Chapter 32
Geopolymer Sourced with Fly Ash and Industrial Aluminum Waste for Sustainable Materials

Sujitra Onutai
Nagaoka University of Technology, Japan

Sirithan Jiemsirilers
Chulalongkorn University, Thailand

Takaomi Kobayashi
Nagaoka University of Technology, Japan

ABSTRACT

Geopolymer is alumino-silicate material which can apply for many applications due to that geopolymers have several attractive properties of high strength, low permeability, high acid resistance, hazardous materials, and immobilization of toxic materials. This chapter presents synthesis of the dense and the porous structures of geopolymer by using fly ash and industrial waste as the raw materials. Aluminum hydroxide waste (Al-waste) and fly ash (FA) were used to synthesis the dense geopolymers for cement materials. The Al-waste based geopolymer influenced the geopolymer strength, when sodium hydroxide (NaOH) concentration was changed at different curing temperatures. As preliminary microwave oven was exposed in the lower NaOH paste of geopolymer, the successful synthesis of geopolymer cement was obtained. In addition, porous fly ash geopolymers was achieved using a household microwave oven. The geopolymer paste was cured within 1 min by using a microwave oven at different output power. Porous geopolymers were formed immediately as ued at 850 W power of the microwave oven.

INTRODUCTION

Geopolymers are known as sustainable materials with eco-friendly process, since these simply can use wastes for raw materials, and have excellent mechanical properties (Kumar & Kumar, 2011; Nazari & Sanjayan, 2015). Usually, the geopolymer materials are activated in a high alkali solution (Davidovits, 2008) because alumino silicate geopolymers consist of tetrahedral AlO_4 and SiO_4 units that occur easily in a polycondensed polymer framework in high-alkali conditions (Davidovits, 1991). In geopolymer materials prepared at low temperatures with high alkali solutions, generally alumino-silicate materials such as slag (Karakoç et al., 2014), metakaolin (Rovnaník, 2010a), and fly ash (Ryu, Lee, Koh, & Chung, 2013) were mixed with alkaline solution. For example, sodium or potassium hydroxide is necessary for dissolving silicon and aluminium atoms from raw materials of natural minerals or industrial waste. The silicate alkaline solution includes:

- A binder,
- Alkaline activator, and
- A dispersant or plasticizer (Abdullah, Jamaludin, et al., 2012a; Nazari, Bagheri, & Riahi, 2011; Somna, Jaturapitakkul, Kajitvichyanukul, & Chindaprasirt, 2011).

The basic forms of the chemical structure have silicon-aluminate 3D structures with cross-linked chain bonds together in the geopolymer matrix (Songpiriyakij, Kubprasit, Jaturapitakkul, & Chindaprasirt, 2010). The condensation reaction of geopolymers proceeded greatly at room temperature (Puertas, Martínez-Ramírez, Alonso, & Vázquez, 2000). At elevated temperatures of 40–95 °C, geopolymerization is improved in the strength of specimens (Bakharev, 2005; Chindaprasirt, Chareerat, & Sirivivatnanon, 2007; Panias, Giannopoulou, & Perraki, 2007; Swanepoel & Strydom, 2002). Dense geopolymer materials having apparent density higher than 1 g/cm^3 were applied for construction materials (Andini et al., 2008). Several reports described the use of metakaolin and fly ash as starting materials in geopolymerization (Duxson, Fernández-Jiménez, Lukey, et al., 2007; Komnitsas & Zaharaki, 2007). Moreover, industrial wastes of various types were used to synthesize geopolymers materials such as:

- Aluminum slag,
- Grey cast iron slag, and
- Blast furnace slag.

Among them, the use of etching surface waste, aluminum hydroxide, is interesting in the raw material for geopolymers. The Al-waste has high aluminum contents, making it suitable for the synthesis of better Al-source of geopolymers. Therefore, it is extremely attractive to investigate the geopolymerization of fly ash and Al-waste as a sustainable source for cement substitute materials.

In contrast, foam geopolymers were synthesized in high- or low-temperature processing conditions for widely diverse applications such as in carriers of catalyzer, adsorbents, sensors, hot gas filters, solid–liquid separation processes, and thermal insulators (López, Sugita, & Kobayashi, 2014a; Strozi Cilla, Raymundo Morelli, & Colombo, 2014; Studart, Gonzenbach, Tervoort, & Gauckler, 2006; H. Wang, Li, Wang, & Yan, 2015). In high-temperature processing, the raw materials and foaming agents (aluminium powder or hydrogen peroxide) were mixed with silica fume in situ foaming techniques. After geopolymerization, the geopolymer sample was sintered at 1000-1200 °C to produce in the high strength of

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

porous geopolymer (Abdullah, Jamaludin, et al., 2012b). Moreover, a low temperature process achieved geopolymerization in an alkaline environment with a foaming agent for the decomposed into the water and oxygen. In this case, aluminium and silicon in fumed silica also initiated the release of hydrogen gas, leading to a porous structure. Porous geopolymer was cured in a conventional oven at 40-70 ºC for 24–48 h in a long curing period (Böke, Birch, Nyale, & Petrik, 2015; Masi, Rickard, Vickers, Bignozzi, & van Riessen, 2014; Rickard, Vickers, & van Riessen, 2013; Somaratna, Ravikumar, & Neithalath, 2010; Vaou & Panias, 2010). Heat curing was applied to improve the reaction and the strength of geopolymer materials. Recently, microwave energy was used for innovative tool in the chemical reactions, thereby creating an inverse temperature profile (Gubb et al., 2011). The benefits of microwave heating also include instantaneous, very rapid heat-up time, and easy to control (Chindaprasirt, Rattanasak, & Taebuanhuad, 2013). The application of microwave oven cure for dense geopolymers prepared from FA and Al-waste was introduced (Onutai, Jiemsirilers, Thavorniti, & Kobayashi, 2015).

Background

As a construction materials, the portland cement and concrete are mostly essential and widely used in the world. The demand of using cement and concrete has continuously increased and tend to grow up in the future (Chindaprasirt et al., 2007). In the estimation, the usage of cement was approximately 2540 million tons (Mt) in 2006. The cement production in 2050 will be estimated around 3680 Mt to 4830 Mt (Hasanbeigi, Price, & Lin, 2012). In this circumstance, many problems are occurred in the cement industry of environmental fields. The greenhouse gases have been liberated into the atmosphere for production process such emitting and becomes the main problem of the global warming, by carbon dioxide emission during the production processes (Flower & Sanjayan, 2007). The amount of carbon dioxide is released into the atmosphere with approximately 0.8 tons/ 1tons in the cement industry (Alaa M. Rashad, 2011; Heath, Paine, & McManus, 2014; Pangdaeng, Phoo-ngernkham, Sata, & Chindaprasirt, 2014). In order to reduce the emission in the cement processes, many efforts have been paid to find the other cementitious materials to replace cement (Davidovits, 1994; Rovnaník, 2010a). Therefore, development of sustainable material is needed for cement and concrete.

In 1950s, Victor Glukhovsky et al. developed alkali activated systems containing calcium silicate hydrated and alumino-silicate phases, which were used to build a tall building. These alkaline alumino-silicate cementatious systems are called “soil silicate” (Komnitsas & Zaharaki, 2007). After 1972, Joseph Davidovits (Davidovits, 1982, 1984; Davidovits, 2008) reported another form of cementitious materials using silicon and aluminum activated in a high alkali solution. The new materials are called “Geopolymer”. The gepolymers are inorganic polymers having three dimensional alumino-silicates in the cementitious materials (Chindaprasirt et al., 2007; Cioffi, Maffucci, & Santoro, 2003; Davidovits, 1991). These materials have frame work of sialate and having silica-alumina networking in the molecular framework. Moreover, geopolymer materials are easily applied for coating and adhesive layers as binder for fiber composites, waste encapsulation (Davidovits, 2008). In addition, cement materials for concrete were proposal for geopolymers produced by condensation reaction. The polymeric process of alumino-silicate and alkali activators is one of other options for alternative green cement. This is due to reduction of approximately 80% of CO_2 emission to the atmosphere as compared with process for the cement. Moreover, geopolymer has an advantage in the production at low temperature and low pressure by using alumino-silicate sources. Also, it can be prepared from natural source in nature and industry such as metakaolin, fly ash, blast furnace slag etc. with a strong alkaline solution (Abdulkareem, Mustafa

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Al Bakri, Kamarudin, Khairul Nizar, & Saif, 2014b; Rovnaník, 2010b). Geopolymers have excellent properties such as high mechanical properties, low shrinkage, fire resistance and durability (Duxson, Fernández-Jiménez, Provis et al., 2007). Summarized geopolymer sourced from waste materials for many applications:

- As concrete and cement (Pavithra et al., 2016),
- Composites (Roviello, Ricciotti, Ferone, Colangelo, & Tarallo, 2015),
- Immobilisation of toxic and radioactive waste (Xu & Van Deventer, 2002),
- Adsorbent for heavy metal ion (Li, Wang, & Zhu, 2006) and
- Fire resistant and protection matrix (Sakkas, Panias, Nomikos, & Sofianos, 2014).

In general chemical structure of geopolymer, sialate (silicon-oxo-aluminate) segments are main chemical framework (Figure 1). This consists of SiO_4 and AlO_4 tetrahedra linked alternately by sharing all oxygen atoms. Alkali cations or positive ions such as Na^+, K^+ and Ca^{++} are charged-balanced of the negative charge of Al^{3+} in IV-fold coordination (Davidovits, 1994). A polymeric structure of (poly) sialate formed constitutes the main building blocks of geopolymeric structure and the empirical formula of polysialates is displayed asfollow (Hanjitsuwan et al., 2014a): M_n $[(-Si-O_2)_z-Al-O_2-]_n$, wH_2O, where M is monovalent cation such as sodium or potassium, n is degree of polycondensation, z is amount of $Si-O_2$ (1, 2, 3 or higher) and w is amount of water.

It is common that geopolymerization can start from room temperature containing silica and alumina unit to be oligomers (dimer, trimer) which provide the actual unit structures of the three dimensional macromolecular edifice. The geopolymerization stages can be supposed into three stages:

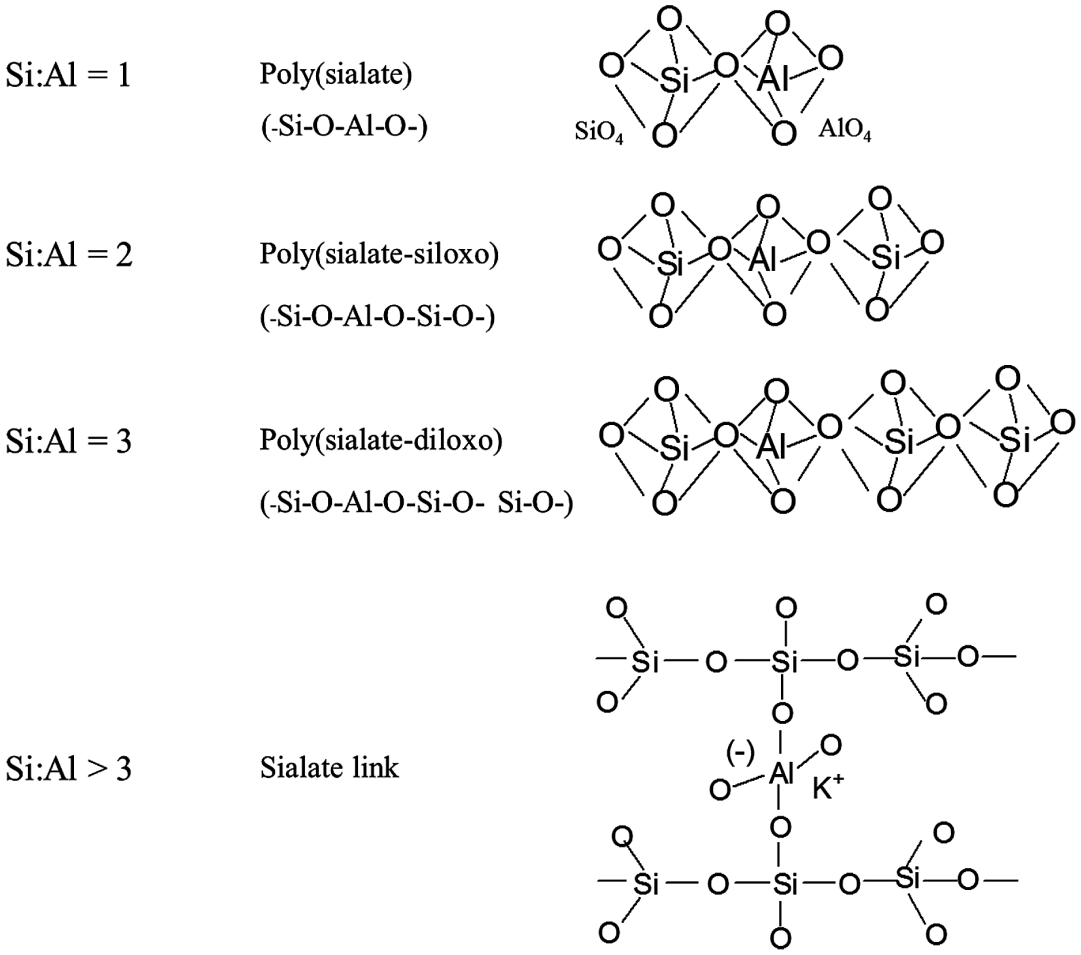
1. Deconstruction,
2. Polymerization and
3. Stabilization (Blackstock, Neill, & Mcintosh, 2012; Muñiz-Villarreal et al., 2011; Yao, Zhang, Zhu, & Chen, 2009).

In geopolymer, the polymerized sialates are linkaged together by the type of sialate (Si-O-Al) and siloxo (Si-O-Si). The chemical structure of polysialate geopolymers includes the classified of polysialates, which are separated into four elementary units according to terms of the Si/Al atomic ratio as followed (Davidovits, 1982, 1984; Davidovits, 1994):

1. For the units, first is sialate and poly(sialate) at Si:Al = 1. These have -Si-O-Al-O- included in the chain and ring polymers from the polycondensation reaction of monomer, ortho-sialate $(OH)_3$-Si-O-Al-$(OH)_3$.
2. In the second unit, sialate- siloxo and poly(sialate- siloxo) at Si:Al = 2, (-Si-O-Al-O-Si-O-) are the chain and ring polymer from the result of condensation between ortho-silicic acid $Si(OH)_4$. These chains have three isomorphs as a linear, mono-siloxo-sialate and 3 cycles.
3. In the third unit, sialate- disiloxo and poly(sialate- disiloxo) at Si:Al = 3, (-Si-O-Al-O-Si-O-Si-O-) are described from the result of condensation reaction between two ortho-silicic acid $Si(OH)_4$. The sialate units are corresponded to form six isomorphs: 2 linear, 2 branched and 2 cycles.
4. Finally for fourth unit, sialate link and poly(sialate- multisiloxo) unit at Si:Al > 3 which are chains from bridge Si-O-Al between two poly(siloxonate), poly(silanol) or poly(sialate) chains.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 1. Chemical structure of polysialates



The geopolymerization process involves:

1. Deconstruction,
2. Polymerization and
3. Stabilization (Yao et al., 2009; Zhang, Zhu, Zhou, & Wang, 2016).

In the deconstruction process, leaching of the solid alumino-silicate materials by alkaline hydrolysis produces aluminate and silicate species (Comrie & Kriven, 2006). The dissolution of the solid particles of the source for geopolymerization occurs at the surface. In high pH alkali solutions, the Si-O-Si, Al-O-Al and Al-O-Si of aluminosilicate source are dissolved (Somna et al., 2011). The alkali metal cations from the activated solution play important role in the geopolymerization and balance out the charge of the aluminium in form of four-fold coordination with oxygen (Lecomte et al., 2006). Then, the polymerization process occurs in the solution. The neighbouring reactive groups formed as Si-O-Na and O-H-Al and small silicate molecules from the alkali silicate thereafter undergo condensation reaction with the liberation of alkali hydroxide to form the preliminary unit for the geopolymerization.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

In the stabilization, the application of mild heat typically between room temperature up to 90 °C causes formation of the preliminary units in the terms of polycondensation. This can form rigid chains or nets of oxygen bonded aluminate and silicate tetrahedral which are similar to cement chemical structure. The higher "curing" temperature produces stronger geopolymer cements as each of the hydroxyl groups in these macromolecules are capable of condensing with one from a neighbouring molecule. It is theoretically possible for any one silicon to be bonded via an oxygen bond and to four neighbouring silicon or aluminium sites. As a result, very rigid polymer network is formed.

Several reports describe the use of metakaolin and fly ash as starting materials in geopolymerization. Moreover, industrial wastes of various types are used to synthesize geopolymer materials. For example, in cement and concrete, Pavithra et al.(Pavithra et al., 2016) developed the geopolymer concrete with fly ash. Moreover, Yeonho et al. (Park, Abolmaali, Kim, & Ghahremannejad, 2016) studied the feasibility of geopolymer concrete to which crumb rubber from recycled tires. Geopolymer cement and concrete showed low shrinkage after drying, less cracks and high strength. Therefore, the production cost of the geopolymer cement and concrete could be in 10-30% cheaper than Portland cement production.

In the adsorption of heavy metal application, geopolymer can be used as the materials for absorbing heavy metal from waste water. In recent years, fly ash based geopolymer was used for Cu and Pb removal from an aqueous solution. The absorption capacity was reached to 92 mg/g and 80 mg/g of Cu and Pb, respectively (Al-Zboon, Al-Harahsheh, & Hani, 2011; S. Wang, Li, & Zhu, 2007). Moreover, the geopolymer not only absorbed heavy metal but also could absorbed dye from waste water. The absorption capacity of fly ash based geopolymer demonstrated approximately 0.12 mmol/g (Li et al., 2006). Geopolymer adsorbents were prepared from silica and metakaolin in different Al and Si components (López et al., 2014a; López, Sugita, Takaya, & Kobayashi, 2014b) and applied for removal of metal ions, Cs^{+} and Pb^{2+}, from other heavy metal ions mixture (López, Sugita, Takaya, & Kobayashi, 2014c). In the application for immobilization heavy metal and radioactive waste, geopolymer was used to immobilize, stabilize and adsorb low amount of radioactive waste in pure and mixed form (Van Jaarsveld, Van Deventer, & Lorenzen, 1997). The results indicated that the fly ash based geopolymer had high property to immobilize lead ion (Lee et al., 2016). Geopolymers acted as the binder to convert semi solid waste to adhesive solid and also immobilized hazardous waste by locking in the three dimensional framework. Moreover, the geopolymer materials could be apply for composites materials, hybrid composite materials for geopolymer and epoxy melamine resins were designed to produce a novel material showing high compatibility between the organic and inorganic phases. In the applications, requiring high temperature resistance is for kitchen tools and plates, coatings and flooring (Roviello et al., 2015). In addition, the geopolymer materials can be used for fire protection possessing excellent physicochemical, thermal and mechanical properties. So, fire resistant geopolymers were developed by the potassium based geopolymers (K-geopolymer) prepared with mixing ferronickel (FeNi) slag, doped with pure alumina (Sakkas et al., 2014).

UTILIZATION OF ALUMINIUM WASTE BASED GEOPOLYMER

Since geopolymers consist of aluminum-silica framework in the chemical structure, the source of Al becomes important especially in cases of waste reuse. Every year, aluminum consumption is increasing for many applications such as anodizing processes for producing decorative and protective films on aluminum and alloys. After etching step, Al-waste in gibbsite phase ($Al(OH)_3$) is wasted: typically

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

about 360 tons/year from various industries is discarded in landfills (Álvarez-Ayuso, 2009; Colonetti, Hobold Kammer, & De Noni Junior, 2014; Ribeiro & Labrincha, 2008). Consumption of fossil fuels in power plants for energy production is increasing, leaving fly ash waste. About 3 million tons/year of such industrial waste are produced by large and small power plants. These wastes should be regenerated to produce novel materials. If people can recycle this, then such material becomes sustainable products that provide environmental, social, and economic benefits. Especially, as renewable resources of both aluminum hydroxide waste and fly ash, these seem to be applicable for reuse in concrete materials. Therefore, approximately 13,500 million tons of Portland cement are manufactured annually using processes that incorporate high heating energy of 1400–1600 °C for calcining raw materials (Detphan & Chindaprasirt, 2009).

Aluminum hydroxide waste (Al-waste) from the aluminum frame industry and fly ash (FA) from power plant were used as the raw materials of geopolymers. Their chemical compositions are presented in Table 1 and Figure 2 shows SEM micrograph of the raw materials for a) Al-waste and b) FA. The Al-waste particles were irregularly shaped, with diameter of about 100 μm. The particle distribution of the Al-waste was 40–110 μm. In contrast, the FA contained spherical particles with about 40 μm diameter in the fine powder. The laser-scattered particle distribution of fly ash showed that the powder size was 0.2–130 μm. Geopolymerization was conducted for Al-waste and FA, when the wastes were mixed with aqueous NaOH solutions of 5, 10, and 15 M concentrations. Al-waste were used for 0, 10, 20, 40, and 60 wt% for the Al-waste at different NaOH concentrations. After geopolymerization precess, the geopolymer bulk were cured at room temperature, 60 °C and 80 °C for 24 h.

As mentioned, geopolymerization in alkaline solution is known to increase the mechanical property of the resultant geopolymers. The properties depended strongly upon silicate and aluminum ratios and on the curing temperature (Görhan & Kürklü, 2014; Hanjitsuwan et al., 2014b; Nazari et al., 2011; Somna et al., 2011). It is important for the present study to examine the dependence of the curing temperature and the NaOH concentration. The flexural strength and compressive strength for each specimen was observed in geopolymers prepared using different aluminium hydroxide contents and NaOH concentrations. Actually,

Table 1. Chemical composition of fly ash and aluminum hydroxide waste

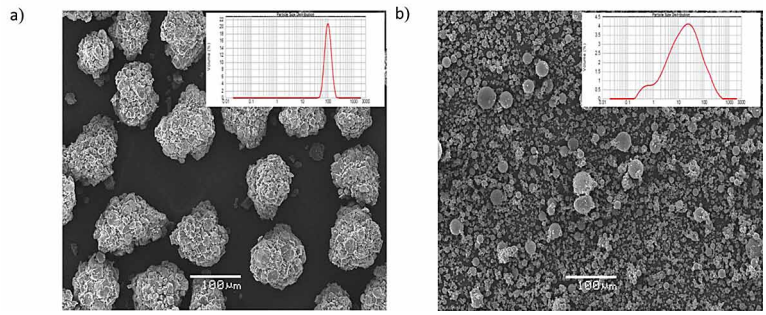
Figure 2. SEM micrograph of a) Aluminum hydroxide waste and b) Fly ash with particle size distribution



a tendency was seen by which the geopolymer strength increased as the NaOH concentration increased. For the flexural strength (Figure 4a), the high strength in 40 wt% of the Al-waste contents was obtained in 5, 10 and 15 M of NaOH concentration. This might be because of the fact that the higher concentrations of NaOH are able to dissolve both silica and alumina in a homogeneous slurry paste. Especially, high strength appeared at 80 °C, meaning that the curing temperature affected the geopolymer strength. After curing at higher temperature, increased bulk strength for the 40 wt% of Al-waste was observed with the maximum flexural strength of 6.05 MPa. A similar temperature tendency was also apparent for compressive strength (Figure 3b). The high compressive strength of 40 MPa was obtained for 40 wt% of Al-waste used in 10 M of NaOH concentration at 80 °C. As a result, slurry containing high alkaline solution was preferred for the condensation reaction to form Si–O and Al–O in the geopolymers. As reported (Görhan & Kürklü, 2014), this preference was mainly attributable to the excellent dissolution of silica and alumina components in the slurry. Therefore, high temperatures enhanced the geopolymerization in the Si–O–Al formation by the condensation. Regarding to development of compressive strength in Portland cement pastes and concrete specimens, the strength increased with increased curing temperature (Chindaprasirt et al., 2007; Somna et al., 2011). However, when the NaOH concentration was 15 M, the compressive strength started to drop. Excess NaOH was the cause of the compressive strength decrease attributable to the alumino-silicate gel precipitation at the early stage (Somna et al., 2011). On the other hand, the temperature was higher than 80 °C, water in the geopolymer slurry was evaporated to produce a porous structure (López et al., 2014a). In addition, the mass loss was capable of forming cracks in the geopolymer matrix because of the thermal shrinkage (Abdulkareem, Mustafa Al Bakri, Kamarudin, Khairul Nizar, & Saif, 2014a). The apparent bulk density of the geopolymer specimens increased when increasing the amount of the Al-waste to 40 wt%. However, as the Al-waste was added with 60 wt%, the apparent bulk density decreased. As seen in Figure 4, the micro CT-x ray technique showed the interior structure of geopolymer matrix in different amounts of the Al-waste. These geopolymers were prepared in the 40 wt% of the Al-waste at 80 °C with 10 M NaOH concentration. The inside geopolymer exhibited numerous cracks and pores for Figure 4a in the no addition of the Al-waste. In cases Figure 4b and 4d for 20 and 60 wt% of the Al-waste contents, the inside structures had fewer cracks, but round pores existed in these geopolymers morphological structure. In contrast, a denser structure was observed in the 40 wt% of the Al-waste (Figure 4c). Especially, in Figure 6d for 60 wt% the Al-waste, many pores were visible in the geopolymer. This result suggests that excess Al-waste caused the decrease of the geopolymer strength.

