechnology developed by scientists working in different disciplines—physics, chemistry, and biology—offers great opportunities. It is providing elimination of both circulating tumor cells and solid cancer cells by targeting cancer cells. In this chapter, inadequate parts of conventional treatment methods, nanoparticle types used in new treatment methods of cancer, and targeting methods of nanoparticles are summarized; furthermore, recommendations of future are provided.

1. CANCER BIOLOGY

Cancer, although one of the world's most widely studied medical conditions, remains as the leading cause of death after the heart failure, accounted for 7.6 million deaths (around 13% of all deaths) in 2008. According to comprehensive, 184 country survey of WHO's International Agency for Research on Cancer (IARC), about 70% of all cancer deaths occur in low- and middle-income countries. Worldwide cancer mortalities are envisioned to continue to rise to over 13.1 million in 2030 (http://globocan.iarc.fr/).

Normal eukaryotic cells tend to increase their number by mitosis and meiosis, and the cell division process is triggered by activation of the metabolic pathways when the cell size and the environmental conditions are favorable. The metabolic pathways that are necessary for cell division include the specific signaling pathways, the transmitting signal molecules, enzymes and proteins (Cooper & Hausmann, 2013). After completion of division process, the cell enters into a new cycle again and the cycle is repeated approximately 50 times before the cell goes to apoptosis. Apoptosis is the death of a cell programmed by specific genes. The reason for the limited number of cell divisions is telomeres, regions of repetitive nucleotide sequences at each end of a chromatid, which protect the ends of the chromosomes from deterioration or from fusion with neighboring chromosomes. Telomeres shorten with each cell division and eventually the cell cannot be divided further, progresses into senescence or dies (Counter et al., 1992).

Some cells, due to hereditary and environmental factors, continue to grow and proliferate even in the presence of cell growth and division inhibitory factors. Thereby, cells start division without special signals. Cell growth is disrupted, cells begin to divide too quickly and telomere shortening stops due to telomerase activity (Yoshida et al., 1997).When unnatural telomerase activity is observed, cell structure changes, adhesion property increases, abnormal signal transduction occurs, tumor suppressor genes are silenced and growth factors and their receptors are generated irregularly. These are typical characteristics of cancer cells. Therefore, the researchers specify that cancer originates in fast-growing and immortal cells. Abnormal cells affect the cells around them and they also lead to deterioration of their functions. The other most important feature of these cells is that they may maintain their lives regardless of the specific microenvironment. Thereby, they can easily spread to the surrounding tissues, blood and entire body (metastasis). These abnormal cells generate new blood vessels around them by secreting vascularization factors, and they can make the metastasis process more quickly and efficiently (Sooriakumaran & Kaba, 2005) (Figure 1).

Figure 1. Emerging hallmarks of cancer for therapeutic targeting (Adapted from Hanahan & Weinberg, 2011)

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Formation of such a cell abnormality is caused by mutations due to environmental factors and/or heredity. X-rays, UV light, tobacco products, diet and obesity, environmental pollutants and viruses are considered the most common environmental carcinogens.

Although many methods have been developed in the treatment of cancer, the WHO figures suggest that a highly effective treatment technique is yet to be found. Surgery, radiotherapy, chemotherapy, immunotherapy and hormone therapy, which are the most commonly used conventional methods have specific advantages and disadvantages. The chosen treatment type depends on the location, the progress status and the type of cancer. The limitations of status quo treatments are commonly due to non-specific bio-distribution and insufficient targeting of the therapeutic agents, poor oral bio-availability, low therapeutic indices, dose-limiting toxicity to healthy tissues, and almost invariably emerging drug resistance and subsequent challenge of providing remissive therapy. Multimodal therapy methods are under investigation, and researchers are looking into developing alternative therapies. Oncology is one of the disciplines that will potentially benefit the most from nanotechnology. The nanoparticle based targeted delivery vehicles can effectively overcome the major challenges in successful clinical translation, including specificity, proper dosage, overcoming various biological barriers and demonstrating better therapeutic efficacy than that of the current clinical standards.

Conventional Approaches for Cancer Therapy

Surgery

Surgery is the oldest treatment method used to treat cancer (Wu et al., 2006). Initially patients who have an operation had died because of excessive blood loss, difficulties of anesthesia and respiratory insufficiency. Thanks to the advances in the drugs and medical sector, the number of deaths caused by operation is significantly reduced and the therapeutic outcomes are increased.

Surgery is the preferred treatment method for initial stages of solid cancer tumors and benign (non-metastatic)tumors. The efficacy of treatment is inversely proportional to the ability of tumor metastasis. Despite the surgery eradicates solid tumors, it generates low success rate on non-solid and spreading tumors (Rani et al., 2012).

Primarily the tissue specimen is removed by surgical cutting and examined by microscopic analysis. The tumor tissue can be removed by surgery if the structure of the tumor is suitable to be removed. Regional lymphatic nodes are excised during the operation to prevent metastasis. To eradicate the metastatic cells, the surgery is supplemented by another treatment modality. One of the most important disadvantages of surgery is that the surrounding tissues can also be damaged besides the tumor tissue during the operation. The entirety of cancer cells must be cleaned during the operation, because even a very small number of remained cancer cells may lead to recurrence of the tumor. To achieve this, some parts of the healthy tissues around the tumor are also removed during the surgery. Substantial tissue loss can lead to physiological and psychological issues for patients. In addition, locations in the body where operation is very dangerous is an extra limitation for the surgery (Haskell & Berek, 2001).

Radiotherapy

Radiotherapy is a treatment method used to destroy the cancer cells that cannot be removed by surgery from tumor tissue (Love et al., 1999; Haskell & Berek, 2001). In some cases, it can also be used to reduce

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

tumor size. In radiation therapy, X-rays, gamma rays and electrons are used. Radiation therapy is used at certain time intervals to provide a period for recovery of the normal cells that are damaged beside the cancer cells during the treatment. Generally, normal cells are less sensitive than tumor cells to radiation. Nevertheless, the dose and location of radiation given to the patient must be arranged very accurately in order to minimize the damage to normal cells (Love et al., 1999). The sensitivity of tumor cells to radiation is also different. Therefore, the effectiveness of radiation therapy is directly proportional to the sensitivity of the tumor to radiation.

Radiation therapy can be used for therapeutic purposes; it can also be used in palliative therapy. Palliative care is also called "comfort care" or "supportive care" given to a patient who has a serious or life-threatening disease, such as cancer, and it can be given at the time of diagnosis and throughout the course of illness. There are two kinds of radiation therapy according to the mode of administration. Beams are generated outside the patient and are targeted at the tumor site in "External Beam Radiation" method (Murray & Robinson, 2011). In "The Internal Radiation" method, the radioactive materials are placed directly into the tumor tissue. The most important parameters for treatment planning and dose calculations are energy loss of radiation, range and scatter of radiation, dose and isodose of radiation (Chopra, 2011).

Radiation therapy kills the cancer cells by damaging their DNA. This treatment damages cells' DNA either directly or by forming free radicals. Damaged cells which are not repaired stop dividing or die. Radiotherapy has serious side effects related to radiation dose, volume of the tissue and administration rate. Radiobiological effects critically depend on the pattern of ionization at the level of the biomolecule. The most common side effects are fatigue, nausea, vomiting, inflammation and edema of the irradiated organ in the early days, and possibly chronic blood supply disorders, neutropenia (sudden drop in white blood cell count), and anorexia (Soussain et al, 2009; Shafiq et al., 2009).

Chemotherapy

Chemotherapy is the use of chemical agents to kill or suppress the growing cancer cells. In contrast to surgery and radiotherapy, chemotherapy is not local and affects the entire body. The main target is rapidly dividing cells in chemotherapy since most cancer cells are characterized by the ability of rapid division. Intestinal epithelial cells, bone marrow cells, mucosal and hair follicle cells and stem cells are rapidly dividing cells in the body and these cells are damaged as well by chemotherapy (Rani et al., 2012). On the other hand, all of the cancer cells are not capable of dividing rapidly. Types of tumors with doubling rate more than 70 days to less than 30 days exist. Due to this non-specificity, selective and/or targeted agents are necessary to expand the effectiveness of chemotherapy. The main target of traditional chemotherapy is prevention of replication and transcription by targeting DNA and thus inhibition of cell growth and division by suppression of protein synthesis. In addition, nowadays, specific protein synthesis pathways, mitotic vehicles, specific antigens and protein kinase inhibitors are studied to target with drugs that may be effective in different cell division phases, and impair the formation of mitotic spindles (Miglarese & Carlson, 2006).

The biggest problem in chemotherapy is toxicity. The toxic effects are often observed because the chemotherapeutic agents have high toxicity and elevated doses are used for the treatment of many cancer types. It is possible to classify these effects under two headings as long and short term toxicity. The short-term toxicity usually emerges quickly and occurs in tissues that have rapid division capability. Vomiting, nausea and dizziness are the main side effects of short-term toxicity (Poli-Bigelli et al., 2003). Long-term

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

toxicity usually leads to carcinogenesis, teratogenesis (defect births) and infertility. In addition to these problems, cancer cells can develop resistance to chemotherapy drugs and this constrains effectiveness of chemotherapy. Drug resistance may occur because of over expression of multidrug resistance genes, membrane uptake reduction and the increasing of tolerance to cytoplasmic detoxification, DNA repair and DNA damage. This situation makes it necessary to have new active substances in cancer treatment continuously (Tiwari et al, 2011; Yap etal. 2009).

All these treatments can be used single or in combination. However the point to be considered is that the damage to the healthy cells may be increased with combined and/or repeated therapies since they are not specifically targeted. In recent years, new methods of treatments are applied in order to reduce exposure rates to normal cells. The most prominent of these methods are immunotherapy and hormone therapy (De Schryver et al., 1992; Fong et al., 2001; Burch et al., 2004). The patient's own immune system fights cancer and reduces treatment-related side effects in immunotherapy. The hormones that help the development of tumor may be stopped, or the activities of the hormones that can fight cancer cells, make cancer cells grow more slowly are increased.

2. NANOPARTICLES IN CANCER THERAPY

Nanotechnology is a research area with the potential to be used in a wide variety of fields from biomedical technologies to textiles and from food packaging to informatics. Nanoparticles (NPs) have been available in all areas of human life for a long history, although the word "nanoparticle" has begun to be used widely with developing nanotechnology in late 20th century. People are exposed to nanoparticles in the air, food and beverages constantly (Buzea et al., 2007). Nanoparticles offer unique physical and biological properties particularly in the medical field to overcome cellular barriers and improve the delivery of various bioactive molecules and drugs as well as to enhance molecular imaging, to facilitate early tumor detection, to implement monitoring of therapeutic response and to minimize side effects. There are different mechanisms for the internalization of nanoparticles by cells influenced by nanoparticles' physicochemical properties (Hillaireau&Couvreur, 2009; Susa et al., 2009). However the biggest obstacle against the development of nanoparticle drug delivery systems is the ambiguity in nano-toxicology issues. Although there are comprehensive studies on nano-toxicology, a definitive concensus has not been revealed yet. Many studies have shown possible negative effects of nano-materials on mammalian cells. However, the number of works to prevail these adverse effects has been limited. NPs need to be analyzed more critically and their effects on organisms must be investigated by well-designed *in vitro* and *in vivo* studies to eliminate this problem.

In this section, general information about NPs that are used in drug delivery and targeting in cancer therapy will be presented with their advantages and disadvantages. Selected nanoparticle-based therapeutics approved by federal agencies or still in clinical trials in cancer treatment are tabulated at the end (Table 1).

Polymeric Nanoparticles

Polymeric NPs are obtained by using natural or synthetic polymers in the core/corona part (Alexis et al., 2008). Polymeric NPs are often used for controlled drug delivery systems. Drugs which are used for therapeutic purposes can be encapsulated in the polymer, or loaded on either the surface or the core

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

(MuFei Tang et al., 2010). NPs can be produced from biodegradable or non-biodegradable polymers depending on the purpose. Biodegradable polymer NPs may be removed from the body through the normal metabolic pathways by eroding into its constituent oligomers. Their degradation and drug release rates or kinetics can be adjusted by changing the physicochemical properties of the polymer and thus they can be used for different delivery systems (Alexis et al., 2010).

Polymeric nanoparticles may cause tissue damage depending on the toxicity and dosage of the polymer by accumulating in certain parts of the body. However, polymeric NPs are the most preferred NPs in drug delivery/targeting systems and cancer treatment due to their higher biocompatibility, lower immunogenicity and toxicity, biodegradability, easy preparation methods and surface functionality (Nahar et al., 2006). Drug delivery systems can be adjusted as controlled, delayed or triggered release from these particles. Some polymer based nanosystems such as Oncaspar® (pegaspargase) that is L-asparaginase modified by covalently conjugating units of mono methoxy polyethylene glycol (PEG) to treat acute lymphoblastic leukemia, Opaxio™ (paclitaxel poliglumex) that links paclitaxel active ingredient to a biodegradable polyglutamate polymer for lung cancer and ovarian cancer treatment and also Livatag, NKTR-102, Taxoprexinare approved by FDA and available in the market or on phase 3-4 trials as shown in Table 1.

The surface of the polymer particles can be functionalized with various methods. Hydrophilic polymers such as polyethylene glycol (PEG), dextran and chitosan are most widely used polymeric NPsdue to their stable surface and their high availability of functional groups to be conjugated, grafted or absorbed to other surfaces and bioactive molecules. Thereby, circulatory half-life of the bioactive molecules is increased and hepatic uptake is reduced (Alexis et al., 2010). Not only drugs which have low molecular weight but also therapeutic agents such as nucleic acids, genes, proteins and peptides can be carried with polymeric NPs. Functional groups on the particle and the surface charge have a great importance for avoiding the phagocytic system cells (Yang et al., 2009). Positively charged particles are taken into the phagocytic cells more than the neutral and negatively charged particles (Alexis et al., 2008). Properties which directly affect the treatment such as circulation half-life and release rate can be arranged as requested by adjusting functional groups on the particle and surface charge (Karmali & Simberg, 2011; Fadeel, 2012; Zaki et al., 2011).

Table 1. Selected nanoparticle-based therapeutics approved by FDA or in clinical trials in cancer treatment

Nanoparticle Type	Product Name	Company	Active Pharmaceutical Ingredient	Situation	References
Biological NPs	CALAA-01	Calando Pharmaceuticals	siRNA	Phase 1b	(Yu et al., 2012)

Liposomal Nanoparticles

Liposomes are artificial spherical vesicles that allow encapsulation of drugs in liquid phase owing to their lipid bilayer structure with sizes varying between 50 nm – 5 μm (Malam et al., 2009). Hydrophilic drugs are transported in the center of liposome whereas hydrophobic drugs are transported within the lipid bilayer (Sharma & Sharma, 1997) (Figure 2). It was put forward that liposomes could be used in drug delivery systems in the early 1970s (Gregoriadis, 1995). Despite more than 40 years have passed after the discovery of liposomes, liposome based systems still has not been exploited adequately today.

Liposomes are classified as conventional liposomes (CL), pH-sensitive liposomes, cationic liposomes, long-circulating liposomes (LCL) and immune-liposomes according to their structures (Sharma & Sharma, 1997). Liposomes help to increase pharmacokinetics, efficiency and bioavailability, and decrease the toxicity of the drug or bioactive agent in the body because these particles can be adopted to target-driven treatments by functionalizing (Drulis-Kawa & Dorotkiewicz-Jach, 2010). However, their use is limited because liposome NPs are not very stable, and do not always remain in desired site for long periods of time to show the therapeutic effect, although local deposition of the drugs is higher when encapsulated with liposomes since liposomes can be internalised quickly by macrophages and other cells in the body (Hatefi & Amsden, 2002). The drug delivery systems based on liposomes are among the most studied nanoparticles such as Myocet, DaunoXome, DepoCyt, liposomal doxorubicin/Caelyx, Mifamurtide (Mepact), Marqibo (vinCRIStine sulfate liposome) have been approved by FDA among other liposomal medicines in pre-clinical or clinical trials as summarized in Table 1.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 2. Liposomes can be used in dual drug delivery. Hydrophilic drugs are transported in the center of liposome whereas hydrophobic drugs are transported within the lipid bilayer

The basis for properties of liposomes is their lipid bilayer structure which forms hydrophilic space inside. Therefore, the instability disadvantage can be eliminated with appropriate modification of this membrane's internal and external structure (Felnerova et al., 2004). Liposomes should be produced with prudently selected methods to be able to load proper amounts of the drugs and adjust the drug release rate (Koudelka & Turanek, 2012).

Dendrimer Nanoparticles

Dendrimers with hollow internal structure are tree-like nanostructures which have been discovered in the 1980s (Tomalia et. al, 1986 (Dang et al., 2012). Due to their three-dimensional structure which is smooth and highly branched, and easy functionalization of their surface, dendrimers are commonly used in medicine, in host-guest chemistry and as catalysts (Luo & Sun, 2007). Dendritic structure can be examined in four sub-classes, (i) randomly hyper-branched polymers around the inner core structure (ii) dendrigraft polymers, (iii) dendrons and (iv) dendrimers. More than a hundred different dendrimers and more than a thousand different surface chemistries are known (Oliveira et al., 2010).

Owing to properties such as high degree of molecular uniformity, monodispersity and multifunctional surface, dendrimers are distinguished from other linear and branched polymers (Devarakonda et al., 2005). One of the most widely used dendrimers is poly(amidoamine) (PAMAM) dendrimer. PAMAM dendrimers possess important properties such as biocompatibility, non-immunogenicity, water solubility and manipulability of their functional groups for binding to variety of guest molecules (Strydom et al., 2013, Ouyang et al., 2010), and can be used for controlling the release rate and increasing dissolution of the drugs with low water solubility (D'Emanuele & Attwood, 2005). In addition to PAMAM; poly(propylene imine) (PPI), poly-lysine (PLy), arborols (ARB), poly(benzyl ether) (PBzE), polyphenylene (PHEN), thiophosphorylphenoxymethyl (methylhydrazono) (PMMH) are also widely used (Caminade et al., 2005).

It has been shown that dendrimers can be used for theranostic applications as well as drug delivery systems due to their compatibility with many nanostructures such as genetic and/or bioactive materials, fluorescent molecules etc. Despite all the potential, the accumulation, redistribution and the adverse

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

effects to other tissues have not been fully revealed (Oliveira et al., 2010), and there is eminent need for large scale *in vivo* studies.

Protein Nanoparticles

Proteins can be used as drugs themselves as well as carriers for drug delivery systems since they are biodegradable, non-antigenic and can reduce unwanted side-effects. Another distinctive advantage of protein NPs is their functional diversity (Vázquez & Villaverde, 2010).Desired proteins can be produced easily by using classical biotechnological methods or recombinant technologies by macro/microorganisms. Although studies on protein nanoparticles have accelerated relatively recently, there are some nano-systems such as Abraxane, Oncaspar and ABI-008 that are FDA approved or are ongoing phase trials as shown in Table 1. Their biocompatibility is high because these protein NPs are synthesized using biological building blocks like amino acids and peptides, and toxic chemicals are not used in provision.

Protein-based drug-loaded NPs produced by albumin have received FDA approval and have been used in clinical applications for some time (Pazdur, 2012; Elzoghby et al., 2012). Enhanced permeability and retention (EPR) effect has an important role for accumulation of albumin in tumor site. The EPR effect, a universal phenomenon in solid tumors, is the property by which certain sizes of molecules (typically liposomes, nanoparticles, and macromolecular drugs above 40 kDa, even larger than 800 kDa) tend to accumulate in tumor tissue much more than they do in normal tissues (Maeda et. al., 2009). On the other hand, some studies show that albumin has a tumor targeting ability by using special pathways to overcome the endothelial barrier in biological environment (Alexis et al., 2010).

Protein-based NPs produced by protein engineering can minimize the toxicity of solvent-based systems. Hydrophilic drugs may be directly toxic when they are given into the body because of their solubility in the water. Protein-based NPs allow loading hydrophilic drugs into hydrophobic formulations (Hawkins et al., 2008).