FLY ASH BASED GEOPOLYMERS

Fly ash is one of source material for geopolymer (Table 2) and is generally by-product obtained from industrial processes. Fly ash is commonly composed of a fine powder consisting mostly of spherical glassy particles (Figure 2) and is produced in coal fired power stations. Fly ash has pozzalonic properties and for example reacts with lime to form cementitious compounds. It is known as a supplementary cementitious materials (Pangdaeng et al., 2014). So the mechanical property of fly ash based geopoly-

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

mers were improved. The use of dense fly ash based geopolymer concrete led to many improvements in overall concrete performance. Some key benefits are included: reduced water content, improved workability, reduced segregation, low heat of hydration, improved finishing, lower drying shrinkage, increased durability, improved long term strength, good carbonation protection, improved resistance to sulfate attack and improved resistance to alkali silica reactivity as listed below.

Moreover, the improvement porous structure of fly ash based geopolymers also was reported for application as shown in Table 3. Moreover, for example, the porous structure of geopolymer materials was observed when microwave method was used as heating source (Onutai, Jiemsirilers, Thavorniti, & Kobayashi, 2016). Fly ash was obtained from Mae Moh Power Plant in Lamphang, Thailand for used as a raw materials. For geopolymerization, sodium hydroxide solutions and sodium silicate solutions were used as activators. The solid fraction in geopolymer mixture was 65 wt%. The ratio of Na_2SiO_3/NaOH solution and SiO_2/Al_2O_3 were fixed at 2.5 and 2.69 at 2-15 M NaOH, respectively. The geopolymer paste was cured by heating in a microwave oven at the different power setting (200-850 W) for 1 min. During microwave heating, the geopolymers temperature were detected by using an infrared thermal scanner as presented in Figure 5. The temperature development was the function of microwave power and sodium hydroxide concentrations. The specimen temperature increased with an increasing incident power and sodium hydroxide concentration. The temperature reached to 65-130 ^oC within 1 min. The aqueous paste of fly ash and sodium silicate contained different NaOH concentrations of 2 M-15 M was cured in the household microwave oven and then the geopolymer paste adsorbed microwave energy. The microwave heating occurred depending upon the NaOH concentration due to the dipolar polarization and ionic conduction mechanisms. Polar molecules such as water produce heat because the water absorbs microwaves as a result of the polarization induced by the external oscillating electric field (Vollmer, 2004). Therefore, the conduction mechanism from charged particles such as Na^+ and OH^- can oscillate back and forth under electric force producing an electric current to heats up neighboring materials through molecular collisions of charged species (Anwar et al., 2015; Vollmer, 2004). Moreover, the heat of geopolymers are increased during geopolymerization as a fact that the geopolymerization process is exothermic chemical reaction (Davidovits, 1991; Jumrat, Chatveera, & Rattanadecho, 2011). When the geopolymer paste was processed to the solid geopolymer, microwave heating was able to achieve higher temperatures in a very short time depending on the NaOH concentration. During the process, the volume of geopolymer specimen are immediately increased. Consequently, the water was vaporized easily at temperatures higher than 100 ^oC. Vaporization of the water might influence the morphology of the geopolymers. Bubbles from evaporation of water were fixed inside the geopolymer sample along with the general heat curing process, producing a porous geopolymer structure (Hanjitsuwan et al., 2014a).

The porous geopolymer morphology in the microstructure was compared in each sample synthesized in a conventional oven at 80 ^oC, with household microwave at 200 W and 850 W power for 1 min (Figure 6). The morphological analysis elucidated that the microstructural changes occurred with heating and curing at 80 ^oC and microwave curing. All samples showed that the ash particles remained in the geopolymer matrix. During the dense morphology of the matrix was created, the rough surface of the geopolymers was observed for the paste having 10 M and 15 M NaOH concentrations. At 850 W of microwave curing, the tendency was extremely effective at higher NaOH concentrations, as depicted in Figures. 6i) and 6l). In the geopolymers cured with 15 M of NaOH concentration, the apparent density was increased markedly when the microwave was operated at 500-850 W. The values of apparent bulk density showed about 0.9 g/cm^3 for the 15 M NaOH concentration at 500-850 W, while these were 1.4-1.5 g/cm^3 for the 2 M and 5 M NaOH concentrations. When the NaOH concentration was increased, the

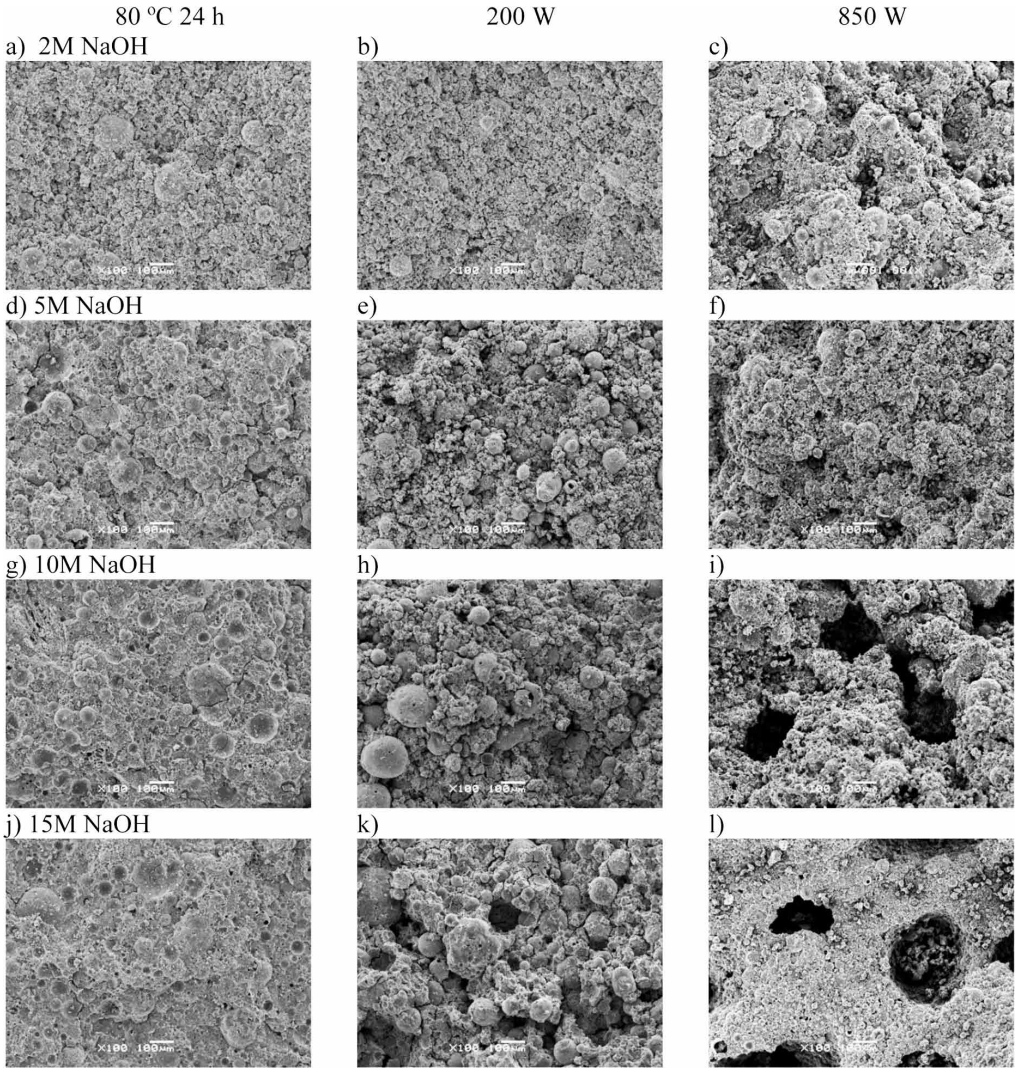
Figure 6. Microstructure of geopolymer sample synthesized by curing at 80 °C 24 h and using microwave radiation at power 200 and 850 W for 1 min



strong alkali rapidly increased the interior temperature, especially in 10 M and 15 M materials at 700 and 850 W. Therefore, the bubbles of the water evaporation seemed to be increased in the bulk porous structure, thereby decreasing the apparent density.

CONCLUSION

In this chapter authors conclude the reuse fly ash and industrial wastes, Al-waste, for producing geopolymers which are sustainable and green materials. In their waste materials, geopolymers were synthesized from fly ash and aluminium waste with different proportions of raw materials for alternative cement. Moreover, when different NaOH concentration and different curing temperature was changed, effect of

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

the alkali was described. Fly ash based geopolymer and synthesis porous geopolymer using microwave radiation from household microwave were also reviewed. The results showed that porous geopolymer was produced at 10 or 15 M NaOH with 850 W of microwave radiation power, due to that the high power of microwave radiation increased the slurry temperature and affected water evaporation in the geopolymer paste. The bulk and porous geopolymers were successfully produced by using FA and Al-wastes.

KEY TERMS AND DEFINITIONS

Apparent Density: The mass per unit volume (or the weight per unit volume) of a material, taking into consideration any voids.

Compressive Strength: The maximum compressive stress that, under a gradually applied load, a given solid material can sustain without fracture.

Hazardous Materials: Any item or agent (biological, chemical, radiological, and/or physical), which has the potential to cause harm to humans, animals, or the environment, either by itself or through interaction with other factors.

Industrial Waste: The waste produced by industrial activity which includes any material that is rendered useless during a manufacturing process such as that of factories, industries, mills, and mining operations.

Mechanical Property: A property that involves a relationship between stress and strain or a reaction to an applied force.

Sustainable Materials: Materials used throughout our consumer and industrial economy that can be produced in required volumes without depleting non-renewable resources and without disrupting the established steady-state equilibrium of the environment and key natural resource systems.

Chapter 33
Removal of Emerging Contaminants from Water and Wastewater Using Nanofiltration Technology

ABSTRACT

Conventional water/wastewater treatment methods are incapable of removing the majority of Emerging Contaminants (ECs) and a large amount of them and their metabolites are ultimately released to the aquatic environment or drinking water distribution networks. Recently, nanofiltration, a high pressure membrane filtration process, has shown to be superior to other conventional filtration methods, in terms of effluent quality, easy operation and maintenance procedures, low cost, and small required operational space. This chapter provides a comprehensive overview of the most relevant works available in literature reporting the use of nanofiltration for the removal of emerging contaminants from water and wastewater. The fundamental knowledge of nanofiltration such as separation mechanisms, characterization of nanofiltration membranes, and predictive modeling has also been introduced. The literature review has shown that nanofiltration is a promising tool to treat ECs in environmental cleaning and water purification processes.

1. INTRODUCTION

Emerging contaminants (ECs) can be broadly defined as any synthetic or naturally occurring chemicals but cause known or suspected adverse ecological and(or) human health effects. This ever-increasing contaminants pose potential environmental and health threat to the living organism (Bolong, Ismail, Salim, & Matsuura, 2009). In some cases, due to low concentration emerging contaminants have likely existed for a long time, which may not be detected until new analytical methods are developed. Hence, some ECs are not necessarily new chemicals, which are from municipal, agricultural, and industrial wastewater sources and pathways (Petrović, Gonzalez, & Barceló, 2003).

There are two reasons why emerging contaminants are of continued concern for the health and safety of consuming public. The first one is the trace level of most ECs with concentration at μg/L or ng/L, and broad range of physiochemical characteristics, which make both detection and elimination extremely difficult (Richardson & Ternes, 2005); And the second one is the adverse health and environmental effects of ECs even at a low concentration. Some intermediate metabolites or transforming products of ECs (especially for endocrine disrupting chemicals) exhibit biologically active effect as well (Diamanti-Kandarakis et al., 2009).

The main issue of ECs is nonexistence of limiting regulations, especially for new compounds, by-products, pharmaceuticals as related to the water and wastewater treatment industry. The first Contaminant Candidate List (CCL) was created in 1998 by United States Environmental Protection Agency (US EPA) for contaminants that are currently not subject to any proposed or promulgated national primary drinking water regulations. Even through many efforts have been devoted, there is limited number of contaminants with Maximum Contaminant Level (MCL) regulated by US EPA.

The main groups of ECs are described in Table 1.

Table 1. Main group of emerging contaminants, definitions and examples

Group	Definition	Examples	Environmental Risks	Comments
Pesticides	Any substance or mixture of substances intended for preventing, destroying, repelling, or mitigating any pest (by US EPA)	Atrazine, Diuron, Alachlor, Diazinon	Probable human carcinogen, endocrine disrupting potential	Dominant group in the list of persistent organic pollutants (Berg, Hagmeyer, & Gimbel, 1997)
Disinfection by-products (DBPs)	The byproducts formed by the reaction between disinfectants and naturally-occurring materials	Trihalomethanes, Haloacetic acids	Increased risk of cancer and liver, kidney, or central nervous system problems	
Endocrine disrupting chemicals (EDCs)	The chemicals which can interfere with body's endocrine system	Estrone, Estriol, Testosterone, Progesterone	Developmental, reproductive, neurological, and immune effects in both humans and wildlife	Certain fish and wildlife are easy to be affected.
Pharmaceutically Active Compounds (PhACs)	Pharmaceutical residues and their metabolites	Ibuprofen, Diclofenac, Diatrizoateb	Inherent potential for a wide range of physiological effects	Potential for induction of proliferation of antibiotic resistance (Van Wyk, 2015)

As most ECs are small organic molecules, most conventional water treatment processes exhibit ineffective removal of emerging contaminants. Given the variety of emerging contaminants, advanced water treatment methods should be suitable for this purpose. The ability to reject small organic contaminants makes nanofiltration membranes almost a nature choice for emerging contaminants. Compared with other membrane system (e.g., microfiltration, ultrafiltration and reverse osmosis), nanofiltration show remarkable potential for the removal of small organic contaminants (Figure 1), since the molecular weight cut-off values of most nanofiltration membranes are in the range of 200 to 300 Da, which coincides with the molecular weight of many ECs of concern.

Nanofiltration, defined as process between ultrafiltration and reverse osmosis, however is a controversial technology. The origin of nanofiltration can be traced back to 1960s, even before the term of nanofiltration was coined at the second half of 1980s (Loeb, Titelman, Korngold, & Freiman, 1997). In the beginning, the nanofiltration was categorized as open reverse osmosis or loose ultrafiltration. By the early 1970s, a full series of first-generation cellulose acetate membrane has been developed by Loeb and Sourirajan (Strathmann, Scheible, & Baker, 1971). The cellulose acetate was the standard material for nanofiltration until the composite nanofiltration was developed (Pepper, 1988). This breakthrough significantly enhanced the performance and popularity of nanofiltration, making nanofiltration membranes widely available. In the last decade, majority of studies on nanofiltration moved to chemically stable nanofiltration membranes. Many pH/solvent stable membranes were developed and commercially available (Musale & Kumar, 2000; Toh, Lim, & Livingston, 2007).

Nanofiltration membranes have been shown to be able to remove turbidity, microorganisms and hardness, as well as a fraction of the dissolved salts, which is similar with reverse osmosis. The initial application of nanofiltration in water industry was pretreatment of desalination process with significantly lower operating pressure, which brings energy-efficient advantages. However it is the high rejection of charged or uncharged organic compounds that makes nanofiltration membranes the suitable option to remove emerging contaminants. Even though the reverse osmosis membrane shows higher rejection of low molecular weight compounds, the lower operation pressure brings nanofiltration excellent efficiency. The use of NF to replace RO shows reduced energy costs and reduced volumes of toxic pollutants for the water treatment. For a typical nanofiltration membrane, the rejection of a divalent ion is above 95%, while the rejection of a monovalent ion can be anywhere between 20 and 80% with 600 - 100 PSI working pressure. For example, NF270 is a commercially available nanofiltration membrane with pure water permeability of 13.5 (L m^{-2} h^{-1} bar^{-1}) (Schaep, Vandecasteele, Mohammad, & Bowen, 2001).

In this chapter, the fundamental of nanofiltration will be introduced in second section, while the application of emerging contaminant removal will be discussed in third and fourth section.

2. FUNDAMENTAL OF NANOFILTRATION

As discussed in the first section, nanofiltration as a pressure-driven membrane has been studied for over 40 years. In this section, the fundamental of nanofiltration will be focused, and the material, the preparation, characterization and predictive models of the nanofiltration will be covered as well.

2.1. Materials and Preparation of Nanofiltration Membranes

There are three major groups of nanofiltration: asymmetric membranes, composite membranes and ceramic membranes. The first two belongs to the polymeric membranes. But the asymmetric membranes can be prepared via one step, the phase inversion method. The classical cellulose acetate membranes are the most important member of this group. Composite membranes are composed of porous nonselective supporting layer coated with a thin-film layer. This multilayer approach offers much more flexibility and control of the synthesis, which makes thin film composite nanofiltration more competitive over asymmetric membrane (Matsuura, 2001; Petersen, 1993; Song, Liu, & Sun, 2005). The membranes based on ceramics are the hot spot especially in the last decade. It has shown higher resistance against organic solvent and high pressure (Benhui, 1996).

2.1.1 Phase Inversion

Phase inversion is the process of controlled polymer transformation from a liquid into a solid state. Immersion precipitation is definitely the most popular method to prepare asymmetric membranes (Mulder, 1996). Since the casting solution of polymer and solvent is immersed into a non-solvent bath (coagulation bath) in typical immersion precipitation, the morphology and the performance of the membrane depends on thermodynamics as well as kinetics. Therefore the resulting membranes can be controlled by the composition of the casting solution, the type of polymer, coagulation medium and post treatment (if any) (Kawakami, Mikawa, & Nagaoka, 1996; Paulsen, Shojaie, & Krantz, 1994).

Even through the asymmetric membranes have been studied for decades, the general quantitative model for formation of asymmetric membrane by immersion precipitation is still under investigation. Based on the previous researches, some qualitative conclusions can be drawn as follows (Schäfer, Fane, & Waite, 2005):

- More charged group in polymer can lead to higher hydrophilic polymer, which would increase water flux of the membranes and alter the salt rejection (Dias, Rosa, & de Pinho, 1998; Stamatialis, Dias, & de Pinho, 1999).
- Increased polymer concentration of casting solution can lead to increased thickness and lower fluxes (Mulder, 1996).
- High interaction between the non-solvent and solvent often produces high porosity of the membrane by addition of additives and increased temperature of coagulation bath (in certain range) (Yeow, Liu, & Li, 2004).

2.1.2 Interfacial Polymerization

The interfacial polymerization has become a very successful and useful method to synthesize the composite nanofiltration membrane, since the concept of interfacial polymerization was first introduced in 1966 (Zimmermann, 1966). Due to better performance of composite membranes over asymmetric ones, many progresses have been made on the preparation of novel composite membranes in the last decade. Among the commonly used monomers, the cross-linked aromatic polyamide composite membrane produced by interfacial polymerization of phenylenediamine (MPD) and trimesoyl chloride (TMC) is still most successful in the present.

Compared with phase inversion, interfacial polymerization brings us more flexible optimization, which makes the research on interfacial polymerization more systemic. The hydrophilicity of polymer is still an important factor on membrane performance. Triamine 3,5-diamino-N-(4-aminophenyl) benzamide (DABA) monomer was used with m-phenylenediamine (MPD) and trimesoyl chloride (TMC) to improve the water flux of membranes, by more hydrophilic (giving rise to lower contact angles), smoother and thinner surface (H. Wang, Li, Zhang, & Zhang, 2010). Membranes with high resistance against chlorine (one of the common disinfectants used in water and wastewater treatment) were also prepared with 1,3-cyclohexanebis(methylamine) (CHMA) in water with TMC in hexane (Buch, Mohan, & Reddy, 2008). Besides the researches in polymer, many studies were performed on porous supports of composite membranes. By using novel support polymers, several thermally/solvent stable composite membranes were synthesized. For example, a thermal stable composite membrane by polymerization of piperazine (PIP) and TMC on poly (phthalazinone ether amide) (PPEA) membrane can function effectively at 80 °C (C. Wu, Zhang, Yang, & Jian, 2009).

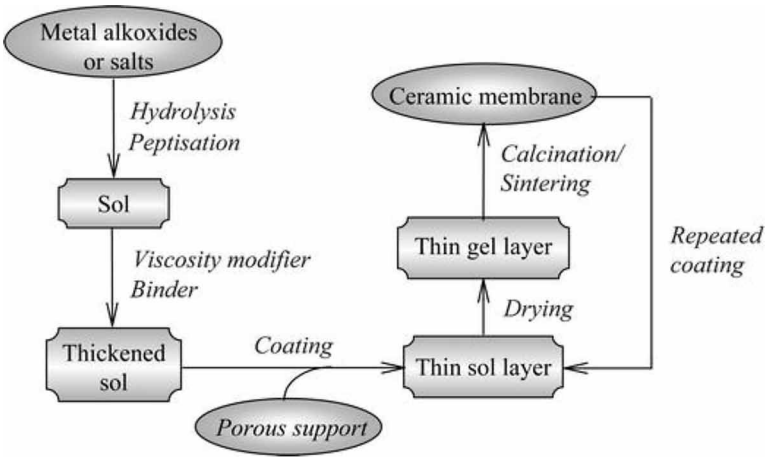
Another important development in composite membrane is the addition of nanoscale particles into film of membranes, which is named as thin film nanocomposite (TFN) membrane. By incorporating of titanium oxide (TiO_2), this hybrid thin film composite show photocatalytically destructive capability on microorganisms, which can be used to solve biofouling problem (Kim, Kwak, Sohn, & Park, 2003). Surface modification of TiO_2 can also increase water flux up to 2-fold compared with the pure polyamide membrane with negligible rejection loss (Rajaeian, Rahimpour, Tade, & Liu, 2013). Multiwall carbon nanotubes (MWNTs)/polyester thin film nanocomposite membranes showed superior high water flux due to the high hydrophilic property (H. Wu, Tang, & Wu, 2010). Similar research with Metal–organic frameworks to yield high flux membrane (3-fold increase in permeance) was performed on polyamide (PA) thin film (Sorribas, Gorgojo, Téllez, Coronas, & Livingston, 2013).

2.1.3 Ceramic Membranes

Ceramic based membranes are a unique class of nanofiltration membranes due to inorganic components. Ceramic membrane shows higher chemical, structural and thermal stability over polymeric membranes. Even though it only holds a small membrane market share, many progresses of ceramic membranes were made, especially in solvent-resistant nanofiltration membrane area (Hendrix & Vankelecom, 2013). Similar to polymeric membranes, support materials are still required for membranes based on ceramic. The difference is mesoporous intermediate layer is usually chosen as support. Al, Si, Ti or Zr oxides can be used to build ceramic membranes (Guizard, Ayral, & Julbe, 2002).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 2. Flow diagram for the preparation of microporous or mesoporous membranes via sol–gel techniques
(Hong & Elimelech, 1997).



The general procedure to prepare active layer of ceramic membrane is sol-gel method, which involves converting colloidal solution into a gelatinous substance (Hsieh, 1996). The general procedure for ceramic membranes is shown in Figure 2.

2.2 Characterization of Nanofiltration Membrane

In this section, characterization for nanofiltration membranes will be divided into performance parameters, morphology parameters, as well as charge parameters to discuss (Artuğ & Hapke, 2006).

For performance, retention of the membrane and permeability coefficient are the most important parameters. By definition, the retention can be calculated with Equation 1:

$$R = \frac{c_f - c_p}{c_f} \tag{1}$$

in which c_f represents the concentration of the feed and c_p represents the concentration of permeate. The permeability is characterized by permeability coefficient (L_p), which is calculated by the slope of plotting the water flux as a function of the pressure.

For morphology, pore size, porosity, surface roughness and hydrophobicity are important parameters. Gas adsorption is usually the first choice to study the pore characteristics of solid materials (Schull, 1948), but for nanofiltration membrane with nanometer range pores (for example, the average pore diameter of NF90 is only 0.68 nm) this method is not accurate any more. Same issue occurs when permporometry is used to measure small pores, which produces same inaccurate results with gas adsorption (Cao, Meijernik, Brinkman, & Burggraaf, 1993). Microscopic techniques, especially atomic force microscopy (AFM) are very suitable for nanofiltration membranes. High resolution images of many commercial membranes were achieved by AFM. Even though several emerging technics or methods were applied to measure the pore size distribution, AFM and SEM are still preferred for the measurement (Otero et al., 2008).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Hydrophobicity is another essential morphology parameter, which is often characterized by contact angle (defined in Equation 2):

$$\cos\theta = \frac{\gamma_{SV} - \gamma_{SL}}{\gamma_{LV}} \tag{2}$$

in which γ_{SV} and γ_{LV} are the surface tensions of the solid and the liquid with the vapor of the liquid and γ_{SL} is the tension of the solid-liquid interface.