Polymersome Nanoparticles

Polymersomes are self-assembled vesicles and synthetic amphiphilic block copolymers, like natural phospholipids and liposomes (Discher, 1999; Sachsenhofer et al., 2007). Although they have similar structure to natural membranes, properties of polymersomes are quite different than the liposomes. To exemplify, their weight, mechanical and thermal stability is higher than those of biological lipids (Sachsenhofer et al., 2007). In addition, polymersomes possess lower permeability compared to liposomes; and the chemical composition, structure and sizes of polymersomes can be changed by adjustment of the block copolymers (Amstad et al., 2012).The size and shape of the polymerosomes directly affect their pharmacokinetics and bio-distribution properties. Under 10 nm, they can be quickly cleared in capillary beds and lymph nodes, while those above 200 nm are rapidly removed from circulation *via* splenic filtration (Ho & Shoichet, 2013). In addition to removal from the body, polymerosomes' shape and size also affecttheir degradation and release behavior, transportation in the body, targeting ability, uptake by immune cells or the targeted cells, thus biocompatibility (Champion et al., 2007;M. Anderson et al., 2008).

Owing to their amphiphilic structure, they can be loaded with hydrophilic and hydrophobic molecules at the same time and targeted toward desired cell types (Surovtseva et al., 2012). The hydrophilic molecules are captured in the core and hydrophobic molecules in their thick bilayer membrane (Amstad et al., 2012). The specific structure of polymersomes allows theranostic drug carrier systems that include

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

both water soluble and insoluble substances such as therapeutic and imaging agents together (Levine et al., 2008). Additionally the surface of polymersomes can be modified by specific biological molecules for targeting the desired tissue sites (Johnson et al., 2011).

Inorganic Nanoparticles

Although it is possible to produce organic nanoparticles such as liposomes, polymersomes and polymeric nanoparticles to design nanoscale drug delivery systems, and many of them are in clinical and preclinical stages, the research on inorganic nanoparticles increase day by day because of their unique optical, electrical, magnetic, and/or electrochemical properties (H. C. Huang et al., 2011). The biological delivery systems (viral carriers) are the most effective carriers for drug delivery, but they tend to cause immune response or mutagenesis so that the success of the cellular delivery of these systems is low. Liposome and polymersome based devices may prevent these problems, but they are often instable and may show toxicity to the cells. Owing to their low toxicity and highly controllable release rates, inorganic nanoparticles are alternatives to organic nanoparticles (Z. P. Xu et al., 2006; Mironava et al., 2013).

Metallic nanoparticles such as gold, silver, iron, titanium, platinum etc. have been used for medical applications like imaging, targeting and treatment of cancer. Easy control of their shape and size, as well as their easy surface functionalization are the main advantages of inorganic nanoparticles as compared to organic nanoparticles (Son et al., 2007).Generally super-paramagnetic iron oxide nanoparticles (SPIONs), due to their magnetic properties and gold nano-vehicles due to their high X-ray absorption coefficient have been widely used as contrast agents. Also SPIONs and gold nano-vehicles can be used in hyperthermia and photothermia treatment where these inorganic particles are heated selectively by application of an external high frequency magnetic field, microwave irradiation, radiofrequency pulses or ultrasound waves leading to thermal destruction of the tumor when targeted effectively. Metallic nanoparticles can also be used in drug delivery systems, but recently other applications are more popular than drug delivery because loading of the drugs on inorganic NPs is more difficult and laborious. However certain gold nano-systems such as Aurimmune (CYT-6091), AuroLase, Auritol and some SPIONs like AntiEpCAM have been used for treatment.

Silver NPs have unique thermal, electrical, optical and antibacterial properties, and they are investigated for diagnostic and conductive applications such as biosensors, imaging and antibacterial dressings. Although known and used for quite a long history, there is still active debate on toxicity and biocompatibility of silver. Titanium dioxide NPs have interesting dielectric and optical properties, and they are also tested as drug eluting vehicles and in photodynamic therapy where these normally non-toxic, light-sensitive particles are exposed selectively to light, whereupon they become toxic to targeted malignant and other diseased cells (Moreno-Vega et al., 2012).

In addition to metallic NPs, quantum dots (Qdots) and carbon nanotubes are also among the most studied nano-systems. Solutions of Qdots of varying size have different color, and the variation in optical absorption each solution illustrates the particle size dependence for each sample (L. Wang et al., 2010; Pathakoti et al., 2013). Qdots can be used both in *in vitro* diagnostics and in imaging systems due to their specific absorption properties.

The selection of nanoparticles intended for medical applications is very imported. In most cases, toxicity is the more important criteria for the selection if the particles will be used especially in vital systems such as central nervous systems (Suh et al., 2009).To exemplify, although Qdots possess very specific optical features, they cannot be used widely in treatment of diseases because of their Cd/selenide

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

core which are very toxic for mammalian cells. In addition to particle chemistry, researchers must also account for other properties of the particles such as geometry, size, dose, surface area and aspect ratio to select the most appropriate delivery system for distribution of the therapeutic agent with minimum adverse effects. For example, many studies specify that size of CNTs' is one of the most important reasons of their toxicity. With increased fiber size, clearance of CNTs by macrophages becomes harder. The surface properties also affect the uptake of CNTs to the cells, their interactions with cell surface molecules and the signaling pathways (X. Zhao & Liu, 2012).

Other Biological Nanoparticles

Some unicellular microorganisms including bacteria with different shapes and sizes are also classified as biological nanoparticles. The different sizes of microorganisms are useful for encapsulating both hydrophobic and hydrophilic molecules. Although biological nanoparticles have been investigated more recently than the other types of NPs, there are some biological nano-systems such as CALAA-01, SGT53-01, ALN-VSP, ABI-009, ASG-22ME on phase 1 trials.Despite some studies carried on animals verify that these nanoparticles show no significant toxicity, there has been a potential for immunological response because of the containment of the microorganism specific lipo-polysaccharides. In addition to unicellular microorganisms, bio-based nanoparticles comprise many agents such as DNAzymes (catalytically active DNA molecules), short interfering RNAs, antisense oligonucleotides, aptamers (oligonucleic acid or peptide molecules that bind to a specific target molecule) and ribozymes (an RNA molecule that is capable of performing specific biochemical reactions). They possess ability of silencing non-desired genes with appropriate design (L. Zhang et al., 2012). In order to obtain an effective medicine for tumors, short synthetic nucleic acid nanoparticles may be designed for the targeted therapy of the genes associated with the disease (Fuessel et al., 2007).

Radiotherapy aims to kill the cancer cells by ionizing radiation and also by regulating the genes that provide resistance to radiotherapy (Ghisolfi et al., 2012). However in many cases, radiotherapy, as well as chemotherapy cannot achieve the success for the treatment due to the presence of cancer stem cells (CSCs) which play a key role in cancer recurrence and resistance (Clarke & Fuller, 2006). It is possible to prevent the development and growth of the cancer cells and even CSCs by using these biological gene silencers. For the most effective treatment, gene silencing and radiotherapy can be used simultaneously. In this case the therapeutic agents can silence the genes that are responsible for radiation resistance and stop the proliferation of the cancer stem cells. Concurrently, radiotherapy may kill the cancer cells that are present in the tumor sites.

3. NANOPARTICLE TOXICITY AND SAFETY

Developments in nanotechnology also caused an increase of concerns about nanotoxicity. Especially the adverse effects caused by nanoparticles on healthy cells must be the priority interest. For this reason, there are many toxicology studies for each type of nanoparticles. *In vitro* toxicity assays used in these studies are different from each other, and their results may sometimes be controversial. European Commission supports Joint Research Center (JRC) Institute for Health and Consumer Protection for safety assessment of nanomaterials, particularly for developing methods for detection of nanomaterials in food and consumer products, validation of analytical methods for nanomaterials and developing standardised

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

protocols for toxicity testing (www.jrc.ec.europa.eu). A forty seven institute consortium FP-7 Project, MARINA, Managing Risks of Nanomaterials, aims for integrated and intelligent testing, integrated assessment, and modular interconnection of knowledge and information for validated science-based risk management methods (http://www.marina-fp7.eu/). NanoLINEN is another consortium of seven European laboratories and Indian Institute of Toxicology Research (CSIR Laboratory) from India to strengthen the research ties in the area of Nanomaterial Toxicology. The goal of this project is to develop robust risk assessment methodologies that will be useful for the community manufacturing and using nano-products (http://www.nanolinen.org/).

Some of toxicity tests which can be used for a variety of different nanoparticles include;

- **Morphological Changes:** Light microscopy.
- **Cell Viability and/or Cell Growth:** Neutral red assay, Trypan blue, Calceinacetoxymethyl / ethidiumhomodimer, Lactate dehydrogenase, Tetrazolium salts (MTT, MTS, XTT, WST), Resazurin or Alamar blue, Propidium iodide, (Choi & Wang, 2011).
- **Celldeath:** Lactate Dehydrogenase (LDH) assay.
- **Apoptosis/Necrosis:** Acridine orange/ethidium bromide, Propidium iodide, Caspase-3 activity, DNA laddering.
- **Oxidative Stress:** Levels of reduced (GSH) andoxidized (GSSG) glutathione, superoxide dismutase (SOD), glutathione peroxidase (GPx), catalase (CT), ROS production, Vitamin E, levels of lipid peroxidation, DCF assay.
- **Visualization of Intracellular Localization:** Transmission electron microscopy.
- **Cellular Uptake:** Radiolabelled nanoparticles.
- **Genotoxicity:** *In vitro* micronucleus test, *Allium cepa* chromosome damage test.
- **DNA Damage:** Comet assay.
- **Cytotoxicity:** Colony forming efficiency test.
- **Hemolysis:** Hemoglobin estimation.