The charge of the membrane can be obtained by measuring the streaming potential, and zeta potential.

2.3 Modeling of Nanofiltration Membrane

It has been 50 years since the nanofiltration concept was established in 1960s. But still a universal quantitative model for the description and prediction of nanofiltration performance has not been founded, though many theories have been established to describe the fundamental. Nanofiltration is a very complex process, because the rejection event occurs on a scale of the order of nanometer, which is very close to atomic dimensions. This would force us to consider the whole process with microscopic concept, which explains why more models of nanofiltration are transplanted from reserve osmosis. The filtration process involves several mechanisms, like steric interaction, charge interaction, adsorption and sorption-diffusion. Complex interactions between solutes, solvents and membranes make the nanofiltration modeling extremely difficult.

This section does not intend to include exhaustive physical equations, and the following will instead focus on the status of each modeling type. From a general point of view, modeling can be founded by experimental phenomena (empirical) or physical mechanism.

The empirical model, Spiegler-Kedem model, was initially founded at 1960s based on the irreversible thermodynamics and all the parameters and coefficients were determined experimentally (Kedem & Katchalsky, 1963). The composite membranes were considered as a “black box”, which meant all the transport processes were not include in the model. This model was successfully applied in reverse osmosis membranes afterwards (Spiegler & Kedem, 1966). A few following researches confirmed the model was only valid under certain conditions, but the main drawback is lack of considering the variety of rejection and the charge effect of the membrane. The concentration dependency on rejection and the electrostatic exclusion are considered in the model developed later in 1989 and 1992 (Perry & Linder, 1989; Schirg & Widmer, 1992). Even though new parameters were included, the application of extended Spiegler-Kedem model was limited due to poor predictive ability.

The other models are based on transport-mechanistic modeling. These physical models take into account the transport mechanisms occurring in the membrane, which can be divided into two branches: space-charged (SC) model (Morrison Jr & Osterle, 1965) and Teorell-Meyer-Sievers (TMS) model (Teorell, 1953). In SC models, the pores on the membrane are considered as charged capillaries. Ions are considered as point charges, which are defined by Poisson-Boltzmann equation; while ion transport is defined by extended Nernst-Planck equation. With respect of TMS models, the radial distribution is neglected. The following researches confirmed two models to show good agreement for capillaries having smaller radius and lower surface charge density, which is the case of nanofiltration (X.-L. Wang, Tsuru,

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Nakao, & Kimura, 1995). Many modified models have been proposed recently based on the similar assumption, which shows a rapid growing realization of physical models.

By limited parameters and soluble mathematic calculations, well-founded models should serve for two purposes: description and prediction. Unfortunately, despite of many accomplishes in modeling of nanofiltration, the current modeling and simulation are more descriptive than predictive. Attempt to combine all current knowledge for a predictive model led to the conclusion that much depended on fitting parameters and not on physically relevant parameters (Straatsma, Bargeman, Van der Horst, & Wesselingh, 2002). For now empirical model for certain membrane is much reliable to predict membrane performance. Hence further research is still needed.

3. REMOVAL OF EMERGING CONTAMINANTS WITH NANOFILTRATION

During the last decade, nanofiltration has become more and more popular in drinking water treatment and wastewater treatment, not only for conventional water softening, but also for the removal of micropollutants, especially organic emerging contaminants. In this section, the removal of different types of emerging contaminants as well as the removal mechanisms will be discussed.

3.1. Removal of Emerging Contaminates

3.1.1 Pesticides

The use of pesticides to control unwanted pests dates back hundreds of years. Pesticides became a severe issue since the hundreds of synthetic organic chemicals were used without regulatory. Some of them can cause immediate toxic effects or act as potential carcinogen with long-term exposure, while some of them show superior stability in natural environment, such as DDT (dichlorodiphenyltrichloroethane). The use of nanofiltration for the removal of pesticides has been investigated by many researchers. To achieve best removal outcome, optimized membrane properties, additives during filtration and different operation conditions have been tried. Table 2 shows high retention of selected pesticides with nanofiltration.

Ghaemi and coworkers performed a series of solid study about removal of nitroaromatic pesticides with modified nanofiltration membranes. They first investigated the effect of sodium dodecyl sulfate (SDS) anionic surfactant as additives in cellulose acetate (CA) nanofiltration membrane preparation. AFM measurements showed addition of SDS decreased thickness of the top layer and performance evaluation indicated higher pure water flux and rejection compared to CA membranes. The rejection of 3,5-Dinitrosalicylic acid (DNSA) and p-nitrophenol (PNP) reached 97.5% and 90% respectively under optimized condition (Ghaemi, Madaeni, Alizadeh, Daraei, Vatanpour, et al., 2012). Then they continued to study the effect of organic acids (ascorbic acid, citric acid and malic acid) as addictive in polysulfone nanofiltration membrane. Following the same strategy, retention of pesticides, 2,4-Dinitrophenol (DNP) and p-nitrophenol (PNP) reached 99% and 90% respectively with increasing hydrophilicity and water flux of the membrane (Ghaemi, Madaeni, Alizadeh, Daraei, Badieh, et al., 2012). Also the effects of addition of amphiphilic fatty acids (palmitic, oleic, and linoleic acids) were investigated on morphology, performance of cellulose acetate nanofiltration membranes and retention of nitroaromatic pesticides. Fabricated membranes presented higher efficiency in retention after the addition of palmitic acid with five pesticides as target solutes (Ghaemi, Madaeni, Alizadeh, Rajabi, et al., 2012). Košutić obtained good

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

results for the removal of arsenic and pesticides from natural ground water. The NF270 nanofiltration membranes exhibited superior permeation rate values, which were more than five times higher than the corresponding values of the reverse osmosis CPA2 membrane. This can be explained by the charge exclusion mechanism during filtration process (Košutić, Furač, Sipos, & Kunst, 2005).

Interestingly some studies indicated dissolved natural organic matter (DOM) could enhance atrazine rejection in most cases and the enhancement was dependent upon the concentrations of the DOM and the atrazine and the ionic strength (Devitt, Ducellier, Cote, & Wiesner, 1998). Some following studies showed the presence of humic acid, sulfates, and chlorides can improve the elimination of certain pesticides (Košutić et al., 2005). But other contrasting results showed DOM can decrease or have negligible effect on micropollutant removal (Devitt et al., 1998). The charge exclusion is found to be the prevailing mechanism of small model compounds retention by the negatively charged nanofiltration membranes. The size exclusion mechanism also is observed to be important but not sufficient for the unionized small organic molecules rejections (Lin, Chiang, & Chang, 2007).

Besides the pesticide itself, the potential of nanofiltration membranes for treatment of groundwater polluted with some of these key transformation products was assessed. It turned out the nanofiltration membranes were capable of rejecting the regular pesticides, but did not give satisfactory rejections of the transformation products due to decreasing molecular size. Filtration system needed to be modified in order to obtain better performance (Madsen & Søgaard, 2014).

3.1.2 Disinfection By-Products (DBPs)

Many DBPs pose potential health risks due to carcinogenic effect with long-term exposure (Waller, Swan, DeLorenze, & Hopkins, 1998). In the past 40 years since the trihalomethanes (THMs) were identified as DBPs in drinking water, significant research efforts have been directed toward increasing our understanding of DBP formation and removal (Richardson & Postigo, 2012; Waller et al., 1998). Several publications have shown good rejection of DBP with nanofiltration. Vedat reported the removal efficiencies of THM by nanofiltration technique with commercial NF200 and DS5 membranes. With

Table 2. Retention of selected pesticides using nanofiltration membranes

Compound	Membrane	Feed Concentration	Retention (%)	Reference
Atrazine	NF45	300 µg/L	91.8	(Van der Bruggen, Schaep, Maes, Wilms, & Vandecasteele, 1998)
	NF90	20 mg/L	95	(Ahmad, Tan, & Shukor, 2008)
	UTC20	5 mg/l	93	(Zhang, Van der Bruggen, Chen, Braeken, & Vandecasteele, 2004)
Simazine	NF70	300 µg/L	88.5	(Van der Bruggen et al., 1998)
	UTC20	5 mg/L	83	(Zhang et al., 2004)
Diuron	NF70	300 µg/L	85.9	(Van der Bruggen et al., 1998)
Isoproturon	NF70	300 µg/L	90.3	(Van der Bruggen et al., 1998)
	ESNA	149 µg/L	98.3	(Plakas, Karabelas, Wintgens, & Melin, 2006)
Isoxathion	NTR-729HF	n/a	99.84	(Kiso, Sugiura, Kitao, & Nishimura, 2001)

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

synthesized fee water, feed concentration and operating pressure show little effect on rejection, while the brominated THMs with higher molecular weight show higher removal efficiency compared with other species of THM (Uyak, Koyuncu, Oktem, Cakmakci, & Toroz, 2008).

Besides removing the DBPs directly, removing the DBP precursors is another promising strategy, like removal of bromide and other organic matters before disinfection to substantially lower the formation of DBP (Kimbrough & Suffet, 2002). Nanofiltration can lead to a high rejection of NOM and a high reduction of THM precursors in water, which can be efficient to reduce THM formation potential (De la Rubia, Rodríguez, León, & Prats, 2008). Commercial nanofiltration membranes, NF70 and NF270 were utilized to remove small THM precursors as well. High removals of THM precursors were observed at high pH values (Lin et al., 2007). Generally this strategy is more effective than directly removing DBPs as the DBP precursors are of large molecular weight.

Due to variety of DBPs, even though most NF studies reported promising DBP and DBP precursor rejections (Blau, Taylor, Morris, & Mulford, 1992; Jarusutthirak, Mattaraj, & Jiraratananon, 2007; Lee & Lee, 2007), removal pattern of individual species should be considered as well (Chellam, Sharma, Shetty, & Wei, 2008).

3.1.3 Pharmaceutically Active Compounds (PhACs)

Pharmaceutically active compounds (PhACs) present an increasingly large group of emerging contaminants. As pharmaceuticals are designed to be biologically active and chemically stable, more than 83 pharmaceuticals have been detected all over the world (Baena-Nogueras, Pintado-Herrera, González-Mazo, & Lara-Martín, 2015). Pharmaceuticals as well as their metabolites can influence none-target organisms with acute or chronic effect. Conventional sewage treatment shows unsatisfactory removal of PhACs, which is at concentration range of μg/L or lower (Heberer, 2002). Many researchers have reported almost 100% retention of PhACs with nanofiltration membranes in their studies. For example, two commercial composite membranes (SR2 and SR3) show 75–95% and 95–100% removal efficiency of five model PhACs with different physicochemical properties (i.e., cephalexin, tetracycline, acetaminophen, indomethacin and amoxicillin) (Zazouli, Susanto, Nasseri, & Ulbricht, 2009). Even in the full-scale drinking water treatment plant, nanofiltration was reported to successfully remove >85% of 12 PhACs (Radjenović, Petrović, Ventura, & Barceló, 2008).

3.1.4 Endocrine Disrupting Chemicals (EDCs)

Steroid hormones such as estrone are prominent in EDCs due to high endocrine-disrupting potency (Colborn, vom Saal, & Soto, 1993). Given the low concentration yet adverse effects in aquatic environment, EDCs have attracted significant interests recently (Andersen, Siegrist, Halling-Sørensen, & Ternes, 2003; Vos et al., 2000). However a definitive list of EDCs does not exist, as most chemicals in commerce have not been tested for endocrine toxicity. Nanofiltration membranes are demonstrated to have fair removal efficiencies for EDCs as well. Removal of estrone and 17β-estradiol with nanofiltration are summarized in Table 3. Numerous studies were also performed with other hormones as reference EDCs. Koyuncu et al. investigated the rejections of estradiol and testosterone (by 64% and 62%, respectively) by NF200 membrane (Koyuncu, Arikan, Wiesner, & Rice, 2008). Pereira et al. utilized the same NF200 membrane and obtained similar results. NF200 membrane rejected the selected hormones with efficiencies higher than 71% (except estriol with only 38% removal) directly from surface water (Pereira, Galinha,

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Crespo, Matos, & Crespo, 2012). Unlike the almost complete removal of other emerging contaminants, nanofiltration didn't work that well in EDCs removal, even the molecular weight of target EDCs was lower than molecular weight cut-off of the membrane in several studies (Sandra Sanches et al., 2012; Semião & Schäfer, 2013).

Even though, in the last decade many researches show promising result of EC revmoval. Most of studies were performed in lab scale without using "real" water. However, regardless of many breakthroughs in materials or configuration of the NF membrane itself, the potential of nanofiltration in industrial application is still underdeveloped.

3.2. Removal Mechanisms of Nanofiltration for Emerging Contaminants

As discussed in the last section, nanofiltration shows generally high retention of emerging contaminants and varying performance for different target micropollutants. Since the molecular weight cut-off values of nanofiltration membranes fall in the same range as the molecular weight of most emerging contaminants, the overall good rejection can be predicted. The reason for variations will be discussed in this section.

Size exclusion is the simplified, yet useful retention model, which basically depends on the pore size of membranes and the physical size of contaminants. In this model, average pore sizes and estimated diameter of solutes are the two key parameters. For the diameter of solute molecule, the most easily estimated method is molecular weight, and predictions of retention coefficient have been made based on molecular weight. Molecular weight cut-off, which is defined as the molecular weight of a solute with retention of 90%, is used as the primary parameter of commercial nanofiltration membranes. As molecular weight is not dimensional parameter, the hydrodynamic volume was tested and provided better prediction than the molecular weight (Meireles, Bessieres, Rogissart, Aimar, & Sanchez, 1995). In

Table 3. Retention of selected EDCs using nanofiltration membranes

Compound	Membrane	Feed Concentration	Retention (%)	Reference

order to take structure parameter into account, Stoke radius was considered as better fit, regarding the molecules as spheres (Fei & Bart, 2001). However, some other methods indicate the molecules are not spherical, and the molecular width and length are calculated as STERIMOL parameters (Kiso et al., 2001). Computer aided methods have been introduced as well, random energetic optimization by software can produce molecular size directly. Recently researchers tend to choose multiple size parameters in order to produce more complicated and accurate predictions, like distribution coefficient, molecular weight, and molar volume, etc. (S Sanches, Galinha, Crespo, Pereira, & Crespo, 2013). In addition, operation conditions, like pH, ionic strength, and concentration of contaminants, can influence actual sizes of the contaminants and the pores (Childress & Elimelech, 2000).

The other models are involving the interactions between contaminants and membranes, which includes electrostatic interaction, physical adsorption, and hydrogen bonding (Braeken et al., 2005; L. D. Nghiem et al., 2004). Estrone is a typical example that size exclusion mechanism is not the dominant factor for retention, due to hydrogen bond and strong hydrophobic interaction with membranes. The accumulation of contaminants could lower the performance of membranes, which explains relatively low retention of estrone with nanofiltration (Braeken et al., 2005; D. Nghiem, Schäfer, & Waite, 2002).

Considering the complexity of nanofiltration process, these mechanisms always work together, even in many cases one mechanism can be a dominant factor, which is difficult to predict.

4. PLANT DESIGN

Even though major studies on nanofiltration are fundamental researches, like novel membrane development and retention mechanism, plant design of nanofiltration with respect to emerging contaminant removal is very crucial in practice.

In water treatment industry, all treatment technics should work together, including nanofiltration. And the pre-treatment and post-treatment may vary based on certain plant. Nanofiltration membranes are usually applied near the end of the long line of water treatment process, while they are used as pretreatment for desalination. For the removal of trace organic contaminants, pretreatment of the feed is extremely important for nanofiltration, which is the main principle in nanofiltration design. Besides to avoid fouling, mechanical damage from solids or oxidization from disinfection can lead to severe effect on performance. Due to the pore size in nanometer range, soluble inorganic and dissolved organic components are the major foulant species (Speth, Gusses, & Summers, 2000). Even though fouling can be minimized, but not prevented, by adjustment of the parameters of filtration process (like module configurations, flow, pressure, pH and temperature) (Maartens, Swart, & Jacobs, 1999), a series of pretreatments are still necessary. In general, the pretreatment for nanofiltration can be designed based on same requirement of reverse osmosis.

In the water treatment, nanofiltration is usually not the final step; the post-treatment may be disinfection and/or pH adjustment. UV-disinfection is used as post-treatment more than chlorination disinfection method, which is installed as a back-up.

5. CONCLUSION AND PROSPECTS

In this chapter, the removal of emerging contaminants with nanofiltration in water and wastewater treatment was discussed. Emerging contaminants, as micropollutants with low concentration, should be rejected efficiently by nanofiltration based on the fundamental understanding of filtration mechanism. Extensive studies in various scale confirmed this repeatedly with different model compounds, nanofiltration membranes. The retention mechanisms and factors affecting the membrane's retention were discussed in many researches. Computer aided analysis also improved the modeling and prediction of the nanofiltration. High retention (complete removal in some cases) of almost all emerging contaminant groups indicates a promising potential of nanofiltration in this area.

On the other hand, these findings are most obtained from laboratory-scale researches, and direct application in water treatment industry is lacking. For the practical application, the pretreatment requirement, module design and post-treatment options are important research topics associating with nanofiltration technology, and urgently need investigations.

The implementation of nanofiltration in the industry is a success story even with several challenges in practice: 1) higher energy consumption than ultrafiltration; 2) pre-treatment is needed; 3) nanofiltration membranes are a little more expensive than reverse osmosis membranes. Although it is unlikely to reach the total area of global, installed membrane for either reverse osmosis or ultrafiltration, it can be expected that large steps forward will be made in the soon future.

ABSTRACT

Landfill leachate is a refractory wastewater and highly polluted with heterogeneous materials which is harmful to the environment and living organisms. Thus, leachate requires efficient treatment system to ensure the quality of final discharge is within the standard limit. Moreover the treatment process must be cost effective in order to be accepted. Many treatment processes were examined for leachate treatment including biological, chemical and physical process. This chapter discuss the treatability of leachate using physical processes such as evaporation, flotation, adsorption, membrane, ultrasonication, air stripping. It can be concluded that physical processes are not recommended to stand alone for leachate treatment. Nevertheless, adsorption and membrane technologies are very effective for post treatment of leachate. Aeration, sedimentation, evaporation, and sonication can be used effectively as pre-treatment processes.

INTRODUCTION

Landfill leachate is considered as a highly polluted wastewater with heterogeneous contaminants that are harmful to the environment and living organisms. Typically, leachates characteristics varied according to the age of the landfill. The young leachate normally consists of biodegradable materials which are suitable to be treated by biological processes. However, intermediate and old leachate mostly contains of recalcitrant materials which are less biodegradable. Thus, physical or chemical treatment is a better solution for this type of contaminant (Bashir et al., 2014).

Satisfactory disposal of landfill leachate is dependent on its treatment prior to disposal. An acceptable treatment is required to avoidpollution of receiving waters to a level which might interfere with their best or future use (Bashir et al., 2014). Technologies for treating landfill leachate can be divided into three categories: chemical methods, physical methods, and biological methods. In this chapter, detail discussions concerning landfill leachate treatment via various physical processes are presented.

Physical methods of wastewater treatment achieve the removal of pollutants by using naturally occurring forces, such as gravity, electrical attraction, and van der Waal forces, as well as by using physical barriers (membrane technology). In general, the mechanisms involved in physical treatment do not result in the chemical structure changes of the target substances. In some cases, physical state is changed, as in vaporization. In other cases dispersed substances are caused to agglomerate, as happens during filtration. Physical methods of wastewater treatment include sedimentation, aeration, evaporation, flotation, and adsorption, as well as membranes (Woodard & Curran Inc., 2006).

The common examples of physical methods would be coarse screening to eliminate larger entrained objects and sedimentation (or clarification). In the sedimentation process, physical phenomena related to the settling of solid particles by gravity are allowed to operate. Usually, this process consists of simply holding a wastewater for a short period of time in a tank under quiescent conditions, allowing the heavier solids to settle, and removing the "clarified" effluent. Sedimentation for solids separation is a very common process operation and is routinely employed at the beginning and end of wastewater treatment operations. Another physical treatment process consists of aeration which is, physically adding air, usually to provide oxygen to the wastewater. Nevertheless, application of basic physical processes such as screening, sedimentation and aeration in treating landfill leachate is ineffective. This is due to the nature and the characteristic of the leachate. Therefore, in this chapter, the authors aim to discuss the mechanism, performance and usefulness of using other physical processes (e.g., evaporation, flotation, adsorption, separation via physical barriers, and sonication) in treating the landfill leachate. It should be noted that the additional physical phenomena used in the treatment of leachate consists of filtration (adsorption). The leachate is passed through a filter medium to separate the solids. As an example, the usage of sand filters or activated carbon filters to further remove entrained solids from a treated wastewater. Then, the flotation is used to float the surface area of the leachate and then skimming or physically remove it from the leachate was carried out as part of the overall treatment process. Moreover, evaporation, membrane technology, and ultrasound are commonly used as a post or a pretreatment of the leachate.

PHYSICAL TREATMENT PROCESSES

Short review and definitions of the most significant physical treatment technologies utilized for the landfill leachate treatment are reported in this section. Comprehensive discussions are presented to provide better understanding about each mechanism process, performance, and limitation.

Evaporation

An evaporation process seems to offer an attractive option for leachate treatment that can cover all ages of the landfill leachate. Evaporation is a treatment process that is able to utilize natural climate condition such as relative humidity, air temperature and wind speed (Alcântara & Castilhos Junior, 2014). The use of natural condition is the main benefit of this process because the operating cost of treatment plant can be reduced. Furthermore, there is no chemical addition required in the treatment process. However, the effectiveness of this process is very dependent to climate condition. Thus, it has been studied as an alternative treatment to the conventional or available treatment for wastewater including landfill leachate especially at the regions where it can be implemented effectively.

Natural evaporation process offered "zero liquid discharge" to the environment by deposing the leachate into open ponds allowing the water to be evaporated. In the past, natural evaporation ponds were used in the evaporation treatment process of landfill leachate. However, it was less sustainable because the leachate may percolate into soil and groundwater. Therefore, artificial ponds with lining were constructed. The combination of the solar heat and wind help in naturally evaporate the leachate and leave concentrated residual in the pond. However, the process is slow and takes a long time. Thus, very large surface area is required for the pond, which is the main disadvantage of this treatment process (Macedonio et al., 2011).Nonetheless, evaporation ponds also generate odour to the nearest town and stored high organic content of water. This is the main reason for more enhancement and development of the evaporation process.

Besides natural evaporation, the landfill leachate can be treated by mechanical evaporation using several unit operations (Afsharnia et al., 2012). The most common mechanical evaporation used is the vacuum evaporation. This technique also offers a high quality of final effluent (distillate water) with the lowest concentration of pollutants for the discharge. Currently, the integrated or combination of evaporation with other treatment and technique has been reported. These processes were aimed to increase the evaporation performance and the efficiency of pollutant removal in landfill leachate. As an example, different techniques such as sono-evaporation and the combination of vacuum evaporation and reverse osmosis were reported by Afsharnia et al. (2012) and Palma et al. (2002). Recently, the use of evaporation panel was suggested in the semiarid climate region (Juazeiro do Norte, Brazil) to increase the evaporation rate, efficiency of the system and whilst reduce the installation area of the leachate treatment (Alcântara & Castilhos Junior, 2014).

Natural/Solar Evaporation

The natural evaporation process has been widely used in mining, water and energy industries (Zeng et al., 2011). The evaporation process is very dependent on the climate condition where the amount of evaporation of the water surface is determined by temperature, wind velocity and humidity (Qasim & Chiang, 1994). It is also common that the evaporation rate decreases during rainy seasons. Hence, the

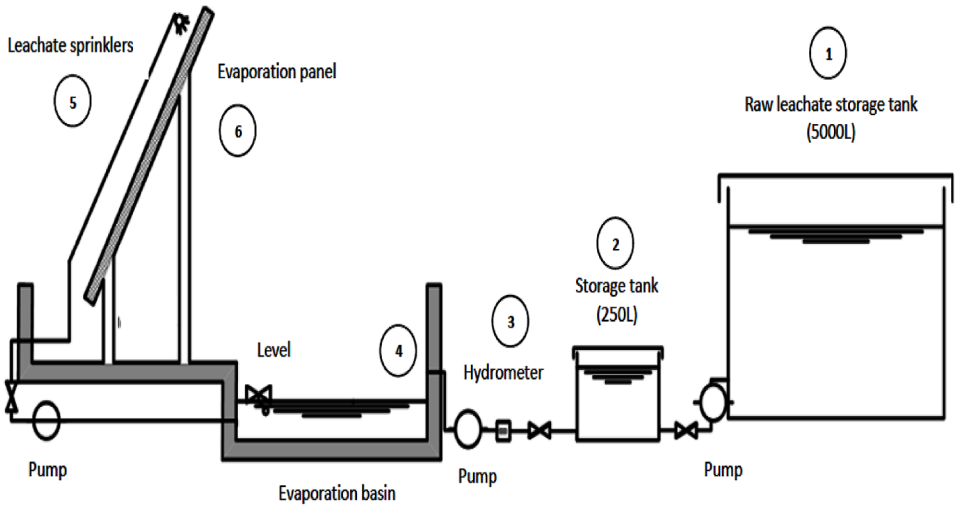
EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

data for these parameters, including rainfall at the selected locations have to be assessed prior to the installation of this treatment. Zazueta (2011) explained the function of each parameter of the evaporation process. The relative humidity is a measure within the range of 0 to 100 percent. The low percentage of relative humidity indicates that the air is dry (low moisture) while the high percentage value shows that the air has high content of moisture. Natural evaporation is more advantages at low relative humidity where the air is dry and has great capacity for moisture. Meanwhile, the wind enhances the evaporation rate by transporting water vapour away from the evaporation surface and surrounding areas. However, the treatment process usually suffers of low evaporation rate at regions with fewer feasible climate conditions. Consequently, a large area is required to increase the evaporation rate. Therefore, many studies have been conducted to enhance the evaporation process in order to reduce the land area for evaporation pond and increase evaporation rate.

According to Ranzi et al. (2009), the natural evaporation with panel is a recent technique that is developed for leachate treatment. The application of the evaporation panel is investigated in order to increase the volume of leachate treated through the natural evaporation especially during rainy seasons. This pilot experimental study was conducted in Florianopolis, Brazil which has a subtropical humid climate. The type of materials used for the evaporation panel play an important role to ensure large volume of water is evaporated. An example of the evaporation panel that has been used was polypropylene panel with beehive structure which has high specific area. The panel was installed at 60^{o} inclination (ideal angle) with the horizontal line to prepare the surface for leachate distribution. The entire medium was wetted by rotating sprinkler whilst the air made a contact with the moistened medium and adsorbed the humidity up to almost the saturation point. Excess liquid was returned to evaporation basin for recirculation. The average evaporation that has been obtained during this study was approximately 111 L/day. Figure 1 shows the schematic diagram for evaporation with panel as suggested by Ranzi et al. (2009).

In another study, an identical pilot plant study was conducted by Alcantra & Castilhos Junior (2014). The difference between both studies was the climate condition where this area has a semiarid climate. Based on their report, average daily evaporation of leachate in this area was3.2 times higher compared to the values obtained by Ranzi et al. (2009) at subtropical humid climate. This study confirmed the

Figure 1. Schematic diagram for evaporation with panel (Ranzi et al., 2009)



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

feasibility of evaporation with panel at semiarid climate. The evaporation efficiency can be calculated from Equation 1 &2 where natural evaporation, E_N (from evaporation pond), precipitation, P and volume of effluent, V_L introduced into the system were considered (Alcantra & Castilhos Junior, 2014). Total evaporation, E_T can be obtained by adding panel evaporation, E_P value and natural evaporation, E_N.

$$E_T = E_P + E_N \tag{1}$$

$$E_P = V_L + E_N + P \tag{2}$$

In addition, the contact area is another important factor that needs to be considered. In this case, the contact area referred to space between water and air where the evaporation process occurred (Alcantra and Castilhos Junior, 2014: Ranzi et al., 2009). Meanwhile Zazueta (2011) has explained the contact area through time available for evaporation to occur. As an example, the water sprayed at greater height and over greater distance has more time for the evaporation process. This is due to the physical-chemical reaction, where the greater contact surface between reagents, the greater velocity of the reaction. Thus, the increment of contact area will improve the performance of the evaporation process. This is the reason for a large size of evaporation pond and tall riser installation of sprinkler. Furthermore, the high sprinkler position has an advantage to fully utilized higher wind speed movement, which then increases the evaporation rate. Besides natural evaporation, another evaporation process method introduced for leachate treatment is mechanical evaporation.

Mechanical Evaporation

Initially, mechanical evaporation method is designed to simulate evaporation abilities to treat liquid with complex composition (Marks et al., 1994). The characteristics of leachate are important to design vacuum evaporation with optimum condition of operation. Commonly pH adjustment is necessary for prediction of vapor and liquid equilibrium for this treatment method. Acidic condition is effective to remove leachate with low volatile organic acids. Conversely, basic condition is better for leachate with high volatile organic acids. There is no optimum pH that suitable for both conditions. Therefore, the multiple stage of vacuum evaporation process may be needed to obtain satisfactory removal of pollutants in leachate. The concern parameters in vacuum evaporation are temperature range, pressure, vapor and liquid fraction and heat duty (Marks et al., 1994). According to Chiumenti et al. (2013), vacuum evaporation was operated by boiling a liquid substrate at negative pressure and temperature is lower than liquid boiling point at atmospheric condition. Basically, evaporation performance can be increased by increasing the temperature. However, the range of temperature that can be applied is limited because the boiling point of leachate is about 100°C at 760mm Hg. Hence the temperature of leachate in pre-heater stage should be less than 100°C unless it is pressurized in order to prevent boiling. Another concern is the steam pressure; as it should be within the reasonable temperature in order to convert the vaporization stage to condensation stage. If the temperature at the evaporation process is low, then the temperature at condense stage would be low too. Consequently, the amount of distillate production is small. Therefore, there is a need for the water recycle in order to obtain a high percentage of return effluent.

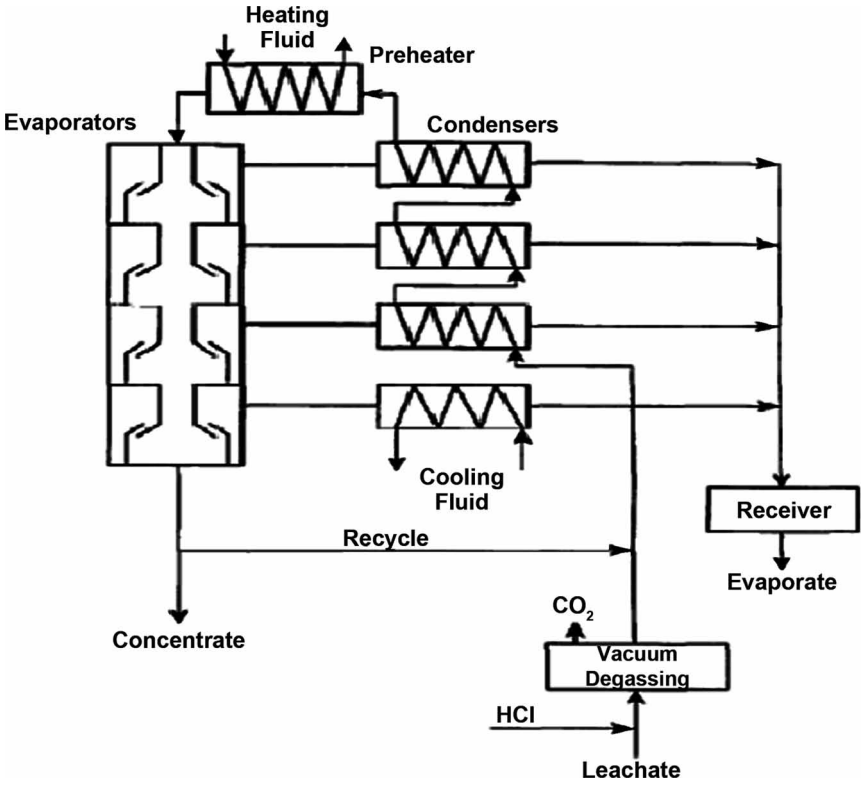
This method produces a high quality of distillate, but large amount of energy is required for the process which leads to high operating cost. In addition, leachate treatment using a vacuum evaporation process may be facing another problem which is scaling. Among developed evaporation technique, ap-

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

plication of force evaporation (leachate evaporated through heating) has been reported by Birchler et al. (1994). They utilized the thermal energy from methane gas production in the landfill to generate the heat for leachate evaporation. Laboratory study of forced evaporation shows that the process required the pH adjustment for optimum removal (e.g. ammonia can be removed effectively in acidic condition while COD and TOC were effectively removed in basic condition). Therefore, a series of evaporation process is needed to remove these pollutants. Figure 2 shows a schematic diagram of a force evaporation process that has been installed in Uttigen, Switzerland. Another study that has been conducted by Marks et al. (1994) focused on the development of a semi continuous batch model to predict evaporation and concentration quality through flash vaporization. Marks et al. (1994) mentioned that the mechanical evaporation process may offer an effective treatment for removing various pollutants in leachate using fewer unit operations compared to conventional method that has several treatments in sequent.

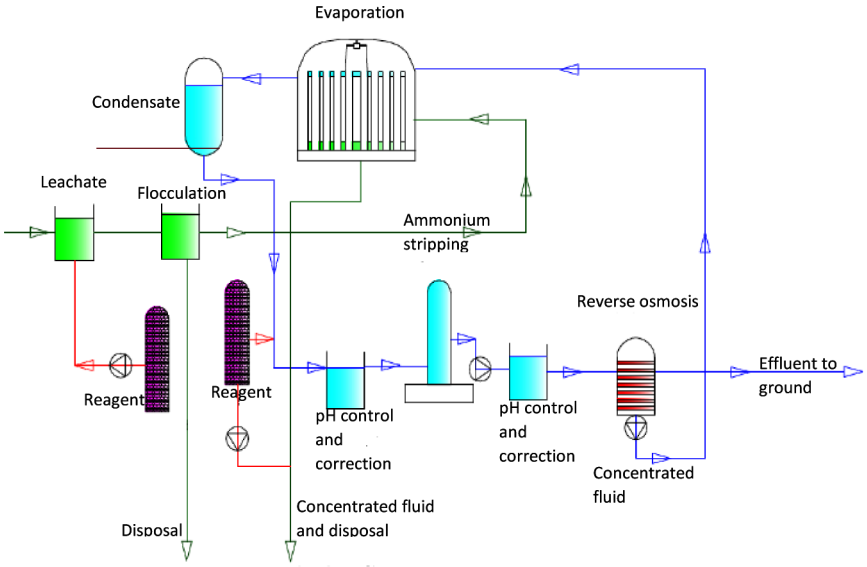
The process started by heating the leachate followed by the evaporation at the reduced pressure. After that, the vapors reached to an equilibrium stage with the residual liquid at the new lower pressure and temperature in the condenser, which produced a high quality of distillate. This study concluded that multi stage flash with recirculation and condensation heat recovery increase the efficiency of returned distillate and reduced the energy usage for steam and pumping. This treatment also leaves less residual/ sludge and produces distillate water that consists of low concentration of pollutants which is safe to be released to the environment. The application of two-stage vacuum evaporation in the leachate treatment was demonstrated by Messineo et al. (2012) as shown in Figure 3.

Figure 2. Schematic diagram for leachate treatment by force evaporation (Birchler et al., 1994)



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 3. An application of two-stage evaporation process in leachate treatment plant (Messineo et al., 2012)



To date, several studies reported that the mechanical evaporation technique is efficient for COD reduction (Afsharnia et al., 2012; Gutiérrez et al., 2007; Palma et al., 2002). Thus, it is recommended for wastewater with high COD contaminant. For example, Gutiérrez et al. (2007) reported that the vacuum evaporation process was able to reduce more than 99.5% of COD from oil in emulsion wastewater. The efficiency of this treatment is depending on the pressure and temperature setting during the process. In vacuum evaporation, the increment of temperature and pressure automatically increases the efficiency of this treatment process, but reduces its effectiveness in removing pollutants. In this case, the volume of distillate is increased whilst the quality of distillate is decreased where higher pollutants concentrations were detected in the distillate.

Besides that, mechanical evaporation processes have been facing scaling problems. Typically, the wastewater contains a large amount of dissolved and suspended solid which leads to high concentration as the water is evaporated. The presence of suspended solid and carbonaceous components in the system contributed to the fouling problem in the evaporator part (Li and Watkinson, 2011; Marks et al., 1994). The scale is formed within the evaporator boilers/ heater when a large amount of liquids is evaporated. Various ions such as Ca^{2+}, Mg^{2+}, SO_4^{2-} and SiO_2 also contributed to the scaling by forming salts during evaporation (Wang et al., 2014). Equations3 to 9 show the reaction between these ions that form crystalline salts which finally lead to scale formation (Wang et al., 2015; Huuha et al., 2010; Najibi et al., 1997).

$$Ca^{2+} + CO_3^{2-} = CaCO_3 \tag{3}$$

$$Mg^{2+} + CO_3^{2-} = MgCO_3(S) \tag{4}$$

$$Ca^{2+} + SO_4^{2-} = CaSO_4 \tag{5}$$

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$Mg^{2+} + 2OH^- = Mg(OH)_2(S) \quad (6)$$

$$SiO_2 + 2H_2O = Si(OH)_4 \quad (7)$$

$$Si(OH)_4 + OH^- = HSiO_3^- + 2H_2O \quad (8)$$

$$Si(OH)_4 + OH^- = H_3SiO_4^- + H_2O \quad (9)$$

The heat losses, which lead to the low heat transfer capacity increase the operating cost and reduce the system lifetimes, is the main drawback caused by scaling. To date, various ways of scale cleaning have been used including chemical, physical, and mechanical method such as deploying anti-scaling, ion-exchange, electric, and ultrasound/ magnetic fields to prevent this problem. The most common and easy method used is addition of scale inhibitors (anti-scalants) into the wastewater to prevent scaling. However, this chemical is less effective in the presence of calcium, magnesium carbonate and silicate scale (Wang et al., 2014; Macedonio et al., 2011).

Recently, Afsharnia et al. (2012) has indicated that ultrasound (sonication) is the best solution for scaling problem. This is because the technique has many effects on compounds in solution. Sonication technique is able to degrade chemical compound through oxidation by hydroxyl radical or by pyrolytic decomposition. As an example, volatile compounds that migrate into bubble usually degrade through pyrolytic reaction occurs within the bubble. Meanwhile non-volatile compounds tend to accumulate in the liquid phase and can be degraded via hydroxyl radical reaction. In terms of scaling prevention, sonication is used to reduce the scale effect by reducing the nucleation time of several materials that form scale. The scale has usually formed in the heating area of the heat transfer equipment which leads to mass crystallization (Zhang et al., 2014). The advantages of sonication technique are less energy consumption and free from chemical application. It is also reported that the combination of sonication with evaporation (sono-evaporation) is able to increase the efficiency of evaporation up to 96%.Furthermore, Wang et al. (2015) suggested that non-thermal plasma (NTP) pre-treatment prior to evaporation process should be implemented to reduce the scale effect. Wang et al. (2015) has studied the influenced of non-thermal plasma (NTP) pre-treatment in reducing the scale effect. Basically, NTP is able to degrade many organic compounds and oxidize several inorganic ions efficiently through a variety of physical (high electric field, intense ultraviolet radiation, an overpressure shock wave) and chemical (formation of radicals and molecular species) effects in water. Similar to sonication, no chemical was added to the evaporators. This technique demonstrates the alleviation of scale effect by removing crystalline matrix (silica) and change the morphology of scale (scale become loose).

Flotation

The flotation system was originally used in mineral (ore) processing for solid/solid separation using stable froth in the mining industries since 100 years ago (Matis and Peleka, 2010; Colic and Morse, 2007; Jameson, 1999). Meanwhile, the application of flotation in water treatment started as early as 1920 in Sweden based on a vacuum system (Haarhoff, 2008). This system was similar to dissolved air flotation (DAF), which is

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

the most common technique of flotation for water treatment today. However, the history of DAF system as is known to date, with the pressurized recycle to produce air bubble was started to be used in the beginning of 1960 (Edzwald, 2010).There are several differences listed by Rubio et al. (2002) between the flotation of ores and the flotation applied to water and wastewater purification including 1) size of bubbles generated to floated the particles, 2) shear rates, 3) stability of the froth at free surface and 4) bubbles surface area. Meanwhile, Matis and Peleka (2010) classified flotation technique into two categories which are dispersed air flotation/froth flotation (for minerals) and dissolved air flotation (for water).

The flotation techniques available are induced air flotation (IAF), electro-flotation (EF) and dissolved air flotation (DAF).More specific definition is given based on the types of floatation used. According to Rubio et al. (2002), IAF formed bubbles mechanically by a combination of high speed mechanical agitator and the injection system, while EF producing bubbles from electrolysis of diluted aqueous at both electrodes. However, in terms of flotation application in wastewater and domestic sewage treatment, dissolved air flotation (DAF) is the preferable flotation technique selected by civil and chemical engineers (Colic and Morse, 2007). Basically, DAF is a flotation technique that produces bubbles from reducing a pressure of water pre-saturated with air at a pressure higher than atmospheric (Leppinen and Dalziel, 2004; Rubio et al., 2002).

Firstly, DAF technique was applied as primary clarification method instead of settling process in several water treatment plants in Sweden, Finland, and Norway by the end of 1960s to 1970s (Edzwald, 2010). Since then, numerous research and studies have been conducted for DAF system development and advances. Many researchers conducted studies to investigate the potential of DAF in treating different types of wastewater. To date, the research has kept progressing to another stage and wider application of DAF system. As an example, Féris et al. (2004) studied the adsorptive particulate flotation process (APF) using 5 different adsorbents namely coal fines, coal shale, charcoal, barite and coal beneficiation tailing (CBT) for removing oils and dyes from synthetics and industrial effluents through 3 different floatation methods (e.g., IAF, MJF and DAF). Meanwhile, Zhang et al. (2014) evaluated that the efficiency of a pilot-scale bioreactor consisted of pressurized aeration and DAF (PA-DAF) for domestic wastewater treatment. There are several studies carried out for treating different types of wastewater via DAF as presented in Table 1 and 2. However, DAF is not the only flotation technique that has been improved and developed nowadays. An alternative flotation processes such as the IAF, MJF and EF have also been utilized in treating wastewater. Table 2 briefly described and list the studies that have been conducted to treat various types of wastewater using these techniques.

Even though flotation technology and application is now widely accepted and used in the purification of drinking water and wastewater treatment to remove pollutant such as colloids, ions, macromolecules, microorganism and fibres (da Rosa and Rubio, 2005; Colic and Morse, 2007; Liu et al., 2007), there are also information concerning on the application of flotation in landfill leachate treatment (Renou et al., 2008). Zouboulis et al. (2003) used flotation as the post treatment process for landfill leachate after biological treatment to remove humic acid (non- biodegradable material). In more recent years, the application of DAF as a treatment method for semi-aerobic landfill leachate was reported by Palaniandy et al. (2010). The study focused on the removing three parameters (i.e., colour, COD, and turbidity). The experimental studies were conducted in three phases starting with the saturator efficiency and the bubble volume concentration followed by the leachate treatment using DAF alone in the second phase. Third phase evaluated the effect of the coagulation process (using alum, $Al_2(SO_4)_3$) prior to DAF. Besides, the combination of ferric chloride ($FeCl_3$) coagulant with DAF was also investigated and reported by Adlan et al. (2011) to determine the efficiency of this technique in treating semi-aerobic landfill leachate.

Floatation Mechanisms

The flotation techniques differ according to the method used to produce the air bubble and its application. Generally, flotation technique was defined as gravitational separation process which is operated by increasing the difference of density between continuous phase and dispersed phase with an additional gas/ air into the wastewater (Painmanakul et al., 2010). The formed bubbles were attached to floc particles and reduced the density (lesser than the water), which allowing it to float to the surface of water (French et al., 2000). The common methods used to generate bubbles are electrolytic, dispersed-air and dissolved air as mention earlier. However, the discussion is focused on the most applied flotation method (e.g.,DAF) in wastewater industries which has more possibility for the leachate treatment. In DAF system, the tank design is divided into contact area and separation area. The contact area at the front end provides an opportunity for bubble-particle collision and attachment. This area is designed to allow enough residence time for the bubbles and particles to collide and attached (Colic and Morse, 2007). The flocsthat are formed during this process are called as bubble-particle agglomerates or floc-bubble-aggregates. These bubble-particles flow together with water and unattached particles into separation zone where the bubble-particles agglomerate rise to the surface of tank. The remaining agglomerates flow with water stream and separated in the filtration stage. High efficiency of floatation process will reduce the frequency of filter media backwash and increase filter lifetime (Leppinen and Dalziel, 2004). Figure 4 shows the schematic diagram in the common DAF system. The main factor that determined the effectiveness of flotation process (collisions and attachment of particles to bubbles) is bubbles properties which consist of shape, size, charge and bubble concentrations in the contact zone.

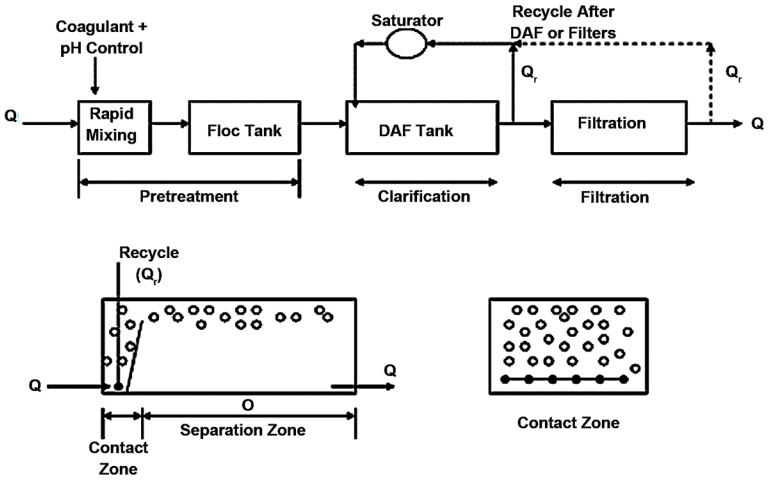
Figure 4. Schematic diagram of DAF system (Adopted from Edzwald, 2007)



Bubbles Shape and Size

In DAF, the effluent from separation zone is used as influent to saturator. This water is saturated with air at elevated pressures up to 5 atm (Colic and Morse, 2007). The bubbles are generated through reduction in pressure of the saturated water which forced to flow through small opening such as needle valves or special orifices (Leppinen and Dalziel, 2004). DAF usually generates small size bubbles which is less than 100μm. In contrast to DAF, larger bubbles are produced in IAF and dispersed air flotation with size of bubbles range between 2-5 mm and 1-10 mm respectively (Colic and Morse, 2007). The bubbles take a shape of sphere when it rises to the surface of water (Haarhof and Edzwald, 2001; Leppinen et al., 2001). Therefore, spherical shape concept was used in DAF models. As example, Leppinen model has assumed that bubble and particle that going to be removed are in spherical shape with density values of bubble typically larger than the density of particles. Thus, in order for agglomerate to rise in the same speed as a solid sphere with equivalent volume and density, the single particle need to have a number of bubbles attach to it (Haarhof and Edzwald, 2001). The shape and size of bubbles produce are basically depending on several factors such as rise velocity, heterogeneous nucleation, bubble growth, injection flow rate, and injection device (Edzwald, 2010).

The average size of bubbles occurs in the contact zone is in the range of 40 – 80 μm. However, if the saturator pressure is increased, the size of the bubbles produces will decreased.There is also a small growth in bubbles size when its float from the bottom to the surface of the water. The size of the bubbles can be calculated using Stoke's law through the measurement of rise velocity (Haarhoff and Edzwald, 2001). The small size of bubbles formed by DAF has an ability to capture a range of particles which made it useful for the removal of particulates in the wastewater. However, the used of small bubbles has a drawback, which is more time is required for the bubbles to rise to the surface. This conditions leads to a larger cell required for the treatment (Colic and Morse, 2007; Jameson, 1999). Thus, this method is inefficient to treat a large volume and high flow rates of effluents (da Rosa and Rubio, 2005). Despite of that, DAF is still more advantages compared to sedimentation process, especially for small particle (Liu et al., 2007). Leppinen et al. (2001) also stated that DAF is able to operate at higher loading rates

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

than sedimentation since the rise speed of flocs can be higher than the speed of individual particles. As a result, smaller surface area or larger flow rates tank can be designed. Currently, the DAF tank with higher loading rates (>20 m/h) more than the previous tank (5 to 10 m/h) are available (Edzwald, 2007).