Nano-vehicles should be fully characterized and tested in order to pass judgment on toxicity. Different test methods, surface modifications, nanoparticle size, shape, dose, surface charge, targeted cells, organisms, and route of administration may obtain different results on toxicity. For further details on nanotoxicity issues, Won HyukSuh et al. 2009 can be referred for a wide analysis about titanium dioxide (TiO_2), iron oxide (Fe_2O_3), silicon oxide (SiO_2) and cerium oxide (CeO_2) nanoparticles and Xingchen Zhao and Liu 2012 is recommended for the effects of different carbon nanotubes on different mammalian organisms and cell lines (Suh et al., 2009; L. Zhao et al., 2011). Although the toxicity caused by characteristic features of different nanoparticles may be diverse, it is possible to generalize the factors which influence the toxicity as follows:

- Increasing the surface area of nanoparticle increases the toxicity significantly more than increasing nanoparticle mass (Stoeger et al., 2006).
- Nanoparticles smaller than 100nm are more successful in drug delivery but these particles lead to more side effects related to respiration compared to larger particles (Donaldson & Stone, 2003).
- Whether nanoparticles are biodegredable or not does not seem to have a significant effect on toxicity. It is possible to do the classification from less toxic toward the most toxic as: (i) biodegradable and larger than 100 nm, (ii) non-biodegradable and larger than 100 nm, (iii) biodegradable and

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

less than 100 nm and (iv) non-biodegradable and less than 100 nm nanoparticles (Keck & Muller, 2013).

- The geometry of nanoparticles may play an important role in nanoparticle toxicity. For example, although single walled or multi walled carbon nanotubes and nano-60 fullerenes are both based on carbon, their toxicity is not the same *in vitro*(Sanvicens& Marco, 2008).
- Generally high concentration of NPs show less toxic effects than low concentration of NPs, because higher concentration of NPs often cause formation of aggregates (Gurr et al., 2005).
- Surface modifications of inorganic nanoparticles can also affect their toxicity (Sanvicens & Marco, 2008).
- Even allotropes of the same material can cause different toxic effects on same organism. For this reason, the chemical structure and crystallinity are highly effective on the toxicity (Buzea et al., 2007).
- Generally it has been strived to form less toxic particles by coating the material surface with various biocompatible polymers. However, in the end it may end up with higher toxicity when the interactions of coating materials with other factors are not known.
- High aspect ratio indicates higher toxicity, because macrophages are unable to phagocytose long fibers (Hoet et al., 2004). Some long fibers break transversely when they degrade in the body and they can be cleared by phagocytosis, but some long fibers such as asbestos break longitudinally and they cannot be cleared by phagocytosis (Oberdörster, 2002).

4. MAJOR CANCER TARGETS FOR NANOPARTICLE SYSTEMS

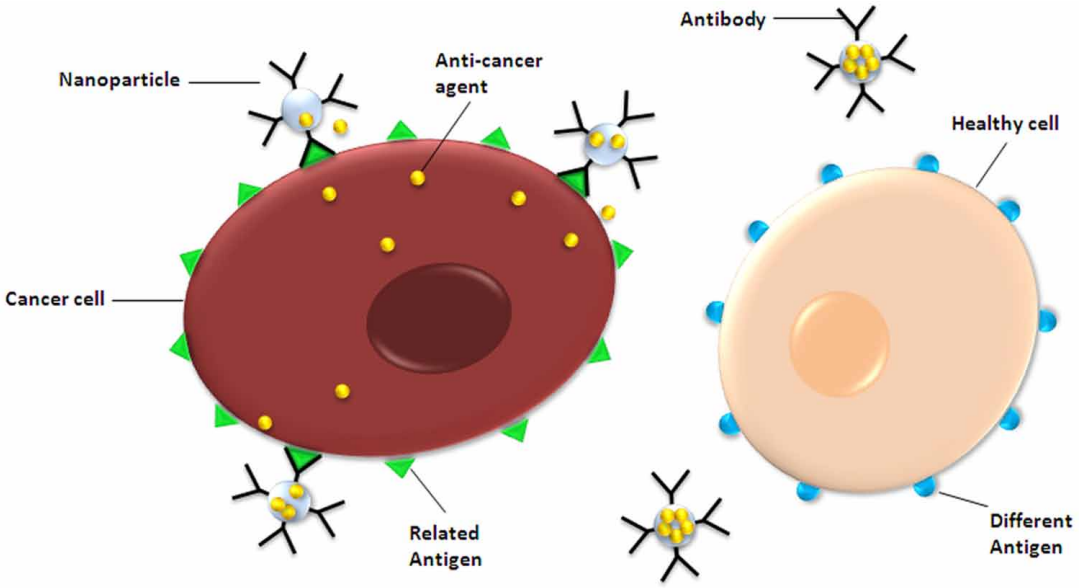
The recovery rate has not increased significantly on cancer patients in the last twenty years in spite of all the advances in tumor biology, cancer biomarkers, surgical procedures and chemo-radiotherapy. Early diagnosis, pathological characterization of the tumors and personalized treatments are substantially candidates to improve recovery rate figures. Negative side effects on healthy cells, especially rapidly dividing cells besides the tumor cells, are the major problem of conventional therapy methods. Researchers have been investigating new therapy methods that specifically target only tumor cells to overcome this problem.

Targeting systems can be examined in four groups;

1. Cell marker targeting,
2. Signaling pathway targeting,
3. Micro-environment (niche) targeting, and
4. Angiogenesis associated targeting.

The best target for the treatment of cancer cells is the molecules which are found in cancer cells but not found in normal cells. However, in practice, this approach is not possible sincecancer cells actually evolve out of normal cells, and therefore, there are no clear distinctive markers. Some of the more commonly synthesized molecules in cancer cells compared to normal cells are considered good targets for therapy. A greater number of cancer cells can be damaged with adjusting the dosage of chemotherapeutics that target these molecules in comparison with conventional therapies.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use



Cell Marker Targeting via Antibodies

An antibody (Ab), also known as an immunoglobulin (Ig), is a large Y-shaped protein produced by B-cells and used by the immune system to identify and neutralize foreign objects such as bacteria and viruses. The antibody recognizes a unique part of the foreign target, called an antigen. The cell membrane contains many surface and trans-membrane molecules such as peptides, proteins, saccharides, antibodies and glycoproteins. Some of these molecules are specific for particular cell types, and can be targeted effectively with monoclonal antibodies for therapeutic purposes. Some surface antigens synthesized by cancer cells are different from normal cells and this circumstance is an important opportunity for targeting *via* antibodies. The main scheme of treatment of cancer by targeting these specific molecules is to attach the nanoparticles only on the cancer cells by integrating these surface markers or affinity molecules to tumor cells, or the molecules that increase the uptake of the nanoparticles into the targeted cells (Figure 3).

Specific antibodies are produced by injecting an antigen into a mammal, such as a mouse, rat, rabbit, goat, sheep, or horse for large quantities of antibody. Monoclonal antibodies (mAb) are monospecific antibodies made by identical immune cells that are all clones of a unique parent cell, in contrast to polyclonal antibodies which are made from several different immune cells (Binyamin et. al., 2006).

Cancer cell signaling pathways are affected by the use of monoclonal antibodies in various ways. Antibodies can be used to prevent communication between the signaling molecules and their receptors. Human tumors express high levels of growth factors and their receptors, and many types of malignant cells are stimulated by these signal molecules. In anti-receptor directed therapies, antibodies targeted

Figure 3. The main scheme of treatment of cancer by targeting via antibodies is to attach the nanoparticles only on the cancer cells by integrating the surface markers (or affinity molecules to tumor cells or the molecules that increase the uptake of the nanoparticles to the targeted cells) that are specific to the cancer cells on the nanoparticles.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

by nanoparticles are bound to cell surface receptors and block their interaction with signal molecules (Baselga& Mendelsohn, 1994; Hicklin et. al., 2001; Capdevila et. al, 2009). MAbs directed against epidermal growth factor (EGF), transforming growth factor (TGF), G-protein, fibroblast growth factor (FGF), IL-2, andIL-6 receptors are examples of this approach. Antibodies can also be used as a vehicle for delivering the chemotherapeutic agents to the tumor sites (Adler &Dimitrov, 2012; Perche et. al., 2012; Cirstoiu-Hapca, 2010). They can damage the targeted tumor cells by releasing their chemotherapeutic agents locally. Another promising approach is to target tumor cells by antibodies that trigger immune response to destroy the cells by body's own defense mechanisms (Miller et al., 2002).

In recent years, targeting studies with surface markers are engineered to target cancer stem cells (Hu & Fu, 2012; Wicha, 2009). For a long time researchers believed that every cancerous cell has the potential to excessively proliferate and regenerate a tumor in consequence of internal and external factors that cause mutations. This model has been called as stochastic model (Wicha et al., 2006; C. Tang et al., 2007; Shackleton, 2010; Chen et al., 2012). Numerous contemporary studies indicate that the formation of tumor depends on the differentiation of a relatively rare cell groupstermed as cancer stem cells (CSCs)due intrinsic and extrinsic inducement (Hanahan& Weinberg, 2011; Clarke & Fuller, 2006; Dean et. al, 2005). The functional capabilities of CSCs are associated with normal stem cells such as the high ability for self-renewal, the capacity to differentiate, active telomerase expression, activation of anti-apoptotic pathways, increased membrane transport activity and immense potential to migrate and evolve (Wicha et al., 2006). Eliminating these cells is very difficult by conventional methods due to their immense resistance to chemotherapy and radiotherapy. Consequently, CSC targeted therapies are escalating fast in literature, and they hold great promise in cancer treatment.

Monoclonal antibodies have some limitations even though they have effective potential in targeted therapies. The most important limitation is that, the antibodies can be used primarily to target surface molecules because they are large proteins and they cannot pass the cell membrane easily. Other main limitation is that different cancer cells possess different markers, and same marker can be found also on some healthy cells causing significant toxic side effects. At present, there is insufficient number of recognized markers and deficient knowledge on them. Antibodies derived from animals can sometimes cause immune reactions. Antibody fragments containing only the variable region of the antibody can also be used for active targeting for less immunogenicity. They retain the specificity for the target, while they result in less foreign body reaction or undesirable interaction with other cells (Byrne et al., 2008).