Bubbles Concentration

The bubbles concentration is determined based on mass, volume and number. The mass concentration (Cb) in contact zone was used to evaluate the efficiency of air transport to the contactor. The bubble volume (Φb) and the number of concentration (n_b) are important theoretical variables in modelling the contact zone performance and estimating floc-bubble aggregate rise velocity (Edzwald, 2010). The mass concentration can be estimated from Equation 10 while the bubble volume and number are calculated based on the Equation 11 and 12, respectively. The same equations are used to determine the concentration of particle concentrations before and after the coagulation-flocculation process as explained by Edzwald (2007). Both calculations are made and compared to determine whether a sufficient number of bubbles available for the attachment to occur.

$$C_b = \frac{\left\{e\left(C_r - C_{s,air}\right)R - k\right\}}{1+R} \tag{10}$$

where

C_b = Mass concentration
e = Efficiency factor
C_r = Air in the recycle flow
$C_{s,air}$ = Saturation air concentration
R = Recycle rate
k= air deficit in the incoming flocculated water (If flocculated water is in saturation, then k=0)

$$\text{ } _b = \frac{C_b}{\rho_b} \tag{11}$$

where

Φ_b = Bubble volume concentration
C_b = Mass concentration
ρ_b = Moist air density for condition of 100% humidity and with the dew point temperature equal to the water temperature is used.

$$n_b = \frac{\text{ } _b}{\pi\left(d_b\right)^3 / 6} \tag{12}$$

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

where

n_b = Bubble number concentration
Φ_b = Bubble volume concentration
d_b = Mass concentration

Bubbles Interactions and Forces

According to Jameson (1999), the attachment mechanism in flotation involved of finite contact angle at the gas-liquid-solid contact line. Based on this concept, particles are made hydrophobic or non-wetting prior to the contact with bubbles. However, Edzwald (2010) stated that this concept is more suitable for IAF or dispersion air flotation where the produced bubbles are larger than 100 μm. In DAF, the repulsive and attractive forces exist between the bubbles or particles that influence the collision and attachment of the bubble-particle. Therefore, instead of wetting perimeter and/or contact angle, these repulsive and attractive forces are more important for the contact between bubbles or bubbles and particles. The bubble-bubble interaction is mostly related to coalescence. There are four types of forces and interactions that affect bubbles coalescence, which are Van der Waals, electrostatic, hydrophobic interaction and hydrodynamic repulsion.

The interactions and forces between the bubbles prevent/reduce the possibility of bubbles coalescence in the contact zone. Meanwhile, bubble-particle interaction and forces explain the collision and attachment of bubbles with particles in water. For air bubbles, the air are mainly consists of non-polar molecules (N_2 and O_2). Thus, molecular interaction has Van der Waals forces. Typically, the bubbles that are generated in DAF carry a negative surface charge. The same charge of bubbles creates electrostatic repulsive forces, which prevents the bubbles from approaching each other. It is hypothesized that negative zeta potential are caused by smaller anion that is resided at the bubble-water interface at a greater concentration than the larger hydrated cations (Edzwald, 2010). However, the negative charge at the bubbles surface can be changed to positive charge with additional of cationic surfactants or polyelectrolyte (Karhu et al., 2014).

Hydrophobic force is defined as the attractive affects bubble-bubble interaction as well as bubble-particle interaction. Despite of that, the origin of this force is unclear (Edzwald, 2010). Another force that affects bubble interaction is a hydrodynamic force/retardation. This force also called as the disjoining pressure, which explains the water between bubble that must be displace to ensure bubble coalescence or attachment of particle to bubble is successful.

Solubility of Air Bubbles

The solubility of air bubbles is also equivalently important. The recycled water entering saturator is normally in equilibrium with atmospheric air based on Henry's Law as describe in Edzwald (2007). Saturator needs to achieve steady state air composition in order to obtain high dissolution of dissolving air exit the saturator. However, the dissolving air in the saturator has kinetic mass (air) transfer limitation (Edzwald, 2010). Thus, 100% dissolution is impossible to be obtained. The efficiency of packed saturator and un-packed saturator is also different with an efficiency of 80-95% dissolving air for packed saturator and lesser for unpacked saturator (Edzwald, 2010).

Flotation Process Performance

The DAF combines with coagulation and flocculation is known to be a successful method for treating water supplies containing algae, organic matter, colour and low turbidity water. The successful/application of DAF in treating different types of wastewater containing oil, dissolved ions, fats and COD is also reported by numerous researches (Liu et al., 2010;El-Gohary et al., 2010). Recently, Palaniandy et al. (2010) investigated the application of DAF in treating semi-aerobic landfill leachate. DAF was used with the coagulation and flocculation process to treat semi-aerobic landfill leachate in term of COD, colour and turbidity. A DAF batch experiment was conducted in three phases consist of examination of saturator efficiency (1st phase), determination DAF treatment efficiency without coagulation-flocculation process (2nd phase) and evaluation of coagulation-flocculation process followed by DAF (3rd phase). Alum was used as the coagulant for this experiment. The un-packed saturator was used for this experiment. The maximum efficiency obtained for this saturator was 73% at saturator pressure of 400 kPa and flow rate of 6 L/min. In the 2nd phase of the testing, the maximum removal efficiency for COD, colour and turbiditywere36%, 33% and 32% at 600 kPa and 6 L/min of saturator pressure and flow rate, respectively. This result implies that the main content of semi-aerobic leachate used consists of mostly insoluble organic and organic matter (small particles). Thus, the DAF alone cannot be performed effectively. This is consistent with Leppinen (2001) statement, where larger particle increased the efficiency of DAF treatment. Therefore, the coagulation-flocculation process is required to increase the effectiveness of DAF treatment. The coagulation-flocculation process was used to destabilize the colloidal material and cause the small particle to agglomerates into larger particle. Thus in the 3rd phase, (coagulation-flocculation process was conducted prior to DAF) the removal of COD, colour and turbidity increased to 79, 70 and 42%, respectively. Besides that, low removal efficiency of the DAF system without the coagulation-flocculation can also be related to the interaction and forces in the collision attachment of bubble-particle as explained by Edzwald (2010) through a single collision efficiency concept. According to this concept, bubble and particle carry a negative charge without additional of coagulant which cause the repulsive force and prevent the bubble and particle to attract to each other.

Coagulation process is an important operating control variable in floatation efficiency performance. Consequently, good coagulation chemistry condition is required in the DAF treatment to formed particle and bubble of opposite charge (produce electrostatic attraction) which is similar to the application of coagulation before sedimentation in the drinking water treatment plant. However, water with high turbidity requires higher dosage of coagulant to increase flocculation kinetics and form a larger floc to settle rapidly (Edzwald, 2007). This is the reason of optimum coagulant dosage obtained during jar test in the leachate treatment was high (9.5 g/L). In contrast, the DAF only requires for the coagulant to formed little charge or neutral condition to produce van der Waals forces between different particles (solid/air), which provides a mechanism for the attachment.

Adlan et al. (2011) discussed the effect of different coagulant used in the coagulation process prior to DAF. In their study, ferric chloride was used instead of alum as the coagulant. In addition, treatment parameters such as pH, flow rate, injection time and coagulant dosage was optimized by response surface methodology (RSM) to obtain the maximum removal of COD, turbidity, colour and NH_3-N.It was concluded that the used of ferric chloride was better than alum for the coagulation process prior to DAF in treating semi-aerobic stabilize leachate.

Adsorption

For the past few decades, enormous amount of research have been conducted concerning application of adsorption process for leachate treatment. Earlier studies focused on activated carbon as adsorbent for the treatment process. Even today, activated carbon is the most efficient and preferable adsorbent for treating COD, heavy metals and NH_3-N. However, frequent regeneration of adsorption column and high price of activated carbon has increase the cost for the treatment process (Kurniawanet al., 2006). Therefore, low cost carbon like materials which are produce from agriculture waste such as rice husk, waste tea leaves, saw dust and bagasse ash were studied as an alternative adsorbent. Besides that, naturally available materials such as limestone and zeolite were also experimented as potential adsorbent for leachate treatment.

Fundamentally, adsorption is defined as the process of multi-components fluid (gas or liquid) mixture attached to the surface of adsorbent by physical or chemical bonding (Foo and Hameed, 2009). Previous studies on activated carbon shown that these materials have superior characteristics including vast surface area (1000 – 1300 m^2/g), large porous volume, controllable pore structure, thermo stability and low acid/base reactivity (Kurniawan and Lo, 2009; Foo and Hameed, 2009). These properties make it possible for activated carbon to remove various types of dissolved organic and inorganic pollutants in liquid and gases. Thus, it is widely used as commercial adsorbent in liquid and gas purification. According to the data reported by several researchers, activated carbon has high efficiency in removing organic constituents but less competent in removing ammonium nitrogen from leachates samples (Halim et al., 2010). Therefore, a number of potential adsorbent were investigated to find a new option to activated carbon for leachate treatment such as Zeolite, limestone, composite media, and etc. Whilst, there are also studies conducted to modify activated carbon surface to increase ammonia nitrogen removal efficiency or produce new composite media by mixing activated carbon with another adsorbent (Halim et al., 2010).

Preparation of Activated Carbon (AC)

In general, the process for manufacturing of AC involves two steps, carbonization of the raw material followed by the activation of the carbonized product. The activation process can be carried out in two ways, either by physical activation (Ph_A) or chemical activation (Ch_A). Pretreatment of the raw material normally conducted before carbonization process. Few preliminary stages involve crushing, milling and sieving for appropriate particle size are important for subsequent handling of the raw material(Alslaibi et al., 2013). During carbonization, the raw material will undergo thermal decomposition in inert atmosphere through gasification by Nitrogen gas. Carbonization process can be carried out using tubular furnaces, reactors, muffle furnace and more recently in a glass reactor placed in a modified microwave oven (Foo and Hameed, 2011). This process known as pyrolysis where the non-carbon elements such hydrogen, nitrogen and oxygen are released leaving a rigid carbon skeleton with a rudimentary pore structure. Based on previous studies, pyrolysis of lignocellulosic material such as olive stones, coconut shells or olive shells will remove most of non-carbon elements in the form of char, tar (oil) and gas where the proportion depends on the parameter during pyrolysis such as temperature of pyrolysis, nitrogen flow rate and heating rate.

Physical activation is normally made by carbonization followed by activation in partial or control gasification at high temperature (Rodriguez-Reiniso and Molina-Sabio, 1992). Activation completed through gasification using oxidizing agent or mixture of it at temperature ranging from700-1100 ^oC to develop the porosity (micropores and mesopores) of the carbonized material (Rodrigues-Reinoso and

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Molina-Sabio, 1992). CO_2 can develop narrow micropores, while steam will widen the initial micropores. Accordingly, CO_2 produced larger volume and narrower micropores (Mohamed et al.,2010) while steam created a larger volume of mesopores and micropores. Meanwhile, in Ch_A, carbonization and activation can be run simultaneously, where the raw material will be impregnated with chemical agent followed by conventional heating at moderate temperature between 400-800^{o}C (Demiral andGunduzoglu, 2010). The chemical agent acts as a deactivating agent where it inhibits formation of tar and develops AC porosity via dehydration and degradation. The pore distribution and surface area is determined by the impregnation ratio between the mass of precursor and the chemical agent chosen. The resulting AC produced is then washed with distilled water or mild acid in order to remove residual chemicals from the material. Nowadays, chemical activation is widely applied for the activation because of its lower activation temperature and higher product yield compared with the physical one (Guo and Rockstraw, 2007). Some additional studies combine the physical activation with chemical activation where it is known as physicochemical activation. In general, physicochemical activation is performed by changing the activation atmosphere of the chemical activation by a gasification atmosphere (steam, CO_2) at higher temperatures or the chemical activation is carried out directly under the presence of a gasifying agent. The combination of both types of carbon activation makes ACs with textural and chemical properties which are different from those obtained by any of the activations alone.

Interactive Behavior and Mechanism of Adsorption

Adsorption can be defined as a mass transfer process by which, a substance is transferred from the liquid or gas phase to the surface of a solid adsorbent and form attachments via physical or chemical interactions. The material removed from the liquid phase is called the adsorbate and the material providing the solid surface is called the adsorbent.

The applicability of a basic theory depends more on the mode of operation than on the particular mechanism of solute uptake. A significant feature of physical adsorption is that the rate of the phenomenon is generally too high and thus, the overall rate is controlled by mass (or heat transfer) resistance rather than the intrinsic sorption kinetics. Therefore, sorption is observed and termed as a "diffusion-controlled" process. In general, there are two types of adsorption i.e. physic-sorption and chemisorption (Seader and Henley, 1998).

1. Physisorption occurs when Van der Waals forces physically attract the adsorbate to the solid adsorbent overcoming the kinetic forces of the adsorbate in the liquid. This can result in either monolayer or multilayer adsorption.
2. Chemisorption occurs when a product of a chemical reaction between the adsorbate and the adsorbent results in a monolayer

Adsorption equilibrium may be modeled with the most commonly applied models i,e. Langmuir and Freundlich isotherm models (Shao et al., 2008; Shi et al., 2009). These two models were originally developed from adsorption. According to Droste (1997), adsorption isotherm describes the relationship between the amount or concentrations of adsorbate that accumulates on the adsorbent and the equilibrium concentration of the dissolved adsorbate. The amount of adsorbate accumulated on the adsorbent is calculated by the difference between the amount present in the initial adsorbate concentration and that remaining in solution after equilibrium with the adsorbent i.e.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$q_e = \frac{\left(C_o - C_e\right) V}{M} \tag{13}$$

where, q_e is the amount of solute adsorbed per unit weight of adsorbent (mg/g), C_o is the initial adsorbate concentration and C_e is the equilibrium adsorbate concentration (mg/L), V is the volume of solution (L), M is the mass of adsorbent (g).

Langmuir Isotherm

The Langmuir isotherm theory assumes monolayer coverage of adsorbate over a homogenous adsorbent surface. A basic assumption is that sorption takes place at specific homogenous sites within the adsorbent.

The Langmuir isotherm can be written as follows:

$$\frac{1}{m} = \frac{QbC}{1 + BC} \tag{14}$$

The linear form of Langmuir isotherm can be written as follows:

$$\frac{1}{(x/m)} = \frac{1}{QbC} + \frac{1}{Q} \tag{15}$$

where x is the amount of material adsorbed (mg), m is the weight of adsorbent (g), C is the equilibrium concentration of adsorbate in solution after adsorption is complete (mg/L). In Langmuir isotherm models, b and Q refers to sorption energy and sorption capacity estimated from the linear relation between (1/(x/m)) and $1/C_e$,

Freundlich Isotherm

The Freundlich isotherm is an empirical equation assuming that the adsorption process takes place on heterogeneous surfaces.

The Freundlich isotherm can be written as follows:

$$\log q_e = \log K + \frac{1}{n} \log C_e \tag{16}$$

Ceis the equilibrium adsorbate concentration (mg/L); x/m is equilibrium amount of the adsorbate, K is roughly an indicator of the adsorption capacity mg/g (L/mg)1/n); 1/n is the constant indicative of the intensity of the adsorption. A value for $1/n < 1$ indicates a normal Langmuir isotherm while $1/n > 1$ is indicative of cooperative adsorption. The plot of log q_e versus logC_e gives a straight line with slope of 1/n. A value of K can be calculated from the intercept value.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

The Freundlich isotherm is based on the assumptions that the adsorbent had a heterogeneous surface composed of different classes of adsorption sites with adsorption on each class following the Langmuir isotherm (Benefield, 1982). The Freundlich isotherm describes reversible adsorption and it is not restricted to the formation of the monolayer (Chen et al., 2003).

Kinetics Models

The experimental efficiency is controlled by the kinetics of adsorption. Several kinetic models are available for predicting the mechanisms involved in the adsorption process. The most commonly used kinetic models are pseudo-first-order and pseudo-second-order and intra-particle diffusion model (Shao et al., 2008).

The pseudo-first-order model:

$$\log(q_e - q_t) = \log(q_e) - \frac{k_1 t}{2.303} \tag{17}$$

The pseudo-second-order model:

$$\frac{t}{q_t} = \frac{1}{k_2 q_e^2} + \frac{t}{q_e} \tag{18}$$

where q_e and q_t are the amount of pollutants adsorbed at equilibrium (mg/g) and at time t, respectively. k_1 (min^{-1}) and k_2 (g/mg min) are the equilibrium rate constants of pseudo-first-order and pseudo-second-order models, respectively.

Traditionally, the kinetics has been described by the first order equation typical of that derived by Lagergren in 1898. In recent years, pseudo-second order rate law has been considered as one of the most appropriate models (Ho and McKay, 1999). Normally, Pseudo first-order kinetic explains that adsorption is due to physisorption-type mechanism (Rao et al., 2002). The pseudo second-order rate indicates how the adsorption capacity of theadsorbate depends on time.

Intra-Particle Diffusion

Intra-particle diffusion is generally characterized by a relationship between the solid phase concentration (q_t) and the square root of time (Kobya, 2004). It can be written as:

$$q_t = k_{id} t^{0.5} \tag{19}$$

where, q_t is the percentage of adsorbate adsorbed (mg/g/$min^{0.5}$), t is the contact time and k_3 is the rate constant for intra-particle diffusion (1/min). Kobya (2004) reported that the higher values of k_{id} indicate an enhancement in the rate of adsorption while large values show better adsorption mechanism which means that the bonding between the adsorbate and the adsorbent is very strong.

Process Performance

It is found that 91% of COD was removed from landfill leachate via granular activated carbon (GAC) (Morawe et al., 1995). Meanwhile, application of activated carbon in powder form was conducted by Diamadopoulos (1994). About 95% of COD removal was achieved during his study. Table 3 summarized related study to adsorption of landfill leachate using different types of adsorbents. Additionally, Kargi and Pamukoglu (2004) reported that PAC exhibits better performance in COD removal compared to powder zeolite in combined adsorption and biological treatment leachates. In contrary, powder zeolite shows significantly better removal efficiency of NH_3-N compared to PAC in the study (Kargi & Pamukoglu, 2004).

Another comparative study was experimented between GAC and limestone for NH_3-N removal using semi-aerobic landfill leachate from PulauBurung (Aziz et al., 2004). This study revealed that GAC is a superior adsorbent than limestone for NH_3-N removal. In conclusion, the effectiveness of adsorbent for NH_3-N removal can be arrange as zeolite > activated carbon > limestone.

Wassay et al. (1999) examined removal of heavy metals in leachate using GAC, granular activated alumina (GAA) and ferric chloride solution. Only GAC shows high removal efficiency of Cd(II), Cu(II), Mn(II), Pb(II) and Zn(II) with the removal percentage ranging from 78 to 96%. Based on the equilibrium study, adsorption capacity of GAC for heavy metals was 21 mg/g and 19 mg/g for Freundlich and Langmuir isotherm model, respectively.

Lately, the study conducted is more focus on the investigation of other adsorbent such as limestone, zeolite and activated alumina, or low cost adsorbent obtained from waste materials such as rice husk ash, bagasse ash and synthetic zeolite. Several factors including high cost of activated carbon, low removal efficiency of NH_3-N by activated carbon, high consumption of activated carbon, frequent regeneration and existing/ availability of materials for low cost adsorbent has driven many researches to find an alternative adsorbent (Li et al., 2010; Halim et al., 2010). Application of low cost adsorbent from coal fly ash for removal of heavy metal ions was reported by Mohan and Gandhimathi (2009). This study shows that 2 g/L of fly ash has a removal efficiency of 39%, 28%, 74%, 42% and 71% for Cu, Mn, Pb, Zn, and Cd, respectively. It is less effective compared to activated carbon in removal of heavy metals as reported by Wassay et al. (1999). However, the results showed that this material has a potential as alternative adsorbent for heavy metal removal in landfill leachate. Currently, low cost adsorbent is extensively study by many researches as an alternative to activated carbon.

PHYSICAL BARRIERS (MEMBRANE TECHNOLOGY)

The conditions of the leachate nowadays which contains harmful chemicals and higher toxicity reach a level where higher purification is needed to protect the environment. Such higher level of purification can be achieved by membrane technologies. A membrane is defined as a material that forms a thin wall capable of selectively resisting the transfer of different constituents of a fluid and therefore, affecting the separation of the constituents (Visvanathan et al., 2000). Normally, the best physical structure of the membrane material is based on a thin layer of material with a narrow range of pore size and a high surface porosity. Various membrane processes that are applied in landfill leachates treatment are; microfiltration (MF), ultrafiltration (UF), nanofiltration (NF) and reverse osmosis (RO). The membrane filtration has proved to be feasible and economic solution, and have been applied all over the world (Ushikoshi et al., 2002; Košutić et al., 2014).

Microfiltration (MF)

Typically, MF (pore sizes; 50-150nm) is applied to filter microbial cells, large colloids and small particles. MF is not appropriate to be used for leachate treatment alone. However, it is strongly required as a pre-treatment method with another membrane process (UF, NF or RO) or in conjunction with chemical treatments in order to eliminate colloids and suspended matter. Ameen et al. (2011) applied the microfiltration

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

as polishing stage after biological treatment of leachate. The MF is capable of extensive removal of solids and suspended matters. In spite of its excellent removal, the MF might not be able to sustain over long period of operation because of physical fouling which causes permanent damage and deterioration to the membrane. Therefore, air-diffuser was introduced to minimize the build-up of particles on the membrane surface. However, the usage of MF was questionable when partnership with other finer filtrations. Previous work by Piatkiewicz et al. (2001) who applied a sequence of membrane filtrations (MF, UF, and RO) concluded that the installation of MF before the UF is unnecessary since the performance of post-treated by the sequence of MF and UF was insignificant as compared with UF alone. Furthermore, their MF required back-flushing every 15 mins to keep the consistency of the filtration rate. The retention time was between 25-35%. Another drawback, MF was unable to effectively treat dissolved organic and inorganic impurities. Thus, hybrid MF-PAC (microfiltration-powdered activated carbon) was introduced to remove microbial contaminants, turbidity and dissolved organic substances. This technology requires less energy consumption as compared with RO and NF, but offers similar organic removal efficiencies (Ince et al., 2010). Visvanathan et al. (1994) reported that about 89.1% COD removal can be achieved by this technology.

Ultrafiltration (UF)

UF is highly efficient to eliminate the macromolecules and tiny particles. It is highly dependent on the construction materials. The UF is commonly installed before the RO or NF/RO system (Bohdziewicz et al., 2001). Since RO has smaller pore size, its fouling-resistance against large molecular weight components of leachate is quite low, in which the UF can be used to minimize the impact. Several studies have applied UF in hybrid processes such as activated sludge-UF-chemical oxidation and activated sludge-UF-RO (Renou et al., 2008).The UF is also exposed to fouling. Previous study indicated that the fouling layer after leachate treatment was 99% inorganic (Syzdek and Ahlert, 1984). The layer did not hinder the passage of organic carbon across the membranes but still resulted in a pressure drop and lower flux. In order to minimize the fouling, the shearing rate could be continuously applied on the membrane surface. According to Bohdziewicz et al. (2001), the installation of UF after biological treatment of landfill leachate was able to remove COD, suspension, and dry matter up to 50, 100 and 7%, respectively. The complete removal of dry matter was very effective to protect and prolong the operations of the subsequent purification by NF/RO system.

Nanofiltration (NF)

Owing to its properties between UF and RO, NF has a place in the removal of recalcitrant organic compounds and heavy metals from leachate (Marttinen et al., 2002). In general, NF has a high rejection for sulphate ions and dissolved organic matter but very low for chloride and sodium. The rejection depends strongly on the solute type, charge valency, diffusion coefficient, and hydration energy. The feed pH of the leachate is critical to control since it influences the charge of the membrane which is closely related to its rejection capacity (Chaudhari & Murthy, 2010). Several studies have applied NF to treat landfill leachate. A recent study applied NF to treat leachate showed more than 85% rejection of total suspended solids, heavy metals, conductivity, and COD. However, the rejection for nitrate and ammonia nitrogen was much lower at 45.4% and 20.5%, respectively (Mohammad et al., 2004). The overall process can be improved if combined with conventional biological-physicochemical treatment. The molecular weight cut-off (MWCO) of NF is also important to be considered as found by Ince et al. (2010).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Previous study combined NF with electro coagulation to treat landfill leachate (Mariam and Nghiem, 2010). The treatment resulted in 67% and 80% of TOC and turbidity removals, respectively, which were an improvement from conventional chemical coagulation. It indicated that electro coagulation is also able to mitigate the fouling on NF. Unlike RO, NF technology has a looser membrane structure enabling higher fluxes and lower operating pressure for the treatment of leachate (Kurniawan et al., 2006). The main problem of NF technology is the membrane fouling.

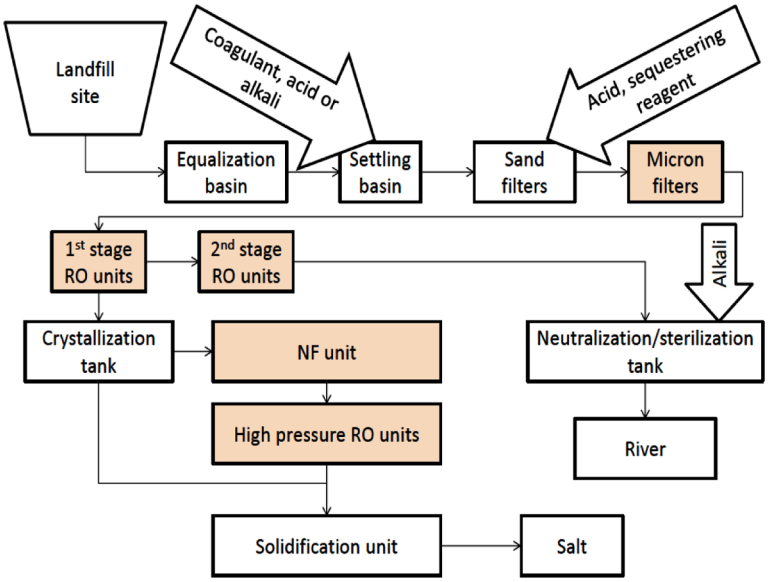
Reverse Osmosis (RO)

Reverse osmosis is able to reject heavy metal concentrations at high efficiency. The usage has started since 1984 where tubular and spiral wounded modules were used to treat landfill leachate. In 1988, Pall-Exekia developed a disc-tube-module to allow the system to be cleaned from scaling, fouling and bio-fouling in an effective manner (Peters, 1996). Basically, RO is used to post-treat effluent of NF and operated at high pressure (Ushikoshi et al., 2002). Example of application of RO units in the treatment of landfill leachate is shown in Figure 5.

RO was applied to treat biological-treated leachate to increase its corresponding effluent quality to meet local standard. The system managed to reduce 97% of COD and 60% of BOD levels. However, the RO was ineffective in removing Total Nitrogen (N_{tot}) to the below discharge limit. In addition, NF was used to produce similar outcomes but better removal of P_{tot} and N_{tot} than RO (Kuusik et al., 2014). The RO was also effective in removing dioxins (99.9%) from leachate (Ushikoshi et al., 2002).

Košutić and his group (2014) utilized RO/NF to further treat effluent of coagulation and filtration treatment of leachate. The yellow effluent turned out colorless after the RO treatment along with significant reduction of the COD, NH_4^+-N, turbidity, pH, TOC and traces of heavy metals which were in compliance with the local standards. The COD was reduced for more than 94.6%. The heavy metals removals were assisted by anion rejection had by the charged NF membranes.

Figure 5. Leachate treatment system at Yachiyo (Ushikoshi et al., 2002)



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

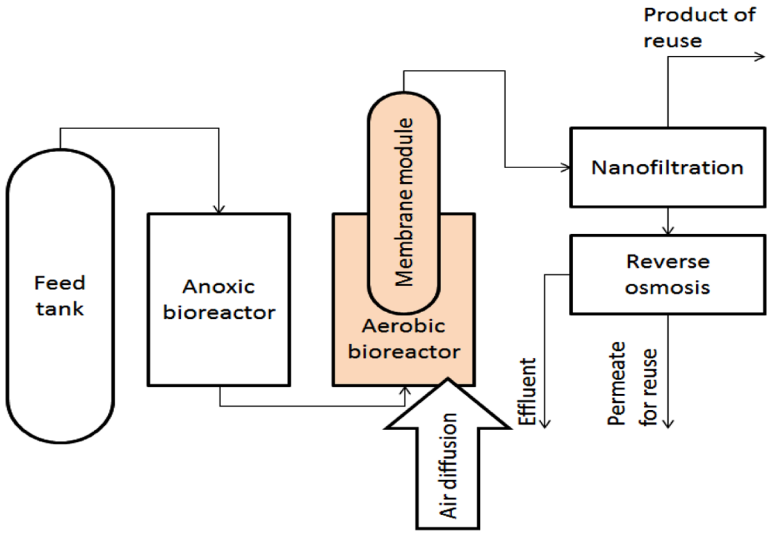
According to Chianese et al. (1999), the operating pressure of RO has effects on the removal efficiency of COD. Higher COD level can decrease the permeate flux through the RO membrane. However, the rejection of COD could be increased by increasing the operating pressure. The work reported an increase of COD rejection from 96 to 98% when the operating pressure was increased from 20 to 53 atm. However, the removals of heavy metals (Cu, Zn, and Cd) were not heavily affected by the increased pressure. RO technology was reported as the most effective in COD removal among different physico-chemical processes evaluated.

Membrane Bioreactors (MBR)

Membrane bioreactor is the combination of membrane separation technology and bioreactors. It is capable to process high concentration of biomass with a low sludge production and outstanding effluent quality. The bioreactor itself functions to effectively decompose the non-biodegradable large molecular organic matter of leachate (Wang et al., 2014). It is an efficient anaerobic biological digestion system by retaining most microbial cells in the reactor to digest high biomass concentration (Ahmed and Lan, 2012). It is capable of treating raw leachate with COD of 13,000 mg/L and achieved removal efficiency of approximately 60% at steady performance (Xie et al., 2014). Figure 6 shows the schematic diagram of MBR combined with NF/RO process. From the diagram, the MBR is placed as the first filtration treatment prior to NR/RO system. Effluent from MBR treatment alone is not enough for safe discharge. Bohdziewicz et al (2008) reported COD removal over 95% using anaerobic submerged membrane bioreactor. However, the removal efficiency degraded as the leachate concentration was increased due to inhibition of microbiological activity.

Like other filtration membranes, the MBR is also susceptible to fouling. In previous study, the MBR was integrated with granular activated carbon (GAC) to assist the treatment of landfill leachate. The presence of GAC at correct dosage could minimize the impact of fouling on the MBR, besides improving the efficiencies of removals of COD and heavy metals (Cd, Cu and Cr). The impact was minimized due

Figure 6. Schematic diagram of anaerobic MBR combined with NF/RO process (Wang et al., 2014)



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

to the improvement of settleability and compatibility of flocs, as well as the increase in particle size. The removal rate of COD and NH_3-N were approximately 90% and 81%, respectively, and relatively stable during the 40 days of process (Wang et al., 2014).

A number of leachate pilot trials have been conducted. Two full scale MBR leachate treatment plants are due to become operational in the UK in 2006. More than 50 full-scale plants have been constructed in Germany, France, Spain and other countries. The main drawbacks of membrane technology and RO implementation in landfill leachate treatment are membrane fouling (requiring extensive pretreatment or chemicals for periodic cleaning of the membranes resulting in a short lifetime of the membranes and decreased process productivity) and the generation of large volume of concentrate which is unusable and has to be discharged or further treated. Also, the membranes required high energy consumption as it needs high operating pressure which shortens the life of the membrane (Renou et al., 2008).

ULTRASONICATION

Basic Principles

Ultrasound is the term given to sound waves above 20 kHz which is the frequency above the range audible to human being. Depending on the application and frequency, ultrasonication is broadly divided into three areas: i) low frequency or conventional power ultrasound (20-100 kHz), (ii) medium frequency or sonochemical effects ultrasound (300-1000 kHz) and iii) high frequency or diagnostic ultrasound (2-10 MHz) (Mason and Lorimer, 1988; Peng et al., 2014). The effect of ultrasound in liquid medium was first recognized by Alfred L. Loonis in 1927.However, the major development in sonochemistry took place in 1980s after the arrival of inexpensive high-intensity ultrasound generators. Recently, the majority utilization of ultrasound in chemical reaction includes synthesis (organic, organometallic and inorganic), polymer chemistry (degradation, initiation, and copolymerization), and nanomaterial preparation and some aspects of catalysis (Mason and Lorimer, 1988).

There are three possible reaction sites in ultrasonically irradiated homogeneous liquids: i) the gaseous interiors of collapsing cavities; ii) the interfacial liquid region between cavitation bubbles and the bulk solution, where high temperature and high temperature gradients exist; and, iii) the bulk solution at ambient temperature, where small amounts of hydroxyl radicals (•OH) diffuse from the interface. The high temperatures (5000 K) and pressures (1000 atm) induced by cavitation in collapsing gas bubbles in aqueous solution lead to the thermal dissociation of water molecules into hydrogen radicals (•H) and hydroxyl radicals (•OH) (Pang et al., 2014; Wang et al., 2008). The removal of pollutants was completed through the production of radicals in the bubble of cavitation that can react with refractory compounds. Sonication in aqueous condition triggers rapid formation, growth, and violent collapse of cavitation bubbles (Figure7).

The implosion of cavitation bubbles produces high energy shockwaves within interfacial films surrounding nearby solid particles. The shockwave has the potential to create microscopic turbulence which highly capable of disintegrating the nearby solid particles besides releasing extreme temperature (Mason and Lorimer, 1998). These chain reactions are known as sonochemical effect where pyrolytic decomposition occurs inside the bubbles. Further details of the phenomena and related theories can be found in Mason and Lorimer (1998)and Sridhar et al. (2010).

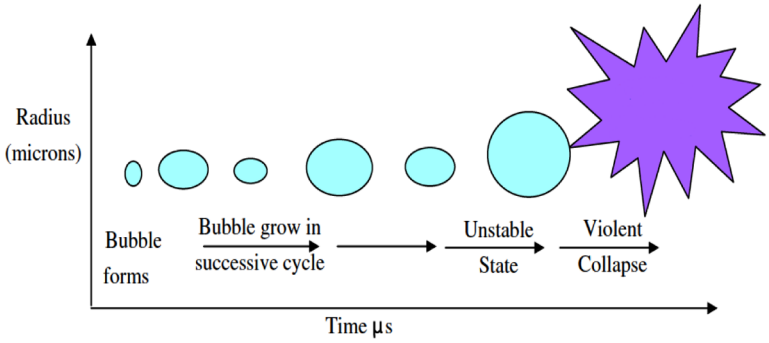
Figure 7. Development and collapse of the cavitation bubble (Sridhar et al., 2010)

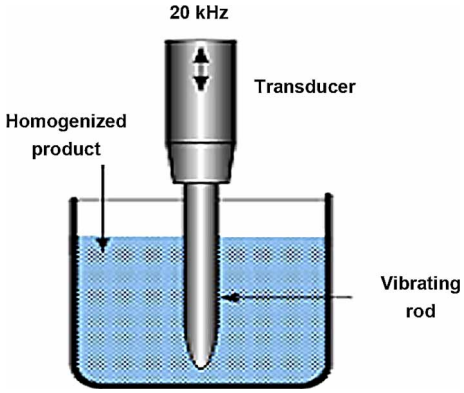


Treatment Efficiency

In environmental engineering, it is used to disintegrate organic contaminants present in water or wastewater which includes leachate treatment. In lab scale experimentation, the source of sonication was introduced directly to the treatment by a probe placed inside the treatment tank or simply immersing the tank itself inside an ultrasonic homogenizer as shown in Figure 8.

In general, the use of ultrasound to degrade chlorinated aromatic and aliphatic compounds, phenol, chlorophenols, nitrophenols, and organic dyes has been reported and well-summarized by Chowdhury and Viraraghavan (2009). The application of sonication has also been extended in the treatment of landfill leachate but presently, available reports are very limited indicating vast opportunities for further investigation (Oz and Yarimtepe, 2014). Wang and his group reported the removal of organic matters and ammonia nitrogen from landfill leachate (Wang et al., 2008). After 180 min of sonication, the removal of ammonia nitrogen reached up to 96%. The ammonia nitrogen was suspected to partly degrade through thermal reactions triggered inside the bubble of sonication. The COD reduction increased depending on the power input which was up to 16% of removal at 150W. The sonication is actually meant to assist thus, it was paired with other processes. Gonze et al. (2003) utilized ultrasound to treat biologically pre-treated landfill leachate as additional treatment since it consumes a lot of energy. The sonication increased the toxicity of the effluent at the beginning of treatment due to the formation of

Figure 8. Ultrasonic homogenizer (substech, 2015)



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

toxic intermediate products. The removal of TOC (70%) and COD (70%) were improved significantly, and it enhanced biodegradability.

The usage of sonication as pre-treatment was also applied to enhance biodegradation of refractory compounds in leachate, which in turn enhanced the treatment efficiency during anaerobic digestion process (Bohdziewicz et al., 2005). The sonication prior to fermentation increased the COD removal efficiency by 7%. The increment was believed to be originated from the changes of chemical structure of slow biodegradation compounds triggered by the sonication. Another pre-treated sonication was studied by Neczaj et al (2007) in partnership with sequencing batch reactor (SBR). Under different modes, the sonicated condition consistently provided enhanced removal rates of COD (80-92%) and nitrogen compounds (67-75%). However, the increment was less than 10% which might not economically feasible since larger energy was consumed. Afsharnia et al. (2012) examined the effect of sonication on the leachate evaporation by distillation. Their experiment rig is as shown in Figure 9. With 25 kHz and 500W and within 10-40 min, the sonication was able to enhance the COD reduction from 84 to 88%. The sonication however, has no effects on electrical conductivity (EC) and heavy metal reductions.

Ammonia Air-Stripping

Ammonia stripping is driven by concentrated aeration of treated leachate at high pH (10.5 –11.5).The practice is very capable removing high ammonium levels. The process is running in the stripping tower, filled with aerated media, which is overflowed by leachate. Treated leachate is collected at the bottom of the tower and gases raise up to the top. The air,polluted with ammonium, has to be treated with sulphuric or chloric acids. Recirculation of treated leachate is often needed to attain discharge limits. Ammonia stripping could be cost-efficient only at very high ammonium levels in the wastewater. Costs are spent on lime addition for increasing pH before the treatment and acid addition afterwards (www.leachate.co.uk, 2014).

HOW TO USE OF PHYSICAL TREATMENT PROCESSES EFFECTIVELY

In general, physical processes contribute effectively in trading landfill leachate. Nevertheless, physical processes are not sufficient to meet the final discharged standard. Thus, normally a combination of several biological, chemical and physical processes is used to treat leachate. Physical pretreatment methods are particularly useful in treating leachate from older/closed landfills that have lower biodegradable organic carbon, or as a polishing step for biologically treated leachate. For example, the most efficient processes (E.g., adsorption and RO) are not recommended for highly concentrated raw leachate due to the operational cost and commonly used for post treatment of landfill leachate in particular prior to discharge to surface water.

In adsorption process via activated carbon, back-flushing is vital as the surface of the carbon becomes coated with the impurities and it avoids clogging. The disposal of the carbon and the flushing effluent should be tackled as they required significant cost. Thus, the process is mainly suitable for: (i) The removal of hazardous organics from industrial leachate and (ii) Removal of color and residual refractory TOC and COD from stabilized leachates. Under optimum conditions, carbon adsorption can achieve99% removal of most organic contaminants but, the capital outlay for their installation is very high and running costs can be high too (EPA, 2000).

RO can be used to cut the amount of a leachate by producing a smaller amount of more concentrated solution "brine" which can comprise 25 to 40% of total amount. It should be noted that the membrane used is very brittle, has a limited life of about 2 years and is susceptible to blockage and pollution; and would only be appropriate at the later stages of a treatment facility in combination with evaporation. Applications of RO may be suitable for leachates with a high inorganic loading and low volumetric flowrates. The capital and running costs of fixing such system would be high. Provision is required for the treating or disposing of the highly concentrated liquors which would be created (EPA, 2000).

In the evaporation process, the leachate is evaporated by a low heat source and separated into distillate and concentrate. The distillate may require additional treatment before discharge as it would include any volatile substances left in the leachate after pre-treatment; and the concentrate could be distilled more into distillate and sludge, the sludge requiring either thermal treatment or disposal to landfill. The practice has not been broadly adopted as it is expensive and like RO, a pre-concentration technique producing a condensate or sludge residue which must be disposed of. Accordingly, there is little design information accessible on this treatment technique (EPA, 2000).

The application of floatation process in wastewater treatment is increasing. Nevertheless, wastewater has a wide range of pollutants since it come from different sources which make it difficult to be treated. At present, the most common floatation technique applied for wastewater treatment is coagulation-flocculation process followed by DAF. However, this method is currently proved ineffective for semi-aerobic landfill leachate treatment. DAF treatment is known to be weak against high turbidity water. Thus, many aspects need to be considered to increase the efficiency of flotation process for the treatment of landfill leachate. Coagulation-flocculation process known to be one of the critical factors that determines the efficiency of the flotation process. Thus, the right coagulant dosage is required to find good coagulation chemistry which ensures the collision and attachment between bubble and particle (Adlan et al., 2011).

Other physical processes such as aeration, sedimentation, air stripping, ultrasonication are commonly used as pretreatment process for landfill leachate. Basically, to reduce organic loading or ammonia, this can lead to enhance the performance of advanced treatment processes.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

CONCLUSION

The age of landfill play a key role when deciding the suitable treatment process for leachate. Typically, biological process is more appropriate for young leachate while physico-chemical treatment is more effective for intermediate and old leachate. Physical processes employed by several researchers to treat leachate. They found that adsorption and membrane technologies are effective in removing pollutants from leachate. However, due to the operation cost, initial organic loading and other aspects, it is recommended to use these processes for post-treatment or leachate polishing. Although employment of flotation process was ineffective, better performance was observed when leachate treated via flotation-coagulation process. Evaporation process seems to offer an attractive option for leachate treatment that can cover all age of landfill leachate. However, further treatment for distillate and sludge are strongly required. Other processes such as sedimentation, aeration, ultrasonication, and air stripping can contribute as pre-treatment processes.

Chapter 35
Heavy Metal(loid) Remediation Using Bio-Waste:
A Potential Low-Cost Green Technology for Cleaning Environment

Sukanta Rana
University of Kalyani, India

Jatindra Nath Bhakta
University of Kalyani, India

ABSTRACT

Heavy metal(loid)s are hazardous, biologically non-essential, non-biodegradable and persistent in nature, which can accumulate in plants and animals as well as in environment especially agri- and aqua- culture ecosystems. It is severely responsible for causing several health hazards problems in human, such as, cardiovascular, pulmonary, hepatic, nephrological, dermatological, neurological disorders as well as carcinogenic effects. Removal of these heavy metals from living systems is extensively expensive and also unsuccessful in sent percent removal. Therefore, in order to protect the environment, the removal of heavy metal(loid)s from polluted effluents is essential before discharging into environment. Besides various treatment technologies, sorption of metal(loid)s using bio-wastes are highly potent alternatives in recent years. The present chapter deals with the removal efficiencies of various bio-wastes, orange peels, waste tea leaves, rice husk, wheat stalk, sugar cane bagasse, coconut husk, sun flower stalk, corn cob, nut shell, water hyacinth, crab shell particle, activated carbons etc. The present discussion has also revealed that bio-waste could be a low-cost eco-friendly and green emerging alternative technology in treating the metal(loid)s contaminated environment without posing any further adverse environmental impacts.

INTRODUCTION

Industrialization, urbanization and population explosion are the prime reason for tremendous environmental pollution in last few decades (Bhakta, Son, & Munekage, 2009; Bhakta & Munekage, 2010). Massive amount of pollutants generating from anthropogenic activities are indiscriminately discharging into the environment which contaminating the life system through the food chain (Jillian, Robert, & Rajakaruna, 2015). Effluents from industries like chlor-alkali, electrical, electronic, electroplating, glass manufacture, photography, oil refinery, pesticide, paint-pigment, plastic, paper and pulp, pharmaceutical, gun, steel etc. contain heavy metals such as, Hg, Cd, Pb, Cr, Cu, As, Ni etc (Tack, Vanhaesebroeck, Verloo, Rompaey, & Ranst, 2005). in extensively high concentration and are disposed into sea, river, canal or pond directly and contaminate them. These metals percolate into ground water and contaminate. Irrigated water is also not safe from heavy metals. Aquatic plants and animals and ultimately human beings are being affected greatly. Domestic wastes (such as, batteries, paints, electrical and electronics goods etc.) have also similar contribution.

Heavy metal(loid)s are hazardous, biologically non-essential, non-biodegradable and persistent in nature and have severe several toxic impacts on lives (Bhakta, Ohnishi, Munekage, Iwasaki, & Wei, 2012). They enter into the body of plants and animals through absorption of water in plants and drinking of water and ingestion of food in animal and get accumulated within tissue. These metals bind to functional groups such as amino ($-NH_2$), imino (=NH), sulfhydryl (-SH), carboxyl (-COOH), phenolic (C_6H_5-), phosphoryl ($-P_2O_5$), imidazole ($C_3H_4N_2$) and phosphate ($-PO_4$) of bio-molecules and form stable coordination complexes within the tissues (Perez Marín, Aguilar Meseguer, Ortũno, & Śaez, 2008; Gönen & Serin, 2012). They tend to form more stable complexes with sulphur and nitrogen ligands than oxygen ligand. Thus, heavy metals are accumulated in liver, kidney, brain, bones, teeth, lungs and blood and damage and impair various systems in human. This accumulation when crosses the critical level causes death of the living machine.

Therefore, decontamination of environment from the severe pollution of heavy metal(loid)s is an urgent issue to scientists. To overcome this problem, many technologies have been developed by researches, sorption, precipitation, coagulation, membrane filtration, etc. so far. Sorption is one of the important technologies in treating the polluted water using various inorganic (chemical) and organic based sorbent media in this respect. However, most of them are expensive and having adverse impact to environment. There is always significant demand in developing the low-cost green eco-friendly technology in this respect. In recent years, biomass based sorbents have drawn much attention to the scientist for applying as a potential sorbent in treating various pollutants of polluted water especially heavy metal(loid)s. Most common domestic biomass wastes (such as - banana peel, orange peel, cotton fiber, cellulose paper, *Eichhornia* plant, coconut coir, waste tea leaf etc.) and different industrial and agricultural bio-wastes (such as, sugarcane baggasse, rice husk, wheat and rice straw, pineapple crown top, sun flower stalk, olive stone, sea weeds, crab shell etc.) have the capability in binding of heavy metal by the process of adsorption and /or absorption, and thus, they can remove heavy metals from polluted water significantly.

The objective of this chapter is to evaluate the bio-sorbent potentiality of biomass waste as a potent low-cost agent of eco-technology in the heavy metal(loid)s remediation of environment. The chapter also concisely discussed applicability of various bio-wastes for remediation of heavy metal(loid)s from contaminated aquatic ecosystem or aqueous solution without harming environment.

CHEMICAL PROPERTIES OF BIO-WASTE

Bio-wastes possess many functional groups such as -COOH, -OH which play important role to bind metal ions coordinately and form a stable complexes resulting sorption. According to Perez Marín, Aguilar Meseguer, Ortũno, Śaez. (2008) and Gönen and Serin (2012), orange peel is made up of cellulose, hemicellulose, pectin, limonene ($C_{10}H_{16}$) and many other low molecular weight compounds which contain hydroxyl (-OH) and carboxyl group (-COOH) as important functional group for heavy metal binding. Banana peel contains pectin such as galacturonic acid which provides –COOH as functional group (Arunakumar, Walpola, & Yoon, 2013). Study also revealed that lignin contains –COOH and –OH as functional groups (Todorcius et al., 2015) those help to remove metals from aqueous media. FTIR analysis showed that activated carbon possessed nitrile (C≡N), alcohol (-OH) and carboxyl group (-COOH) (Rajesh, Pujari, & Uppaluri, 2014), tea wastes possess phenolic hydroxyl group (-OH), alcoholic hydroxyl group (-OH), carboxyl group (-COOH) and amino group ($-NH_2$) (Dwivedi & Rajput, 2014). It is apparent that the binding of metals with these functional groups and formation of complex is the basic principle of bio materials in removing toxic pollutants especially metals from ambient environment.

COMMON BIO-SORBENT PREPARATION PROCESS

Although, there are variations in developing the bio-sorbent from biomass, basic processes followed in different cases are almost same. Bio-wastes are processed to develop adsorbent in the following subsequent ways:

- **Collection:** Bio-wastes such as, orange or banana peel, cotton fiber, cellulose paper, *Eichhornia* plant, coconut coir, waste tea leaf, sugarcane baggasse, rice husk, wheat and rice straw, pineapple crown top, sun flower stalk, olive stone, sea weeds, crab shell etc. are collected from local market or houses.
- **Washing:** The collected wastes are washed thoroughly under tap water to remove any particulate matter and are sprayed with distilled water thereafter.
- **Chopping:** The large biomass can be chapped into small pieces.
- **Drying:** Chopped wastes can be dried by air or hot air oven at specific temperature (generally 70 - 80^0C) for certain period.
- **Pyrolysis:** This step is followed only to prepare activated carbon (AC). A certain amount of dried sample is taken and heated at high temperature (generally 500^0C) using micro-oven or other device for a period to carbonize fully and then it is cooled.
- **Crushing:** Dried materials or pyrolysed biomass are crushed to powder by mortar and pestle or mix grinder machine.
- **Sieving:** Powdery substances can be sieved by sieve of various mesh size. After sieving, the dried powder or carbonized powder can be used as sorbent.
- **Depigmentation:** This process is followed in some cases for producing the bio-sorbent. Biosobent substrates are soaked with alkaline-ethanol solution made of 95% C_2H_5OH and 1% NaOH at 1:1 ratio by volume at 25^0C for 24 hours and pigments like chlorophyll, β-carotene and other low molecular weight compounds are removed. Or, substances are boiled in distilled water at 85^0C for 30 minutes to remove colors. Now, the de-pigmented substances are hot air oven dried at specific temperature for specific periods.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

CHEMICAL ACTIVATION OF BIO-SORBENT

The metal removal activity of bio-sorbent or other sorbent can be improved by means of activation using various chemical agents or heating process. Some activation processes generally followed in this regard are discussed hereunder:

- **Amination(-NH_2):** According to Shrestha, Kour, Homagai, Pokhrel, & Ghimire (2013), samples are charred with concentrated H_2SO_4 and then is washed with distilled water till neutrality. It is oven dried at 80^0C for 24 hours. The charred samples are chlorinated with $SOCl_2$ in the presence of pyridine at 0^0C and then heated at 70^0C for 30 minutes. Now, it is washed with distilled water. The chlorinated sample is mixed with ethylene-di-amine (NH_2-CH_2–CH_2-NH_2) and Na_2CO_3 in the presence of di-methyl-sulphonide ($DMSO_3$) and heated at 70^0C for 6 hours. Then, the aminated adsorbent is washed with 0.1M HCl and followed by distilled water till neutrality. Finally, the sample is oven dried at 70^0C for over night.
- **Xanthate:** It is described by Liang et al. (2012) as follows. About 50 ml of 4M NaOH are added in dried sample (about 15 g) taken in an Erlenmeyer flask, and is stirred magnetically for 3 hours at 25^0C. Then, 10 ml of carbondisulfide (CS_2) is mixed and allowed to settle it for one hour. The precipitated mixture is washed with acetone and then is dried in desiccator. Finally, the product is xanthate that can be used as adsorbent.
- **H_2SO_4 Activation (Liang et al., 2012):** Sizable and dried sample is mixed with concentrated 1N H_2SO_4 in a ratio of 1:2 (w/v) at a temperature of 150^0C for 24 hours. Then the mixture is washed with distilled water, kept in 1% $NaHCO_3$ solution and then is filtered. Finally, the solid matter is oven dried at 105^0C till to obtain a stable weight which acts as strong adsorbent.
- **NaOH Activation (Liang et al., 2012**): About 200 g of dried matter is mixed with 1L of 0.1M NaOH solution and is left for 24 hrs. Then it is neutralized with distilled water wash. Now, it is oven dried at 105^0C and is ready to use as potential sorbent.
- **CH_3OH Activation (Liang et al., 2012):** A mass of raw material after chopping is mixed with methanol (purity: 99.9%) as per as 9 g/633ml and a small quantity of 0.1N HCl is added. The mixture is heated at 600^0C for 48 hrs. Then it is washed thoroughly with distilled water and filtered. Finally, the sample is oven dried at 50 – 60^0C till to gain a constant weight.
- **Methylation (Liang et al., 2012):** Dried sample is mixed with a formaldehyde-acetic acid solution as per as 9 g/180ml and is shaken for 6 hrs. The blended solution is prepared by mixing of HCHO with CH_3COOH in a ratio of 1:1 (v/v). It is then washed with distilled water, filtered and oven dried at 50 – 60^0C up to a constant weight.
- **Acetylation (Liang et al., 2012):** Refluxing of chopped raw matter in acetic acid as per as 12g in 64 ml at 80^0C for 10 hrs adds acetyl group (CH_3-CO-) to the adsorbent. The acetylated substance is washed with distilled water filtered and oven dried at 50 -60^0C up to a constant weight.