Targeting Signaling Pathways

Signaling (or signal transduction) pathways are the cascade processes existing in the cells to perform specific cellular tasks. For example, a cell needs signaling molecules and pathways that are activated by these molecules to grow and divide. The signal molecules, including growth factors and inhibitors, must be attached to receiver cell's surface receptors for activation of the signaling pathway (Cho et al., 2007; Lee et al., 2013). When the signaling pathway is activated, the information that comes from receptor reaches into the cell, may even be delivered to DNA. Activation of the signaling pathways leads to accumulation of proteins that are inhibiting or activating the cell response. The amounts of proteins which stop and start cell division are under control in normal cells. On the other hand, the amount of the activator molecules and proteins that promote the cell proliferation are increased in cancerous tissues. Therefore, the inhibition of the aforementioned pathways has a high potential for preventing the uncontrolled proliferation of cancer cells (Kelleher et al., 2012). The main purpose of targeting signaling

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

pathways are blocking a molecule in the pathway to stop interaction with other molecules and thus blocking the signal transduction (Leonarduzzi et al., 2010). For instance, targeting of the Mitogen Activated Protein Kinase (MAPK) pathway has a potential for therapy since the dysregulation of this pathway is observed in many cancer types (Wancket et al., 2012). The MAPK pathway is controlled by a complex cascade mechanism through extracellular signals in normal cells. Disruption of this pathway leads to increased cell proliferation, angiogenesis, metastasis and increased cell survival, thus cancer development (R. Xu et al., 2011). The biggest problem in the MAPK pathway inhibition is that, pathway has several signal molecules that activate this pathway, and other signal molecules can activate the pathway even if a specific molecule is inhibited (Lugli et al., 2006). Several studies have shown that more than one signal protein and/or pathway must be targeted simultaneously. The chemical agents are given to the patient orally or intravenously in conventional methods, where the agents can be inactivated before showing any therapeutic effect since they are passing through different compartments in the body such as the gastrointestinal tract. On the other hand, drug doses must be very high to show the desired effect since the drug is distributed throughout the entire body, and inhibition without targeting increases the side effects (Diaz-Moralli et al., 2013). Nanotechnology is used to overcome these problems as it allows the production of multifunctional transport systems that can implement multiple genetic and pharmaceutical agents (Nair et al., 2010). The surface of the nanoparticles can be functionalized with molecules that inhibit signal pathways as well as with chemotherapeutic agents targeting other schemes. The most effective treatment method will emerge when different targeting systems are used in a single nanoparticle. There are several options for pathway selection, including Notch signaling pathway and mitochondrial signaling pathways to overcome drug resistance, phosphoinositide 3-kinase (PI3K) pathway and nuclear factor-κBto induce apoptosis in tumor cells, transforming growth factor-β signalling pathway to attack promotion of tumor growth, invasion and colonization of secondary organs, phosphatidylinositol 3-kinase (PI3K)/Akt pathway to suppress angiogenesis, etc. Recently, targeting apoptosis pathways in cancer stem cells is also under investigation (Signore et. al., 2013; Fulda &Pervaiz, 2010)

Niche Targeting

The local microenvironment, or niche, of a cancer cell plays important roles in cancer development (Hu & Polyak, 2008). Thereby, targeting tumor microenvironment is another commonly used method for targeting studies for cancer therapy, and particularly metastasis prevention (Joyce, 2005). The microenvironment of the cancer has a direct effect on life and behavior of the cancer cells. Cancer cells are fed by the niche and the exchange of necessary molecules can be mediated through this microenvironment. Extracellular matrix (ECM), an important part of the cell niche, contains components such as collagen I-III-IV, decorin, hyaluronan,versican, fibronectin, laminin and osteonect in that can contribute to developing of tumor resistance to chemical agents (Ioachim et al., 2002; Sung et al., 2005). For example, laminin and fibronectin was shown to provide resistance to apoptosis while collagen I-III-IV, versican and osteonectin increase the proliferation of tumor cells (Whatcott et al., 2011).

Desmoplasiais defined as the formation and proliferation of fibroblasts and fibrous connective tissue, especially in solid tumors. Desmoplasia causes a significant increase in the synthesis of ECM proteins (Walker, 2001), preventing perfusion of chemotherapeutic agents. In order to overcome the chemoresistance, targeting of these ECM proteins has a very high potential. For example, hyaluronan, which is a component of ECM and provides protection of connectivity and rigidity of connective tissue, is over-produced in tumor cells due to desmoplasia. Excessive hyaluronan concentration in ECM causes

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

increased interstitial fluid pressure and limits entrance of any substance from outside (Whatcott et al., 2011). Chemo-resistance may be reduced by targeting hyaluronan viahyaluronansynthetase inhibitors or through destruction of these molecules by enzymes such as hyaluronase.

The slightest alteration -even a single amino acid replacement- in the components of ECM generates variations in the physicochemical properties of the tissue and also leads to changes in the cellular phenotype and cell-matrix relations. It has been shown in various studies that ECM is needed to protect the structure and polarity of tissues. ECM components of cancer cells differ from normal tissues. Abnormal ECM also influences cancer development indirectly *via* influencing stromal cells' behavior including fibroblast cells, immune cells and endothelial cells. These stromal cells continue synthesis of the abnormal ECM creating the appropriate microenvironment for migration of cancer cells and formation of new vessels(Y. Tang et al., 2005). ECM also has an important role in reaching of the cancer cells to surrounding capillaries and lymph nodes. Local tumors constitute appropriate microenvironment by imposing necessary changes in the ECM in order to maintain their survival. Most of the tumor cells die when they leave their microenvironment, a type of apoptosis called *anoikis*. Therefore, it has been a subject of curiosity how the metastatic cancer cells can adapt and continue to live in other parts of the body. Some studies specify that cancer cells which have receptors for ECM components exhibited a higher survival rate than those without these receptors (Lu et al., 2012). Survival rates of cancer cells can be significantly reduced by targeting these ECM receptors. To prevent the development and spreading of cancer, multiple ECM components can be targeted with appropriate nano-tools.

Angiogenesis-Associated Targeting

All living cells in the body need oxygen and nutrients in order to survive. For this reason, all the living tissues are nourished with capillary blood vessels. Since the cell division in tumors is faster than normal physiological conditions, the capillaries become insufficient for the expanded tumor size. Cancer cells often secrete particular growth factors tore-model the ECM and form a suitable microenvironment to trigger the sprouting and growth of new capillary blood vessels (Chatelain et al., 2011). This phenomenon is defined as angiogenesis, and it is vital for tumor tissue to grow and reach its maximum extent (Nishida et al., 2006). The blood vessel cells (endothelium) only divide about once every 3 years, and do not form new capillaries in normal tissues when they are in a quiescent state. However, they are activated within the tumor site and they form new capillaries due to these secreted angiogenic factors within (Liekens et al., 2001).Once activated, these endothelial cells begin to divide at an accelerated pace and also secrete matrix metalloproteinases(MMPs) that degrade the extracellular matrix (ECM) further allowing other endothelial cells to migrate towards the tumor (Petros&DeSimone, 2010).

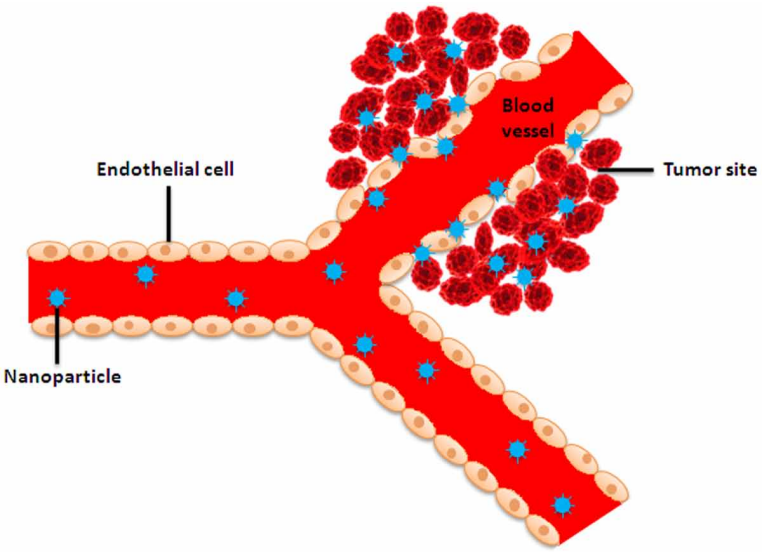
A lot of molecules that promote endothelial growth and the formation of new blood vessels are convenient for targeting angiogenesis for cancer therapy (Makrilia et al., 2009). In tumor tissues, the balance between inhibitors and activators that are present in normal tissues is disturbed; the numbers of activators are increased and the formation of new blood vessels is begun by rapid proliferation of endothelial cells. Rapid vascularization also helps metastasis, as the cancer cells find more chance to enter the blood stream. Even when the tumor is removed or destroyed by means of any therapy, the cancer has high risk of recurrence (and/or metastasis) due to these cancer cells that had already entered the circulatory system. The prevention of tumor vasculature before the tumor reaches the critical size is crucial (Bjerkvig et al., 2009). Developments in nanotechnology and discovery of molecules that are capable of inhibiting angiogenesis have led to a boost in studies targeting angiogenesis. Some of these

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

studies include targeting molecules and pathways that cause the alteration on the extracellular matrix structuring which provides appropriate environment for the formation of new vessels. Another approach is targeting angiogenesis activators or sending angiogenesis inhibitors directly to the tumor site. The most important criterion to achieve success is detection of the primary tumor before reaching critical size for metastasis. Nanotechnology offers important opportunities for early diagnosis and treatment of the tumor. There are many proteins including vascular endothelial growth factor (VEGF), basic fibroblast growth factor (BFGF) and platelet-derived growth (PDGF) that promote angiogenesis (Ishihara et al., 2002; Li et al., 2006). It has been shown that the installation of the nanoparticle delivery systems with the inhibitor antibodies to these growth factors improve both accumulation of the nanoparticles in the tumor tissue and toxicity of the anti-cancer drug on the tumor cells. The treatment of the tumor by targeting multiple angiogenesis activators along with other anti-cancer drug will ensure the most effective cure.

5. TARGETING SCHEMES

The effectiveness of vehicles used in cancer therapy is measured by their ability to eliminate tumor cells without harming healthy tissues (Byrne et al., 2008). Multi-drug resistance, exposure of the entire body by the treatment and related side effects, insufficient efficacy levels of the drugs given orally or viasystemic circulation due to different parameters such as pH of different body compartments, and the increasing number of cancer patients force researchers to discover alternative therapies. Nanotechnology, by enabling specific targeting to the affected area, offers great opportunities for the elimination of these problems. For instance, the targeted chemotherapeutic agents with pH-sensitive nanoparticles may remain intact until getting into the area of the appropriate pH. Heat-sensitive nanoparticles enable elimination of unwanted cells by generating local heat by external forces such as magnetic field when they reach the desired location (Yu et al., 2012). Although there is a large amount and variety of nanodevices under investigation, the number that received FDA approval and can be used in the medical field is very small (Alexis et al., 2010). Nanomaterials produced for cancer treatment should have several additional properties such as high selectivity, high penetration ability, multi-functionality, appropriate pharmacokinetic and pharmacodynamics characteristics, therapeutic and diagnostic properties, high biocompatibility, causing low immune response, high physical and chemical stability (Chopra, 2011; Rani et al., 2012). Nanotechnological therapeutic devices that are implementing several of these parameters will provide glorious change in the development of new cancer therapeutics (Swami et al., 2012).



There are three basic methods used to target the nanoparticles to desired tumor sites; *passive targeting*, *active targeting* and *triggered targeting*. In order to develop the most efficient system, these methods used for diagnosis and treatment of cancer must be analyzed thoroughly, and combinations of the three methods may also be used for improved success.

Passive Targeting

Owing to their size, NPs can accumulate in many tumor tissues several times higher than other parts passively *via* the *enhanced permeability and retention* (EPR) effect (Maeda et al, 2009;Wu et al., 2006). This accumulation is a non-selective process that occurs due to "leaky," underdeveloped tumor vasculature that allows macromolecules of a certain size range to accumulate in the tumor(Figure 4).The gap junctions between adjacent endothelial cells in tumor tissues are much larger than those in normal blood

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 4. NPs can accumulate in many tumor tissues at several times higher rates than other parts of the body passively via the enhanced permeability and retention (EPR) effect due to "leaky," underdeveloped tumor vasculature

vessels (Kazuo, 2011). The macromolecules can exit the circulation owing to the leaky vasculature, but remain at the tumor site as a result of impaired lymphatic drainage properties (Petros & DeSimone, 2010; Wang & Thanou, 2010; Mousa & Bharali, 2011; Sailor & Park, 2012).

There is no need for specific biomarkers in passive targeting (Rani et al., 2012; Danhier et al., 2010). The structure of the blood vessels supplying normal tissues is very tight and permeable for particles smaller than 10 nm. In contrast, the blood vessels that feed the tumor tissues lose their tight structure and become permeable as their pore dimensions become 100 nm – 1 μm (Emerich & Thanos, 2006; Cole et. al., 2011). Using these features, drug loaded nanoparticles can be sent to tumor site by the circulatory system and accumulate without needing any cell surface markers; thereby, sufficient amount of medication can be sent to the tumor site without giving high doses of medications to the patients (Kim et al., 2011; Sailor & Park, 2012; Swami et al., 2012). The most important points to consider in this method are the size, surface properties and duration of exposure in the circulation of the used nanoparticles. The nanoparticle surface must be hydrophilic to be protected from macrophages. If otherwise, this can be achieved by modifying the surface with a hydrophilic polymer. The polymer most widely used for this purpose is poly(ethyleneglycol) (PEG),called 'stealth' polymer (Egusquiaguirre et al., 2012). However, hydrophobic surfaces are more suitable for penetrating into the tumor cells and thus increasing efficiency and efficacy. The dilemma may be solved by functionalizing the nanoparticles with a copolymer which has both hydrophilic and hydrophobic domains (Cho et al., 2008).

It has been shown that positively charged nanoparticles are easily taken up by cells, but they cause immune reactions. Therefore, for clinical applications, neutral or negatively charged nanoparticles are preferred (Gratton et al., 2008).

Particles less than 5 nm are rapidly cleared from the circulation through extravasation or renal clearance. Nanoparticles that are smaller than 100 nm can be phagocytosed by the reticuloendothelial system cells (mainly by macrophages). For larger particles sized in the range of up to few micrometers, accu-

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

mulation occurs primarily in the liver, the spleen and the bone marrow. Spherical particles in100–200 nm size range have the highest potential for prolonged circulation because they are large enough to avoid uptake in the liver, but small enough to avoid filtration in the spleen (Kim et al., 2011; Petros & DeSimone, 2010; Huile et al., 2011).

Nanoparticle degradation rate and duration of exposure in the circulation should be appropriately engineered to increase the effectiveness of treatment and in order for the concentration of nanoparticles in the tumor site reach the desired level.

In addition to leaky vasculature, the acidic conditions of the tumor microenvironment can also be exploited to deliver antitumor therapeutics selectively to the tumor tissues by designing nanodevices to obtain a pH-controlled drug release (Egusquiaguirre et al., 2012; Danhier et al., 2010; Manchun et al., 2012; Shen et al., 2012).

Passive targeting has some limitations; it may not show the same success in each cancer because of the fact that the EPR effect varies depending on the tumor site, tumor size and the patient, and there can even be huge differences in different areas of a single tumor (Jee et al., 2013). The duration that the nanoparticles will stay in circulation intact (half-life)should be long enough and their structures should not degrade or release the therapeutic agent before reaching the target tumor site (Oh et al., 2013).

Active Targeting

When low nonspecific binding and internalization of the drug by the cells is highly desirable, the carrier system must be functionalized by conjugation of receptors to specific ligands, like monoclonal antibodies (mAb), short peptides or RNA aptamers for *active targeting* (Figure 3).The ligands bind to receptors that are overexpressed on the surface of rapidly dividing cancer cells. For example, many types of cancer cells overexpress transferrin and folate receptors due to the high metabolic demands generated by rapid proliferation, and this makes conjugation of transferrin, folic acid or antibodies to these receptors a successful targeting approach for engineered nanoparticles (Petros&DeSimone, 2010). If the targeted receptors activate endocytosis pathways and are present in excess on the surface of tumor cells, the success of the penetration of nanoparticles and thus the success of chemotherapeutic agents are increased (Gary-Bobo et al., 2012).

Most obvious target is the surface markers expressed by the specific cancer cells. There is tremendous amount of literature trying to identify specific markers for these cells (Hu & Fu, 2012; Adler & Dimitrov, 2012). But the main challenge of active targeting tumors is that the cancer cells are often very similar in characteristics to its surrounding healthy tissue, and finding specific markers is troublesome.

Other popular approaches are to target tumor vasculature via vascular endothelial growth factor receptor (VEGFR), $\alpha_v\beta_3$ integrin, vascular cell adhesion molecule-1 (VCAM-1), and to target cell proliferation viahuman endothelial receptors (HER), transferrin (Tf) receptors, and folate receptors, instead of the tumor cells. As these molecules have less phenotypic variations and they are not specific to cancer type, they are easier targets (Kumar & Li, 2001; Byrne et al., 2008; Goel et al., 2011).

There are several biological barriers at the cellular level that an engineered nanoparticle must overcome. For example, the cell membrane blocks diffusion of complexes larger than ~1 kDa. The blood-brain barrier (BBB) is one of the strongest barriers in terms of delivery of cancer therapeutics. The blood-brain barrier is a physiologic obstruction to the delivery of systemic chemotherapy to the brain parenchyma and central nervous system (CNS), since endothelium in the CNS is distinctly different from the vasculature found in the periphery. Passive delivery does not work in CNS malignancies, because

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

the leaky vasculature is not present in CNS, and only highly lipophilic molecules can passively diffuse through BBB to reach CNS. Therefore, nanodevices cannot be accumulated specifically to tumor cells in the brain without the active targeting (Zhan & Lu, 2012; Zhou et al., 2012; Chen & Mitchell, 2012).

Concentration of surface ligands is another parameter in active targeting scheme that affects the ligands' targeting efficiency. Higher ligand densities are used as a method of increasing the probability of nanoparticle interactions with cell receptors (Wang &Thanou, 2010).

The immobilization of the ligands to the nanoparticles is another important parameter of concern since several ligands have three dimensional, tertiary structures. If the immobilization is random, it can alter the ligand's 3-D configuration and reduce or completely block its binding capacity to the target cell. Therefore ligands need to be selected or engineered to bind onto the nanoparticles in a site specific manner in order for their activity to be retained.

Triggered Targeting

Certain nanoparticles can be activated by the external forces for diagnosis and treatment after given to the patient's body owing to their unique characteristics. This targeting type is named *triggered targeting*. Magnetic nanoparticles are used commonly in this targeting scheme and magnetic field is used as the trigger. Magnetic NPs given into the body can be positioned to the desired tumor site by applying external magnetic field (Pradhan et al., 2010).

This method also includes triggering nanoparticles targeted with active or passive methods for drug release with stimulus. Potential stimuli can be electromagnetic or electric fields, pH, solvents, heat, ultrasound, mechanical stress, irradiation and chemical or biological agents. Nanodevices which are sensitive to these stimuli can be reacted by changing their chemical, electrical, optical, superficial or permeation properties (Schmaljohann, 2006). Drugs can be released from heat-sensitive nanodevices within specific temperature ranges. The systems that are designed for higher temperatures than the body temperature are used in this method. After the accumulation of the nanoparticles in the tumor site, this area is heated locally until it reaches the necessary temperature and drug release is provided (May & Li, 2013; Liu et al., 2010). The biggest disadvantage of this system is that, the healthy tissue around the tumor can also be damaged because this region reaches hyperthermia temperature. Therefore, studies are being directed to non-thermal treatment methods. One of the most promising methods is photodynamic therapy, where light-sensitive nanosystems are exposed to irradiation after sent to tumor site. Drug delivery system is activated by irradiation and the drug can be released in a controlled manner (Derycke& de Witte, 2004; Keall, 2011).Using ultrasound sensitive nanodevices is another promising approach (Mo et al., 2012; Paliwal&Mitragotri, 2008).The biggest advantages of triggered targeting are that they do not need any invasive operation and they potentially can overcome the problem of drug resistance since they release the therapeutic agent only in the desired region of the body (Rapoport et al., 2004).