SORPTION MECHANISM OF BIO-SORBENT

The mechanism of bio-sorbent is mainly based on the high affinity of functional groups to metal ions to attached to solid sorbent to make a stable complex till the saturation of all functional groups. Bio-

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

sorption follows many mechanisms which may vary bio-mass to bio-mass and also may adopt many mechanisms simultaneously in a sorption process. Some mechanisms described by a number of scientists are summarized here in the following:

Trans-Membrane Transport

This mechanism is mediated by trans-membrane protein across the membrane from extracellular medium into cytosol (Ma, Jacobsen, & Giedroc, 2010). Cu^{2+}, Zn^{2+}, Ni^{2+}, Co^{+}, Mn^{2+}, Fe^{3+} and Cd^{2+} can be transported by this mechanism (Ma, Jacobsen, & Giedroc, 2010). Metal binding to cell wall is essential prior to transportation (Ahalya et al., 2003). This mechanism is applicable only for living cells like bacteria (*Escherichia coli)*, fungi (*Saccharomyces cerevisiae)* etc.

Physical Adsorption

The van der Waal`s force causes the adsorption of divalent ions like Zn^{2+}, Cd^{2+}, Cu^{2+}, Co^{2+} etc. to the cell wall of dead plant biomass. The components (cellulose, hemicellulose, pectin, limonene, etc.) of cell wall act as potent adsorbent in this process sorption.

Ion Exchange

Cell wall polysaccharides (such as alginates in marine algae) of living microorganisms uptake divalent metals (Cu^{2+}, Cd^{2+}, Zn^{2+} etc.) with exchanging of Na^{+}, K^{+}, Ca^{2+} and Mg^{2+}. This mechanism has been described in *Aspergillus niger* (Ahalya, Ramachandra, & Kanamadi, 2003).

Complexation

Complex formation between di-metalic ions with amino ($-NH_2$) or carboxyl groups (-COOH) of polysaccharide components of cell wall forming coordination bond is another mechanism for removal of Ca^{2+}, Mg^{2+}, Cd^{2+}, Zn^{2+}, Cu^{2+} and Hg^{2+} from extracellular solution and these metals get accumulated within cell. Most of the microorganisms (*Pseudomonas syringae, Zoogloea ramigera* and alga *Chiarella vulgaris etc.)* are found to uptake metals by this mechanism.

Precipitation

It is associated with mechanism of formation of metallic compound which precipitates in the solution. This is one of the active defense mechanism of microorganism in the presence of toxic heavy metals like Cd^{2+}, Hg^{2+}, Pb^{2+}, Ni^{2+} etc. Here the metal interacts with cell surface and a metallic compound is formed.

BIOSORPTION INFLUENCING FACTORS

Metal sorption capacity of bio-sorbent is significantly influenced by a number of factors, such as, initial concentration of metal ions, pH, temperature, quantity of adsorbent used and number of functional group. The highest metals sorption capacity of bio-sorbent is found at specific conditions or states of

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

aforesaid factors, i.e., optimum condition of influencing factors. It is varied from sorbent to sorbent on the basis of their chemical properties and functional groups responsible for sorption mechanism. The per cent of removal was greater with decrease in initial concentration of metal ions (10 – 200 mg/L) and with increase in amount of adsorbent used at pH 5 and 25^0C (Gönen and Serin, 2012). Most of the experiments showed that maximum removal was recorded at the pH range 4 – 7 (Yasuda, Ozaki, Nohata, Ohshiro, & Sonda, 2010; Gönen and Serin, 2012; Mohammed, 2012; Ahn & Kim, 2016). The amount of adsorption increased with increasing pH vales up to 7 (Ahn & Kim, 2016). Under optimum condition, the amount of adsorption was followed the order $Pb^{2+} > Cu^{2+} > Cd > Zn^{2+} > Ni^{2+}$ (Shrestha et al., 2013; Dwivedi & Rajput, 2014) and Co > Cd > Zn (Mohammed, 2012). Temperature was a great influencing factor. Lower temperature was conducive for better adsorption whereas higher temperature inhibited the adsorption (Rakshit, 2004). Metal – sorbent interaction studied in all experiment between 25^0 – 30^0C reported that the adsorption capacity was not influenced by the temperature because adsorptions were isothermal (Bhakta, Rana, Lahiri, & Munekage, 2014; Dwivedi & Rajput, 2014; Ahn & Kim, 2016). Presence of undesirable metal ions – K^+, Ca^{++}, Na^+, Mg^{++} etc. and surfactans in the aqueous solution reduced adsorption capacity but sulfonated (-HSO_3) and carboxylated (-COOH) adsorbent showed better adsorption in the presence of surfactants (Ahn & Kim, 2016). Adsorption capacity also depended on porosity and fineness of adsorbent (Rakshit, 2004) and was proportional to porosity, surface area (Figure 1) and to some extent to incubation period (Figure 2) (Bhakta et al., 2014). It is also found that sorption mechanism is also significantly depended on the amount of sorbent and concentration of metals in the solution (Bhakta & Munekage, 2013).

After Bhakta et al., 2014.

SORPTION KINETICS

The metal sorption capacity of adsorbent can be estimated using mass balance relationship at room temperature in following (Bhakta & Munekage, 2013).

$$q_e = \{(C_0 - C_t) \times V\}/M \quad (1)$$

where, q_e – sorption capacity (mg/g), C_0 and C_t – concentration of heavy metal (mg/L) in aqueous medium at time 0 and t respectively, V – volume of the solution and M – quantity of adsorbent Sorption isotherm capacity can be calculated by Freundlich and Langmuir isotherm equations. The Freundlich isotherm equation is as foloows:

$$x/m = kc^{1/n} \text{ or, } \text{Log } (x/m) = \text{Log } k + 1/n \text{ Log } c \quad (2)$$

where, x – quantity of metal adsorbed (g), m – quantity of adsorbent (g), x/m – amount of metal adsorbed per unit mass of the adsorbent, c – equilibrium concentration of metal, k and n – empirical constants depending on the nature of adsorbent and adsorbate and the temperature.

The relationship between the number of active sites of the surface undergoing adsorption and pressure is explained by Langmuir equation –

$$\theta = kp/(1+kp) \quad (3)$$

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

where, θ – number of sites of the surface which are covered with gaseous molecules, p – pressure, k – equilibrium constant for distribution of adsorbate between surface and gaseous phase.

Langmuir isotherm adsorption equation is valid at low pressure because, (1+kp) is negligible and θ = kp ; but at high pressure (1+kp) equals to kp. Then, θ = kp/kp = 1 that is not found in reality.

Adsorbent sorption capacity for metals can also be calculated by the alternative Langmuir equation –

$$q = q_{max}\, bc_{eq} / (1 + bc_{eq}) \quad (4)$$

where, q - metal accumulated per adsorbent (mg/g), q_{max} – maximum uptake of specific metal corresponding to site saturation, ceq – metal residual concentration at equilibrium and b – ratio of rate of adsorption and rate of desorption

Monolayer adsorbate of Langmuir isotherm was replaced by BET equation which was on the basis of poly layer adsorbate developed by couple action of van der Walls force (physical adsorption) and valence forces (chemisorption) with adsorbent. The surface area of adsorbent can be quantified by the following BET equation -

$$p / v(p^0-p) = 1 / v_m.c + (c-1)/v_m.c \text{ x } p/p^0 \quad (5)$$

where, v – volume of gas adsorbed under pressure p, p^0 – saturated vapor pressure at same temperature, V_m – volume of gas adsorbed when the surface is covered with a unimolecular layer and c – a constant for a given adsorbate. When, $c = e^{(E1 - EL)/RT}$ in which, E_1 – heat of absorption in first layer and E_L – heat of liquefaction of the gas

The metal removal percentage from aqueous media can be quantified following the equation:

$$Re = \{(C_0 - C_t) /C_0\} \text{ x } 100 \quad (6)$$

where Re – removal (%), C_0 and C_t – concentration of heavy metal (mg/L) in aqueous medium at time 0 and t respectively.

SOME CASE STUDIES

Although, varieties of waste biomass have been employed as bio-sorbent to remediate the contaminated water using the metal bio-soorption mechanism, some of them are summarizing in following:

Orange Peel

The adsorption property of a xanthate produced from mixing dechlorophyllated and dried orange peel with carbon disulfide (CS_2) was investigated by Liang et al. (2010) and was shown that the maximum adsorption capacity was 77.60 mg/g for Cu^{2+}, 76.57 mg/g for Cd^{2+}, 218.34 mg/g for Pb^{2+}, 49.85 mg/g for Zn^{2+} and 15.45 mg/g for Ni^{2+}. Orange peel after proper washing with double distilled water was oven dried at 70^0C for 24 hours and was then crushed to powder. About 50 g of the crushed matter was socked with a mixed solution of 250 ml of C_2H_5OH and 250 ml of 1% NaOH at room temperature for 24 hours to remove chlorophyll pigments and other low molecular weight compounds.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Khalfaoui & Meniai (2012) used crushed and dried orange peel and chemically activated orange peel as sorbent in an experiment of Cu^{2+} removal from aqueous solution and reported that the removal efficiency was 75% in case of orange peel and more than 99% in activated peel. The orange peel was activated with concentrated H_2SO_4, NaOH, CH_3OH and acetic anhydride ($C_4H_6O_3$).

An adsorption study carrying out mixing 0.2 g of orange peel with 100 ml of $Ni(NO_3)_2$ of 10 – 200 ppm using an orbital shaker operating at 200 rpm revealed that greater percentage of Ni^{2+} removal was achieved with decrease in initial concentration Ni^{2+} and maximum removal was observed at pH 5 at room temperature (Gönen & Serin, 2012). Solutions were adjusted to the optimum pH prior to the addition of adsorbent.

Rajput et al. (2015) also conducted similar experiment using 0.5 g of finely crushed (particulate diameter: < 3.35 mm) and dried orange peel and maximum 78% Pb^{2+} ions was removed at optimum condition at room temperature from a solution of $Pb(NO_3)$ of 1000 ppm.

Banana Peel

Arunakumar et al. (2013) used banana peel as adsorbent to remove heavy metals from their aqueous solution and showed that the adsorption capacity of banana peel was 2.55 mg/g for Co^{2+}, 5.71 mg/g for Cd^{2+}, 5.80 mg/g for Zn^{2+}, 6.88 mg/g for Ni^{2+}, 7.97 mg/g for Pb^{2+} and 28.0 mg/g for Cu^{2+}. They also reported that more than 100 millions tone of banana are produced annually world wide and about 40 million tones of peel remains unused.

Waste Tea Leaves

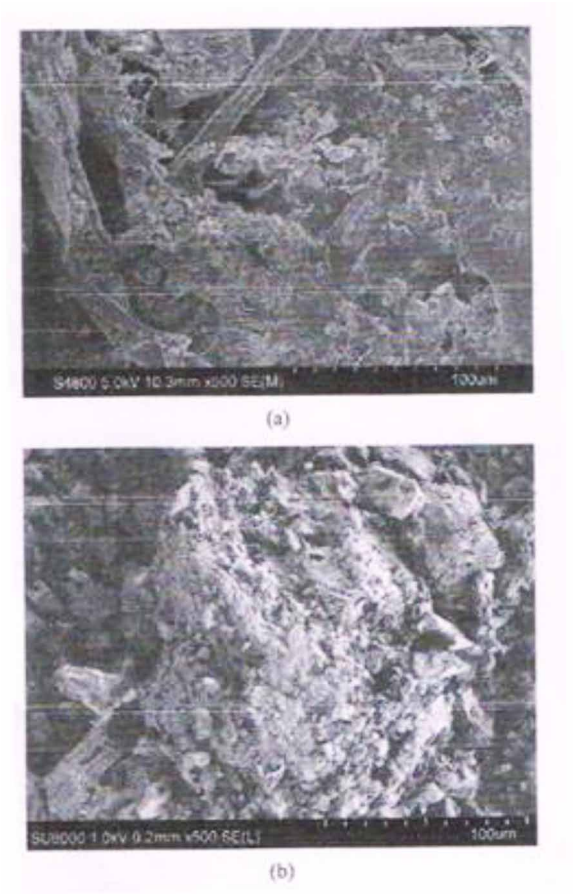
Mohammed (2012) used black tea waste as an adsorbent to remove Co^{++}, Cd^{++} and Zn^{++} from wastewater. In an experiment, he allowed to interact 0.5 g of black tea waste with the aqueous solution of these heavy metals for 30 minutes at pH 6 and observed that the adsorption capacity of the black tea waste was 15.39 mg/g for Co, 13.77 mg/g for Cd and 12.24 mg/g for Zn. Tea waste collected from tea stall and restaurant was used to adsorb Cd^{++} and Cu^{++} from the aqueous solution of $Cd(NO_3)_2$ of 1 g/L and $Cu(NO_3)_2$ of 1 g/L respectively and a removal efficiency of 87% for Cd and 89% for Cu was observed (Dwivedi and Rajput, 2014). The crude tea waste was decolorized boiling in distilled water at 85^0C and was then dried in hot air oven at 105^0C for 12 hours. These dried leaves were pounded to powder of about 120 µm in size and that was used as sorbent as per 0.5 g for 100 ml solution.

Shrestas et al. (2013) removed Cd^{++} and Pb^{++} from wastewater using aminated tea leave as sorbent. The tea leaves were first oven dried at 80^0C for 24 hours and then they were pounded and sieved to pass through 212 µm mesh. Then the sizable leaves charred with concentrated H_2SO_4 followed by distilled water wash and oven drying at 80^0C for 24 hours. The charred sample was chlorinated with $SOCl_2$ in the presence of pyridine followed by amination with ethylene diamine $(CH_2NH_2)_2$ in the presence of Na_2CO_3 and dimethylsulphonide ($DMSO_3$) at 70^0C (Figure 3). The dried aminated leaves were active absorber for Hg^{++} and the adsorption capacity were 83.04 mg/g for Pb^{++} and 57 mg/g for Cd^{++}.

Green tea leaf is also a good adsorbent for heavy metals. Catechin extracted green tea leaves was used in removal of Cr^{6+}, Fe^{3+}, Cd^{2+}, Co^{2+}, Cu^{2+}, Mn^{2+}, Ni^{2+} and Zn^{2+} from their aqueous solution and the removal was increased with increasing the catechin extraction time i.e., a negative correlation between Catechin content in leaf and % of removal (Yasuda et al., 2010). The extraction at pH 4 accompanied with stirring for 30 minutes at room temperature was best for optimum adsorption for Cr^{6+}, Fe^{3+} and Pb^{2+}

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 3. Scanning electron microscope images of waste tea leaves before (A) and after amination with ethyle diamine (B)



whereas, at pH 6 for Cd^{2+}, Co^{2+}, Cu^{2+}, Mn^{2+}, Ni^{2+} and Zn^{2+}(Yasuda et al., 2010). Chemically modified used tea leaves i.e., thiolated (-SH), sulfonated ($-HSO_3$) and carboxylated (-COOH) tea leaves can be used as Cu^{2+} sorbent. Cu^{2+} were removed up to 53%, 22% and 19% by thiolated, carboxylated and sulfonated used tea leaves respectively at pH 7 (Ahn and Kim, 2016). They observed that, the adsorption efficiency of thiolated leaves was decreased in the presence of salt and surfactants whereas, the sulfonated and carboxylated leaves showed better adsorption in the presence of surfactants.

Rice Husk

Rice hush collected from rice mill is also a good adsorbent. Ye, Zhang, Zhang, Wu, and Du (2012) estimated its physical properties - surface area - 438.05 m^2/g, bulk density – 0.3086 g cm^3, porosity – 0.38 by fraction and chemical composition (by weight) – cellulose – 34.4%, hemicellulose-29.3%, lignin – 19.2% and ash – 17.1%. Ngah and Hanafiah (2008) used rice husk as an adsorbent for removal of Pb, Cd, Zn, Ni and As from both ground and surface water and found that treated hush showed better performance than untreated ones because, it created problems like – low adsorption capacity, high BOD, COD and

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Total Organic Carbon (TOC). Dada, Ojediran, and Olalekan (2013) treated the rice husk collected from mill to soak H_3PO_4 from its solution and used the treated husk as adsorbent in his experiment for heavy metal removal and found that the adsorption capacity of the adsorbent for Pb^{2+} was 138.89 mg /g at pH 6.3 – 6.5. Lashkenari, Davodo, and Eisazadeh (2011) reported that the adsorption capacity of polyanilinated rice husk for As (III) was 34.48 mg /g at pH 10 and at a dosage of 10 g/L.

Rice Straw

Raw rice straw is very poor or no metal sorbent because it lacks of any functional group for metal binding. Rice straw treated with NaOH was a good adsorbent for removal of Cr^{6+} and Ni^{2+} from their aqueous solution and its adsorption followed Lagergren second order kinetics (Brahmainah et al., 2015):

$$t/q_t = 1/k_2q_e^2 + (1/q_e)t$$

where, k_2 – rate constant (g/mg-min.), q_e and q_t – amount of adsorbate adsorbed (mg/g) at time t and time at equilibrium time e. Washed, Dried and powdered straw samples was used for the study. About 16 g of powdered sample was mixed with 240 ml of NaOH solution and was kept for 24 hrs at room temperature. It was then oven dried at 100^0C for 24 hrs which was treated as potential sorbent.

Sugar Cane Bagasse

Sugar cane bagasse procured from food canning processing industry could remove 96.4% of Cd^{2+} from an aqueous solution of 20 mg/L. The bagasse was first washed with distilled water, then oven dried at 60^0C for 24 hrs. The dried substance was milled to powder and sieved into a particle size of 0.5 – 4 mm which was used as adsorbent (Kumar & Sahu, 2013). Sugar cane bagasse polymerized with acrylic acid and acrylamide using N,N-methylene bis-acrylamide as a cross linker used as an highly effective adsorbent as much as 268 mg/g for Cu^{2+}, 300 mg/g for Cd^{2+} and 700 mg/g for Pb^{2+} (Kong, Ren, Wang, & Chen, 2014). About 98% removal of arsenic (As) was also reported using sugar cane bagasse with adsorption capacity 11.9 mg/g at pH 9.0 (Tagermina, Ebadi, Nasernejad, & Ghafori, 2014).

Wheat Straw

Partially de-lignified Ca^{++}-Mg^{++} ion exchanged product was developed from ligno-cellulostic wheat straw to remove Pb^{2+}, Cd^{2+}, Hg^{2+}, Co^{2+}, Ni^{2+}, Mn^{2+}, Zn^{2+} and to de-toxicate Cr^{6+}. A strong affinity to Pb^{2+}, Cd^{2+}, Cu^{2+}, Zn^{2+} and Hg^{2+} and a weak affinity to Co^{2+}, Ni^{2+} and Mn^{2+}, were observed (Krishnami, 2016). Lignin is a polymer and possesses many functional groups like – (-COOH) and (-OH). Lignin extracted from wheat straw by boiling in alkaline solution acted as strong adsorbent for Cu ions (Todorcius, Bulgariu, & Popa, 2015). The adsorbent was prepared by addition of 1.25 g of lignin powder to 25ml of Cu $(NO_3)_2$ solution of 10^{-2} mol/L and was shaken for 24 hrs to obtain equilibrium condition and then the lignin was separated by filtration.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Sunflower Stalk

Jalali & Aboulghazi (2013) reported that fine particles derived from sun flower stalk was a potent sorbent that showed maximum removal efficiency 97% for Pb^{2+} and 87% for Cd^{2+} from a solution of 1g/L at pH 5.0 and adsorption capacity 182 mg/g and 70 mg/g for Pb^{2+} and Cd^{2+} respectively. The adsorbent was prepared by washing with de-ionized water until the effluent was colourless. The stalk then was oven dried at 60^0C for 24 hrs, ground to power and passed through 2.0 mm sieve.

Coconut Husk and Shell

Coconut husk rich in tanin is a good adsorbent. It removed 90% of both Cu^{2+} and Pb^{2+} at pH 5.0 (Abdulrasad & Baseru, 2010). Coconut shell treated with acid and coated with chitosan resulted 93% removal performance for Zn ions at pH 6.0 and temperature 25^0C during 3 hrs of interaction of adsorbents of 30 g/L with metal solution (Lim & Aris, 2014).

Palm Fruit Fiber

Palm fruit fiber was an excellent bio-sorbent which was proven in an experiment done by Ideriah, David, and Ogbonna (2012) that resulted 100% removal of Pb and Cu ions at pH 10 and room temperature (Figure 4).

Nut Shell

Chemically treated cashew nut shell showed a great removing potential of heavy metal ions from their contaminated aqueous solution with maximum adsorption capacities - 406.6 mg/g for Cu^{2+}, 436.7 mg/g for Cd^{2+}, 455.7 mg/g for Zn^{2+} and 456.3 mg/g for Ni^{2+} following Langmuir isotherm (Kumar et al., 2012). They reported that Cu ions were removed by 100% at pH 5.0 and at 30^0C. Chest nut shell treated with 4% NaOH solution was more efficient sorbent for removal of Cd^{++}, Pb^{++}, Pb^{++} and Zn^{++} s compared to chest nut shell treated with acid formaldehyde because alkaline treatment caused swelling of adsorbent with increased surface area of adsorbent coupled with more negative charge on particle surface (Vàzquez et al., 2012).

Corn Cob

Excellent metal removal efficiency by corn cob was observed as much as 95.05% for Cr^{6+} at pH 5.4 and 4.18 hrs of interaction, 99.9% for Ni at pH 6.5 and 2.38 hrs and 91.35% for Zn at pH 6.5 and 0.15hrs from electric industrial effluents by fixed bed column technique (Ali, Khalid, & Majid, 2014). Corn cob collected from market was crushed by grinder and mixed with de-ionized water in a shaker for 24 hrs and then washed with fresh de-ionized water. These were put in a large glass baking dish and dried at room temperature. Now, the sorbent was treated with 10% HCl solution for 6 hrs at 30^0C followed by wash with double distilled water and oven dried at 125^0C for 24 hrs. Then the samples were sieved to 4 mm and stored in plastic bottle for usages as potential sorbent.