Triggered targeting systems mainly consist of four steps;

1. Giving nanoparticles into the systemic circulation or locally to particular area,
2. Accumulation in the tumor site (actively or passively),
3. Activation of the vehicles by external forces, and
4. Processing to apoptosis of undesired cells (Chatterjee et al., 2008).

Thermal therapies have been used to treat cancer for a long time and are based on killing cancer cells by heating them up to 45°C (Martirosyan, 2012). There are basically two types of thermal treatments; magnetic nanoparticle-based hyperthermia and photothermia. Inorganic nanoparticles used in these systems can be utilized for both tumor imaging and treatment. Gold NPs are good contrast agents due to strongly absorbing and scattering capability in the near-infrared (NIR) region of the radiation spectrum. Absorption band can be adjusted by tuning gold nanoshell thickness, changing shape and size of the NPs. Recently, carbon nanotubes have been also used in photothermal therapy due to their naturally NIR absorption property. Long-wavelength laser irradiation is applied in the body in photothermal therapy and NPs (particularly gold NPs) absorb irradiation and generate heat to kill cancer cells (X. Huang et al., 2006). The efficiency of the treatment depends on nanoparticle concentration and laser power. In order to ensure death of cancer cells without killing normal cells these two criteria should be standardized (Lal et al., 2008).

First attempt to hyperthermia had been done by Gilchrist and his coworkers in 1957 and iron oxide particles were distributed in lymph nodes of dogs and after exposure to alternating magnetic field,5°C increase in temperature was observed. Magnetic nanoparticle-based hyperthermia is based on the heating of nanoparticles under exposure to alternating magnetic field by energy absorbing. However main disadvantage of hyperthermia is that healthy tissues can also be affected because of the nonselective heating (Hilger et al., 2005; Cassim et al., 2009; Johannsen et al., 2010; L. Zhao et al., 2011). Therefore, only cancer cells must be heated by using selective systems such as active targeting. The therapy also can be achieved by not only killing cancer cells but also activating anti-cancer immunogenicity with hyperthermia (L. Zhao et al., 2011). Low pH and hypoxic conditions are more effective for hyperthermia.

Hyperthermia has fewer side effects than chemotherapy and radiotherapy. Hyperthermia increases perfusion and oxygenation, therefore the chemotherapeutic agents are taken into the tumor cells easier and formation of free radicals may be enhanced (Cassim et al., 2009). For this reason, hyperthermia gives better results in therapy if it is used in conjunction with chemotherapy and/or radiotherapy (Martirosyan, 2012). Magnetic properties of the particles, magnetic field strength, frequency of oscillation, and cooling capacity of the blood flow in the tumor site have effect on the extent of temperature rise (Monica Tang et al., 2009). However, heating rate and time should be controlled to avoid damaging of healthy cells.

6. NANOPARTICLE-MEDIATED GENE THERAPY

The main objective in cancer gene therapy is the development of efficient, non-toxic gene carriers that can encapsulate and deliver foreign genetic materials into cancerous cells. This genetic material can inhibit the expression of a specific defective gene or express a normal gene. The classical media for gene delivery is viral vectors, but these have great disadvantages in terms of their safety, immunogenicity, and limited capacity of carrying transgenic materials. Nanotechnology has enabled the development of new, non-viral vectors for gene therapy like cationic polymers such as poly(ethylenimine) (PEI) and poly (L-lysine) (PLL), cationic peptides and cationic liposomes. Yet, these non-viral vectors are less efficient than viral vectors, but they have great promise for improvement (El-Aneed, 2004).

There are four major problems to be solved for success of cancer gene therapy (Scanlon, 2004):

1. Identification of key target genes critical for disease pathology and progression;
2. Identification of the appropriate therapeutic gene to inhibit disease progression;

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

3. Optimal trans-gene expression for suppressing the target gene;
4. Delivery of therapeutic product to the target tissue at an efficient dose.

Small interfering RNAs (siRNAs) are new tools for gene therapy. They silence the expression of specific target genes by mediating RNA interference (RNAi) in mammalian cells. They have demonstrated great potential in cancer therapeutic applications caused by abnormal gene over-expression or mutation (Wang et al., 2010).Chemical modifications as well as nanoparticle conjugation of siRNAs, aptamers, ribozymes, antisense (AS) oligonucleotides (ONs), and microRNAs (miRNAs) are shown to improve the pharmacokinetic and pharmacodynamic properties, reduce immunogenicity, increase target affinity and specificity, decrease susceptibility to nuclease degradation (Singh et al., 2010; Zheng et al., 2012; Lam et al., 2013; El-Aneed, 2004).

As in previous schemes, tumor vasculature is another viable target for gene therapy simply on the basis of anatomical accessibility. Particularly, combination of transductional and transcriptional targeting should allow a higher selectivity against tumor vasculature. Antiangiogenic molecules such as angiostatin and endostatin regulating proliferation of normal endothelium are suitable as therapeutic mediators. Several cytotoxic gene products like ricin and diphtheria toxin can also be targeted and may be used to destroy tumor vascular endothelium directly (Bazan-Peregrino et al., 2007).

7. FUTURE PERSPECTIVES

Nanotechnology is beginning to allow scientists, engineers, and physicians to work at the cellular and molecular levels to produce major advances in life sciences and healthcare. Nanotechnology holds the promise of novel and more effective treatments for serious human health issues. Utilisation of nanoparticles in diagnosis and treatment is becoming widespread, and these particles are en route to become indispensable in the medical arena. The diagnosis and the treatment of diseases can be combined by nanoparticles (*theranostics*). This combinatorial approach provides "point of care" cure without needing repeated treatment steps such as biopsy which damage the patient physiologically and psychologically. Although many nanodevices and production strategies have been produced to date, the challenge still remains in creatively integrating the different functionalities into single full-featured tools.

Another challenge is that, there are no reliable control mechanisms or standards of nanoparticles' biocompatibility. The results may differ from method to method or even from laboratory to laboratory. To achieve the implementation of nanoparticles in clinical or preclinical level studies, international agencies must accelerate focused work on the development of *in vitro* and *in vivo* validation assays as well as standards for production of nanodevices that possess desired properties.

At present, the main cell types that are targeted in the tumor vasculature are endothelial cells and stem cells. However, tumor vasculature also includes pericytes and smooth muscle cells that could be important targets for nanoparticle based drug therapies.

Like normal stem cells residing in a "stem cell niche" that maintains them in a stem-like state, CSCs also require a special microenvironment to control their self-renewal and undifferentiated state. The "CSC niche" is likely to be the one of the most compelling targets in the nanoparticle based treatment of cancer.

Advanced delivery strategies are critical to fully harness the power of RNA and the flexibility of RNA-based therapeutics. The future prospects of RNA-based drugs and gene delivery will require biochemical refinements to minimize off target toxicity and immunogenicity.

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

Each type of nanoparticles has its own distinguishable advantages and disadvantages. Utilisation of individual characteristics of different types of nanoparticles will help improve multifunctional nanotheranostics and development of personalized medicine. Every person has a unique metabolism, genetic background and health history, and is affected differently by the internal and external factors. Therefore, even if each disease has same or similar symptoms, it progress diversely in each individual, and diagnosis and treatment must be performed on the basis of patient's own information. This difference is more prominent in diseases such as cancer caused by body's own cells' mutations and differentiation. Thanks to nanoparticle based personalized approaches it will be possible to develop patient-specific therapies in near future. It is anticipated that the patient's own antibodies can be used and concentrations of drugs and targeting systems may be adjusted according to the individual needs.

The production of controlled, uniform and functionalized nanoparticles and systems are developing very quickly. Comprehensive investigations have been made to overcome existing problems such as toxicity, non-biodegredibility, insolubility, non-effective targeting and more promising results are obtained each day. Future nano-systems will include the necessary tools for both diagnosis and treatment, and they will be activated from outside in order to ensure local and specific treatment. Thus, using unnecessary amounts of toxic chemicals will be prevented. Advanced nano-systems can be engineered to determine pathogen microorganisms and harmful cells that are in motion and they can be incorporated protective and preventive properties supplementary to the body's own immune system.

With an ideal hybrid nano-device, it may be possible to treat different diseases simultaneously and effectively without causing any adverse effect on the patient by efficiently controlling the release rate and concentration of the therapeutic agents. Improved sensitivity and selectivity will allow diagnosis of the disease at a very early stage, or even reveal the disease before it commences. To attain these goals, research groups must be multidisciplinary so that engineers, doctors, fundamental scientists and materials scientists can collaborate.

KEY TERMS AND DEFINITIONS

Cancer: A serious disease generally characterized by uncontrolled proliferation of cells whose metabolic activities are disrupted.

Conventional Therapies: Used to describe traditional cancer treatment methods used in clinic today.

Gene Therapy: A technique that uses genetic modification to treat or prevent disease.

Nanoparticle: A small particle whose two or three dimensions are between 1 – 100 nm.

Nanoparticle Drugs: Drugs or drug delivery systems, which are approved and/or under phase trials.

Nanoparticle Toxicity: The possible threats of nanoparticles to the patients.

Targeted Therapy: A relatively new method for the treatment of diseases by targeting specific organs, tissues, cells, and even biomolecules.

ABSTRACT

Nanomedicine, an offshoot of nanotechnology, is considered as one of the most promising technologies of the 21st century. Due to their minute size, nanomedicines can easily target difficult-to-reach sites with improved solubility and bioavailability and reduced adverse effects. They also act as versatile delivery systems, carrying both chemotherapeutics and imaging agents to targeted sites. Hence, nanomedicine can be used to achieve the same therapeutic effect at smaller doses than their conventional counterparts and can offer impressive resolutions for various life-threatening diseases. Although certain issues have been raised about the potential toxicities of nanomaterials, it is anticipated that the advances in nanomedicine will furnish clarifications to many of modern medicine's unsolved problems. This chapter aims to provide a comprehensive and contemporary survey of various nanomedicine products along with the major risks and side effects associated with the nanoparticles.

INTRODUCTION

Nanotechnology has been proved significantly beneficial to society by producing major advances in areas of energy, food and agriculture. However, the role of nanotechnology in the advancement of healthcare is most promising. Nanomedicine is an application of nanotechnology to healthcare which utilizes improved physicochemical and biological properties of nanoscale structures for better diagnosis and treatment of diseases. Nanostructures usually possess unique properties. They allow the miniaturization of biomedical devices, leading to quicker and integrated operations. Again, nanometer size of these structures permits them to efficiently interact with the biology of living organism. These aspects keep

the promise to render achievements in nanomedicine, resulting in big impact on preventive medicine, diagnosis, therapy and follow-up care.

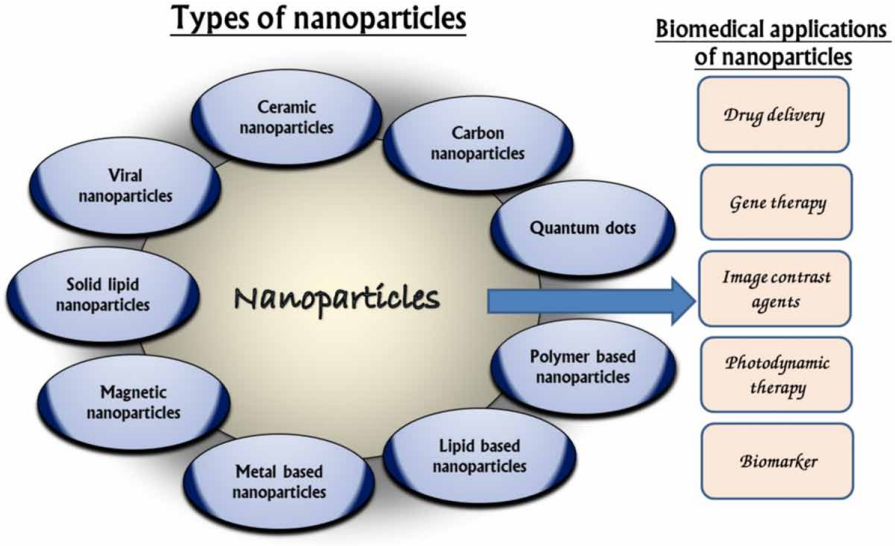
Nanotechnology could provide improved *in vitro* diagnostic tests with more sensitive detection technologies or advance nano-labels detectable with high sensitivity after binding to disease-specific biomarker present in the sample. Moreover, nanotechnology allows size reduction of biomedical lab tests leading to significant reduction of the sample volume, potentially expensive reagents like monoclonal antibodies and most importantly time required. These advantages of nanomedicine in the area of diagnostics render quick and cost effective detection of a disease.

Since last decade, the role of nanotechnology in therapeutics has been studied extensively. Nanotechnology based delivery systems has shown promising results in targeting only diseased tissue and hence increasing the efficacy and limiting the side effects of therapeutics. Moreover, nanotechnology based delivery systems also have the ability to combat with drug solubility, permeability and early clearance issues associated with small molecules and biologics. Multifunctional nano-delivery systems evolved recently have the capability of simultaneous targeting, diagnostic and therapeutic action. Therefore, targeted delivery systems and nanotechnology-assisted regenerative medicine will play the central role in future therapy. This chapter discusses about various nanostructures and their application in diagnosis and therapy of diseases.

NANOSTRUCTURES IN MEDICINE

Nanoparticles are materials with overall dimensions in the nanoscale i.e., under 100 nm and offers exiting prospects for the development of novel, clinically pertinent diagnostic and therapeutic multifunctional systems. In recent years, these materials have emerged as imperative players in contemporary medicine, with clinical applications extending from carriers for drug and gene delivery into tumor to contrast agents in imaging (see Figure 1). Indeed, there are few instances where nanoparticles facilitate analyses and remedies that merely cannot be implemented otherwise. The aim of this chapter is to highlight the major categories of nanoparticles employed in modern medicine and their uses.

Polymer Based Nanocarriers



Polymeric nanoparticles are biodegradable systems in the range of 10-200 nm. Ease of surface modification and ligand functionalization renders them excellent pharmacokinetic control and can be used to deliver a plethora of chemotherapeutic agents.

Polymeric Drug Conjugates

Polymeric nanoparticles comprises of nanosized solid particles or capsules consisting of natural or synthetic polymers such as albumin, chitosan, poly ethylene glycol (PEG) etc. to which the drug is attached. Drug molecule can either be adsorbed or encapsulated on the polymeric nanoparticle structure (Luo et al., 2010; Mora-Huertas et al., 2010) and the release occurs via desorption, diffusion or nanoparticle erosion in target tissue (Torchilin, 2008). Recently Abraxane nanoparticles (albumin bound paclitaxel) have been employed in clinics for metastatic breast cancer treatment (Gradishar et al., 2005). HPMA and PEG are the most extensively used non-biodegradable synthetic polymers (Duncan, 2003). PEG coating

Figure 1. Types of nanoparticles and their biomedical applications

on PLGA (polylactic-co-glycolic acid) nanoparticles have shown to improve their stability (Torchilin, 2005) and stealth properties. These drug-biodegradable polymeric nanocarrier conjugates are non-toxic and non-thrombogenic. They are also non-immunogenic as well as non-proinflammatory, and they neither activate neutrophils nor affect reticuloendothelial system (des Rieux et al., 2006). PLGA conjugates have been widely used as representative chemotherapeutic agents in clinics both *in vitro* and *in vivo* and have displayed encouraging capabilities to evade the shortcomings of their free drug counterparts (Li, 2002).

Polymeric Micelles

Self-assemblage of amphiphilic block copolymers such as poly (ethylene oxide)-poly (β-benzyl-L-aspartate) and poly (N-isopropylacrylamide) polystyrene, in aqueous media results in the formation of a nano-sized core/shell structure documented as polymeric micelles. The outer shell confers stability to the hydrophobic core region which serves as a drug reservoir, thereby rendering the polymers water solubility. Micelles can be readily altered with small functional groups, enhancing their targeting capability and their specific accumulation in pathological tissue is attributed to its small size (Qiao et al., 2010). External stimulus such as pH, temperature, ultrasound etc. can be used to control the drug release (Rapoport, 2007) but low drug incorporation stability and low loading efficiency limits the targeting ability of the polymeric micelles (Yamamoto et al., 2007; Seow et al., 2007).

Dendrimers

Dendrimers are highly branched synthetic polymeric molecules emerging radially from a central core. Dendrimers can be easily customized for optimal activity, mode of action, pharmacokinetics, steadiness and biocompatibility. The precision with which their size and surface functionality can be tuned makes them highly promising nanoscale molecules for pharmaceutical applications. Dendrimers offer colossal scope for solubilization of hydrophobic compounds, and can be readily altered with guest molecules (Yang

EBSCOhost - printed on 2/11/2023 5:31 AM via . All use subject to https://www.ebsco.com/terms-of-use

et al., 2009). The easily malleable surface properties of dendrimers enables their simultaneous conjugation with various molecules such as therapeutic drugs, targeting ligands and/or imaging contrast agents etc., yielding a dendrimers-based multifunctional drug delivery system (Svenson and Tomalia, 2005).

Lipid Based Drug Carriers

Liposome

Liposomes are 80–300 nm size range nano-scale spheres comprising of a lipid layer surrounding the drug (Sunderland et al., 2006). They are spherical vesicles which form simultaneously on dispersion of lipids in aqueous medium. Liposomes have been noted to increase the solubility of drugs and augment their pharmacokinetic properties, such as the therapeutic index of chemotherapeutic agents, fast metabolism, and reduction of deleterious side effects and increase of *in vitro* and *in vivo* anticancer activities. A drug is incorporated in liposomes by the encapsulation process and its release from liposomes depends on the liposome composition, pH, osmotic gradient, and the surrounding environment (dos Santos Giuberti et al, 2011).

Surface modification of liposomes using a biocompatible polymers such as PEG decrease their recognition by macrophages thereby increasing the stability of the liposomal formulations as well as their circulation half time (Torchilin, 2005). Moreover, to promote accretion in the desired destination, liposomes are fabricated with ligands enabling them to identify and bind to precise cell clusters. The herceptin/trastuzumab antibody is employed to target the Her-2 antigen expressing breast cancer cells (Colbern et al., 1999). RGD is utilized to target integrins that are upregulated by proliferating endothelial cells of the tumor vasculature (Lee and Low, 1994). Customized nanoscale liposomes have been indicated to possess excellent pharmacokinetic profiles for the transport of DNA, antisense oligonucleotide, siRNA, proteins and chemotherapeutic agents. First liposomal formulations of the anti-cancer drug doxorubicin were launched under the trade names such as Doxil®/Caelyx® or Myocet® in beginning of the 1990s.

Solid Lipid Nanoparticles (SLNs)

SLN are particles made of solid lipids i.e. Lipids that are solid at room temperature and also at body temperature, (e.g., highly purified triglycerides, complex glyceride mixtures or waxes) and stabilized by various surfactants (Kovacevic et al., 2011). SLN`s possess substantial physical stability, good tolerability, protect the accumulated drug from degrading and act as a meticulous drug delivery vehicle.

PEGylation of SLN`s checks their clearance from circulation by liver and spleen (stealth property) and drug-tumor targeting is assisted by PEG-coated polymeric NPs (Parveen et al., 2012). Stealth SLN escalates the tumor accumulation, augmenting the activity of antiparasitic and antifungal drugs incorporated with the nanoparticles, and also permit brain delivery of anticancer drugs incapable of traversing the Blood Brain Barrier (BBB) (Zara et al., 2002). Thus, these modified SLNs may have great potential for targeted gene delivery (Yu et al., 2010).

Metal Based Nanoparticles