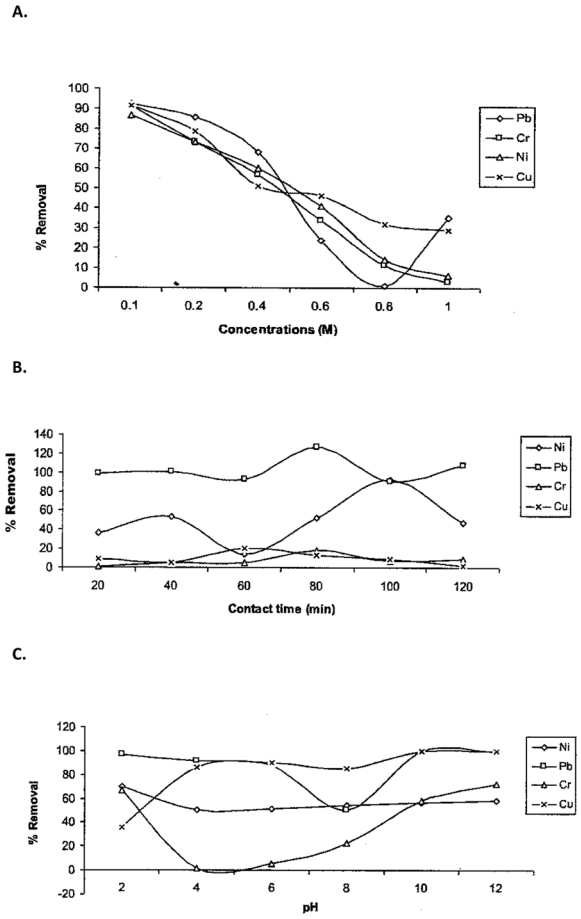
Figure 4. Removal efficiency of metal ions by palm fibre with respect to different concentrations of metal ions (A), interacting time (B) and pH values of aqueous solution of metal ions. 2.0 g of dried fibre was used in 50 ml of metallic solution.
After Ideriah et al. 2012.



Weeds

The most irritating aquatic weed water hyacinth (*Eichhornia crassipes*) has tremendous adsorption capacity for metal ions. An experiment carried out by Dixit, Dixit, and Goswami (2015) using pulverized matter from dried water hyacinth as sorbent revealed that the removal efficiency were 98 - 99% for Pb, Cd, Cr and Zn (Table-1).

The marine algae (*Sargassum myriocystum*) has been reported to be one of the potential adsorbent for Pb ions when 2g of dried algal biomass was mixed with a solution of Pb of 1000 mg/L with pH 5 and allowed to interact for 60 minutes at room temperature and a maximal removal of Pb^{2+}s was observed by 89.75% (Sweetly et al., 2014). Fresh algae were washed with distilled water to remove salt and sand particles and oven dried at 60^0C overnight. It was then acid washed to remove sorbent inhibitors – Ca^{2+}, K^+, Mg^{2+} and Na^+s. Solid samples then was the dried at room temperature for 3 - 4 days until stable weight. The adsorptive performance of sea weed (*Caulerpa serrulata*) for copper, lead and cadmium ions

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Table 1. Removal efficiencies of water hyacinth of several heavy metals from aqueous solution of different concentration at room temperature

Heavy Metal	Initial Concentration (mg/L)	Quantity of Adsorbent Used (g/L)	Removal Efficiency (%)
Pb	10	2.5	93
Cd	10	3.0	82
Cr	10	1.5	82
Zn	10	4.0	75
Pb	50	3 – 4	98 – 99
Cd	50	3 – 4	98 – 99
Cr	50	3 - 4	98 – 99
Zn	50	3 - 4	98 - 99

After Dixit et al., 2015.

from an aqueous solution was investigated by Mwangi and Ngila (2012) before and after ethelenediamination of the adsorbent and was resulted that the adsorption capacities of aminated sea weed were 5.27 mg/g for Cu, 2.12 mg/g for Cd and 2.16 mg/g for Pb ions whereas, the capacities for untreated sorbent were 3.29 mg/g, 4.57 mg/g and 1.06 mg/g for Cu, Cd and Pb ions respectively at pH 4 – 6. About 10g of green weeds was suspended in 200 ml of N,N-dimethyl formamide (DMF) followed by drop-wise addition of 35 ml of thionyl chloride ($SOCl_2$) at 80^0C under mechanical stirring. The chlorinated weeds were then washed NH_4OH solution to neutralize and the sample was vacuum dried at room temperature. Thereafter, the sample was reacted with 25 ml of ethylene 1-2-diamine under reflux with mechanical stirring for 3 hours. The solution was filtered through a sintered glass filter and vacuum dried at room temperature for 24 hrs.

Crab Shell Particle

Crab particles have strong affinity to heavy metals and chemical treatment causes more and stronger affinity. Budin, Subhramanium, Tair, and Ali (2014) produced particle from shell of crab (*Scylla serata*) and cockle (*Anadara granosa*) and used as sorbent as per as 0.5 g/L to remove lead and chromium ions from an aqueous solution of Pb and Cr of 1 g/L respectively and observed that the maximum removal efficiency of shell particles was 97.45% for Cr^{6+}s and to some extent low for Pb^{2+}s at pH 4.0 and room temperature. They also reported that sorption capacity of crab shell particle was better than cockle shell. The crab was first boiled and its shell was separated. It was then washed with distilled water and sun dried. The dried shell was pulverized and sieved of 0.5mm in size that was used as sorbent.

The adsorption capacity of pretreated crab shell particle (*Portunus sanguinolentus*) – 71.46 mg/g at pH 4.5 and 25^0C for zinc ions was also reported from an experiment of Zn^{2+}s removal from an aqueous of 100 mg/L performed by Senthil and Parthiban (2011). Waste shells of the crab were collected from Marina sea beach, washed with distilled water and then sun dried. It was now crushed to desired size by ball mill. The particle was washed with 0.1M HCl solution for 4 hrs to remove $CaCO_3$. It was then washed with de-ionized water and sun dried. Thereafter, these particles were soaked in 1%NaOH solution overnight at room temperature to remove bulk protein. The residues (chitin) were then rinsed with

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

de-ionized water and oven dried at 100^0C for 6-7 hrs. The chitin was soaked in 50% NaOH solution for 2 hrs to remove some or all acetyl residues (CH_3CO-) and all chitin molecules were converted to chitosan molecules which were finally sun dried and acted as potential sorbent.

Activated Carbon (AC)

Activated carbon is also a highly potent sorbent for heavy metal due to its numerous pore, large active surface area and good mechanical properties (Cai and Jia, 2010). Heavy metal ions – $Cr^{6+,}$ Cd^{2+} and Cu^{2+} were removed from aqueous solution by the sorbent – activated carbon developed from peel of Colombian orange through pyrolysis treatment at 823 K and the adsorption capacity of activated carbon was exhibited greatest for Cu^{2+} ions because of its size and pH (Moreno-Pirajan & Giraldo, 2012).

Bhakta et al. (2014) experimentally showed that activated carbon generated from microwave mediated pyrolysis of banana peel, orange peel, cotton fiber and cellulose paper waste, was a potent mercury (Hg^{2+}) sorbent. He reported that the Hg sorption efficiency or capacity was directly proportional to the surface area, porosity and carbon content (C) in that activated carbon. He estimated the following parameters (Table-2) and calculated the Hg removal efficiency of activated carbon used as sorbent as per 0.05 g/L for removal of Hg from an aqueous solution of $HgCl_2$ as concentration as 100 µg/L and concluded that the removal performance was better in cotton fiber and paper waste than other banana and orange peel (Table-2). He also cited that other components (such as, K_2O, CaO, SiO_2 and Cl) in activated carbon (Table-3) inhibited sorption process and thus reduced sorption capacity of activated carbon to Hg ions.

Rice husk carbonized at 400^0C showed the adsorption capacity as high as 2.69 mg/ g for Ni^{2+}, 5.28mg/g for Zn^{2+} and 6.01mg/g for Pb^{2+} (Taha et al., 2011). An equilibrium and kinetic study of Ni^{2+} using activated carbon developed from bamboo (*Bambuseae*) as potential adsorbent carried out by (Rajesh et al., 2014) resulted that the BET surface area, metal uptake and metal removal efficiency of the adsorbent were 116 m^2/g, 121.72 mg/g and 92.47% respectively from a an aqueous solution of Ni of 50 – 300 mg/L at pH 2-10, adsorption dosages 0.02 – 0.1g/50ml and interaction time 15 – 300 minutes. The bamboo stem was cut into small pieces and then pulverized and sieved to 78µm. About 10 – 20 g of the powder was mixed with 14 ml of H_3PO_4 and heated at 150^0C in muffle furnace operated with N_2 gas flow at atmospheric pressure for 2 hrs. The mixture was sintered at a temperature range of 600 – 700^0C for 4 hrs. It was then cooled to normal temperature in flowing N_2 gas. Finally, the sample was washed with distilled water till pH 7 and dried at 105^0C for the use as adsorbent.

Table 2. Surface area, porosity, carbon content and removal efficiency of activated carbon generated from orange and banana peel, cotton fiber and cellulose paper waste

Activated carbon generated from	BET surface area (m^2/g)	Micropore surface area (m^2/g)	Micropore volume (cc/g)	Hg Removal efficiency (%)
Banana peel	115	51	0.0628	85
Orange peel	109	43	0.0519	84
Cotton fiber	138	65	0.0910	95
Cellulose paper waste	119	54	0.0791	94

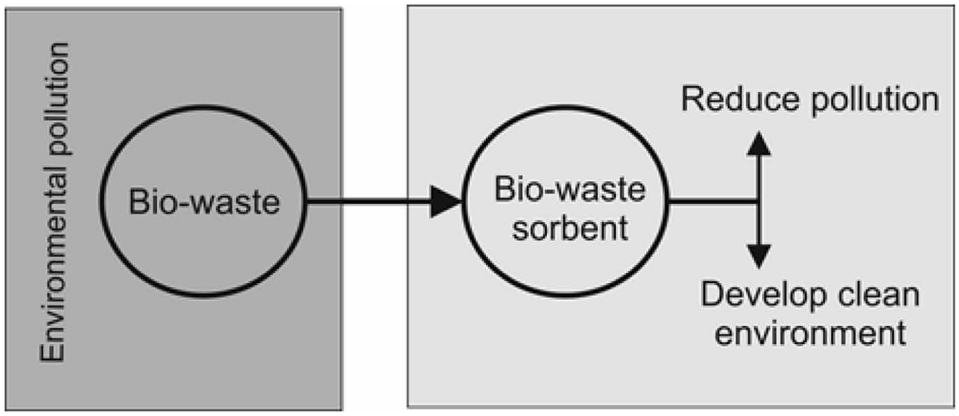
COST EFFECTIVENESS AND ENVIRONMENTAL BENEFIT OF BIO-WASTE TECHNOLOGY

The generation of bio-wastes is unlimited throughout the world. They are available and easily collected from houses, markets and industries without any cost. The preparation of bio-sorbent is very simple and follow some physical processes such as washing, drying, powdering and sieving but some sorbent undergo chemical treatment for addition of more functional groups such as ethylenediamination, methylation, acetylation etc. for binding metal. Carbonization process takes place in micro oven. There is no mechanical complexity no such costly infrastructure is required. Application of adsorbent is direct mixing with contaminated water. Small quantity of sorbent is well efficient in removing metals approximately 90%. All mechanical set up are cost reducing. Technology does not demand expert engineers and personnel; rather, skilled labours are enough to carry out the process involved in technology. The spent sorbent of bio-waste has no further adverse environmental impacts since; it can be recycled and can be converted into building materials (such as ingredient of brick). Besides, this technology converts the bio-waste into wealth (Figure 5). Therefore, it is absolutely a low-cost economically feasible technology for the present scenario of environmental pollution.

Figure 5. Bio-sorbent of bio-waste is a wealth of environment



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

CONCLUSION AND FUTURE PROSPECTS

Summarily, it can be concluded that bio-waste are capable to remediate the heavy metal(loid)s from their concerned solution at significantly higher rate (75% - 100%) at specific pH and at around room temperature. Additionally, chemical modifications can increase its removal efficiency. The removal efficiencies of various bio-wastes, orange peels, waste tea leaves, rice husk, wheat stalk, sugar cane bagasse, coconut husk, sun flower stalk, corn cob, nut shell, water hyacinth, crab shell particle, activated carbons etc. are extensively high and can be recommended as a low-cost media for treating the metal(loid)s contaminated environment. It would be a low-cost, environment friendly, feasible metal(loid)s treatment green technologies in developing and under developed countries.

Recently, researches also reported that algae are promising for heavy metal remediation due to its low cost, non polluting and high sorptive capacity (Dwivedi, 2012). The capacity depends on the interaction between heavy metals and alginate compounds located within cell wall of algae. So, further research will be focused on binding mechanism and some chemical modification for better sorption. These algae can also provide clue for development of more effective sorbent. Culture of microalgae in heavy metal contaminated medium can be a great effective green technology in heavy metal remediation. Because, extracellular polysachharides, lipid and fatty acid components in cell membrane may bind heavy metal and thus microalgae can be a potential sink for heavy metal. Filamentous fungi have a great sorptive potential for Pb, Zn, Cd, Cr, As and Ni because they can produce large amount biomass within short time (Siddiquee et al., 2015). So it can be a potential sorbent.

Development of potential sorbent from bio-waste and its application in removal of heavy metal(loid)s from wastewater or their contaminated aqueous solution are a low cost, eco-friendly and green technology which is available and feasible in underdeveloped countries. Further research is needed to increase its perfection and performance. Further study is also needed to search alternative high performance low cost biomass waste and green technology. In conclusion, it can be summarized that bio-waste has significant prospect as a low-cost and green metal(loid)s removal technology for leaning the contaminated environment.

KEY TERMS AND DEFINITIONS

Bioaccumulation: Formation of stable complexes between bio-molecules and non bio-degradable inorganic substances within tissue.

Bio-Waste: Unnecessary biomass produced from living body of animals and plants.

Chemical Modification: Covalent addition or alteration of functional group or groups of bio-molecules by chemical treatments for better efficiency.

Green Technology: Biomass based technology which has no harmful effect on environment.

Heavy Metal: Metal and metalloid with high density ($> 5 g\ cm^{-3}$) in earth`s crust.

Metal Binding Groups: Functional groups of bio-molecules which can bind metal ions covalently, non-covalently or ionically and form a complex.

Remediation: Removal of hazardous substances from an environment.

Sorption Kinetics: Rate of adsorption or absorption process or reaction of heavy metal to bio-molecule.

Sorption: Adherence or entrance of metallic ion within cell or tissue.

ABSTRACT

Biological process for environmental preservation and treatment is not a new technology. It was used a decade ago until now. The most important tools in biological processes are the microorganism and upstream instruments (bioreactor, pond and others) to run the process. Furthermore, the efficiency of the process depends on many factors such as temperature, pH, type of microorganism, conditions, and other nutrients. To understand the factors that will affect the process, mechanisms of microorganisms to treat or protect the environment must be considered. For leachate treatment, biological process is one of the most widely used techniques for low cost and environmentally friendly.

INTRODUCTION

An understanding about the mechanism and principle of microorganism is advantageous to ensure the success of leachate treatment by biological process. Therefore, this chapter starts with an explanation on the principle of microorganism, followed by the mechanism of leachate treatment through biological process. Biological treatment could be divided into two processes; upstream and downstream. Upstream

is related to process in the lagoon, bioreactor, pretreatment or additional treatment. Meanwhile, downstream is a process to purify effluent and discharge to river or return to landfill. Both of these systems are the main topic of discussion in this chapter. The dangers of untreated leachate to biological life such as human and environment are discussed at the end of this chapter.

PRINCIPLE OF BIOLOGICAL TREATMENT

Biological treatment is a type of treatment that uses biological material as an activator like microorganism and organic material. Leachate treatment using biological process is due to the respect to the environment and cost of process. Several requirements are needed by biological or microorganism in order to grow, such as nutrients, microbiological components, environmental condition, inhibition factors and pretreatment process. We will further discuss the topic about the concept and requirements of biological treatment for landfill leachate, especially by microorganisms. Microorganism is a small and tiny biological creature. It can be grouped as bacteria, fungi, algae and yeast. Classification is based on their characteristics through biochemistry test and DNA sequencing.

Nutrients

Nutrients are one of the most important things to a microorganism. It provides energy sources to the bacteria and supports cellular biosynthesis. In a natural environment, certain bacteria can grow in a certain environment due to the compounds that contain some amount of nutrient. Requirement of nutrients varies due to types of microorganism and environment. These nutrients can be found in the form of organic and inorganic compound, water, macromolecules and micro molecules. These nutrients serve several functions of the cell. Table 1 shows the function of every major nutrient to the bacteria cell.

Table 1. Major nutrients of bacteria and its functions (Todar, 2012)

Nutrient	Source	Function
Carbon, C	Organic compounds, CO_2	Main constituent of cellular material
Oxygen, O	Water, Organic compounds, CO_2, O_2	Constituent of cell material and cell water, O_2 is electron acceptor in aerobic respiration
Nitrogen, N	NH_3, NO_3, Organic compounds, N_2	Constituent of amino acids, nucleic acids nucleotides, and coenzymes
Hydrogen, H	Water, Organic compounds, H_2	Main constituent of organic compounds and cell water
Phosphorus, P	PO_4	Constituent of nucleic acids, nucleotides, phospholipids, LPS, teichoic acids
Sulphur, S	SO_4, H_2S, organic sulphur compounds	Constituent of cysteine, methionine, glutathione, several coenzymes
Potassium, P	Potassium salts	Main cellular inorganic cation and cofactor for certain enzymes
Magnesium, Mg	Magnesium salts	Inorganic cellular cation, cofactor for certain enzymatic reactions
Calcium, Ca	Calcium salts	Inorganic cellular cation, cofactor for certain enzymes and a component of endospores
Iron, Fe	Iron salts	Component of cytochromes and certain nonheme iron-protein and a cofactor for some enzymatic reactions

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Other nutrients that are needed by the microorganism, but in a small amount, are called as trace elements. These elements are needed due to their function as a cofactor for the essential enzymatic reaction in the cell of microorganism or as a vitamin for the microorganism. The trace nutrient usually comes out in the form of ion elements like Mn, Co, Zn, Cu, and Mo. Table 2 shows the function of those nutrients to the microorganism cell.

Nutrition consumption and metabolic adaption can be used as an indicator to characterize microorganism. Nutrients are consumed by microorganisms to build up the organic molecules and thus, enhance the building of their cells. Cell of microorganism can be divided into two; toprokaryotes and eukaryotes. In terms of nutrient requirement, the major difference between the types of cell is that prokaryotes are much more highly required compared to eukaryotes. In the biological treatment process, the nutrients contained in the wastes become one of the major factors for the growth of microorganisms. This is because they used the organic material as a food source and all of the organic matters are measured using Biochemical Oxygen Demand (BOD) technique and Chemical Oxygen Demand (COD). In this biological treatment, the microorganism removes the organic matter that is contained in the waste water and reduces the pollutant.

Bacteriology

Bacteria are one of the most abundant microorganisms that are commonly applied in the biological treatment. Normally, bacteria can be identified by their species or families based on three elements, such as morphology, biochemistry reaction and DNA sequence. The common morphologies of bacterial are coccus(spheres) and bacillus (round-ended cylinders). However, some bacteria have unusual morphologies, such as helically twisted cylinders (spirochetes), cylinders curved in one plane (selenomonads) and other morphologies(Madigan and Martinko, 2005; Salton and Kim, 1996).

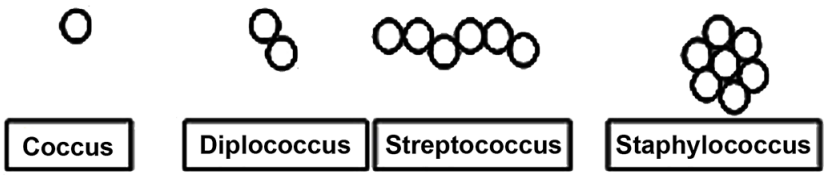
Figure 1. presents the types of cocci morphologies. This first group of bacteria is called coccus due to their spherical morphology. The diplococcus is the coccus bacteria that are in pair arrangement. Meanwhile, bacteria in a chain arrangement is called streptococcus and lastly,a cluster of coccus is known as staphylococcus. This type of bacteria causes a much different type of common diseases. The examples of the bacteria are *Staphylococcus aureus*, *Neisseria meningitides* and *Streptococcus pyrogenes.*

Table 2. Micronutrients for microorganism's cell

Nutrient	Source	Function
Manganese, Mn	Manganese salts	Major classes of ion transporters in prokaryotes (Andrea *et al.*, 2007).
Cobalt, Co	Cobalt salts	As a cofactor and activator for enzymes (Hausinger, 2007), fixes nitrogen during amino acid production, single cobalt atom is the central metal component in the vitamin B_{12}(Raux*et al.*, 2000).
Zinc, Zn	Zinc salts	An essential trace element for the growth of most organisms, required for multiple cellular function(Gielda & Dirita, 2012).
Copper, Cu	Copper salts	Copper atom contained in the protein, required for defense against oxidative damage, act as electron carriers(Magnani & Solioz, 2007).
Molybdenum, Mo	Molybdenum salts	Enzyme component (xanthine oxidase, sulphite oxidase, aldehyde oxidase) (Spears, 1999).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 1. Morphologies of coccus type bacteria (Okafor, 2011)



Meanwhile, Figure 2 shows the morphologies of bacilli group. This type of bacteria group is in cylindrical form. The arrangements of these bacteria are in single-cell bacteria called bacillus or in the chain shape like streptobacillus. They also have several types of arrangement for bacillus group, like diplobacillus, trichome, palisade, and coccobacillus. This type of bacteria can give positive and negative impact to our health. Some examples of bacillus species are *Escherichia coli*, *Corynebacteriumdiphteriae*, and *Bacillus anthracis*.

Figures 3, 4 and 5 show other morphologies such as vibrio, spirillum and spirochete. Vibro's morphology has a comma-like shape or curve rod shape (Figure 3). Basically, this type of bacteria lives in the aquatic environment. Most of these bacteria can cause diseases. The example of vibrio bacteria is cholera that can cause diarrhea and dehydration symptoms to patient(Saritha, 2015).

Figure 4. presents the morphology of spirillum. This morphology has a more rigid spiral shape. It has no outer sheath and endoflagella, but bacteria with many turns can look like spirochetes. Some examples of spirillum bacteria are *Campylobacter jejuni* and *Helicobacter pylori*(Perez and Martin, 1996).

Figure 5. shows the morphology of spirochete, which is a long, thin and flexible corkscrew shape. It typically moves in a distinctive rotating manner that allows it to become mobile in mucus-lined tissue or a place that is viscous. This bacteria contain outer sheath and endoflagella, but lack bacterial flagella. The examples of this type of bacteria are *Treponemapallidum* and *Borreliaburgdorferi*.

For more details of bacterial characteristics, biochemistry test should be conducted, where the reaction of bacteria with some chemicals will be recorded and analyzed. Besides that, DNA analysis can also be applied for faster and accurate result (Busse et al., 1996).

Figure 2. Morphology of bacillus type bacteria (Saritha, 2015)

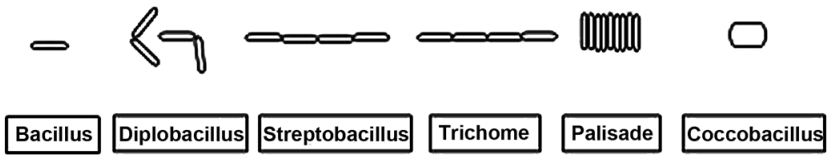


Figure 3. Morphology of vibrio type bacteria

Figure 4. Morphology of spirillum type bacteria

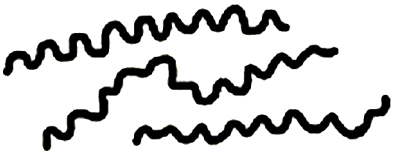
Figure 5. Morphology of spirochete type bacteria



Nowadays, the leachate treatment already includes the use of bacteria to enhance the treatment process and also to reduce its capital and processing cost. There are many types of bacteria involved in the treatment of leachate. Table 3 shows the studies done by previous researchers on the treatment of leachate around the world.

Based on the Table 3, it is already well known for the biological treatment of waste water around the world. There are a lot of advantages by using the biological way to treat waste water due to its minimal capital and maintenance cost, efficiency in degrading pollutants like organic matter and its improved flexibility of waste water treatment using bacteria.

Environmental Condition

In the real situation, application of bacteria in the biological treatment will consume proteins, carbohydrates, lipids and trace elements in the substrate or wastewater. However, the performance of bacteria depends on their metabolite and environmental conditions. In terms of environmental condition, it totally depends on the type and characteristics of the bacteria. Every bacterium has its own environment required in order to survive and grow in the optimum range. Typically, some bacteria can survive in a hot environment (thermophilic bacteria), while some have the tendency to give optimum reaction in cold or common temperature (phsyophilic and mesophilic bacterial) (Boundless, 2015). In many cases, bacteria have the tendency to give optimum reaction in high moisture condition and some of them can tolerate saline environment and etcetera. Therefore, the environmental condition must be considered in order to provide the most suitable environment for bacteria to grow. This section will discuss environmental conditions in detail for common bacteria that have been used in the biological treatment.

Table 3. Leachate treatment through biological process

No	Case	Bacteria	Result
1	Study about various method used to treat of untreated leachate (Kamaruddin *et al.* 2014).	*Pseudomonas* isolates, *Bacillus* isolates, *Burkholderia* isolates	Over the years studies show that the changes of compound in leachate due to mankind activities make the treatment varies according to the compounds in the leachate.
2	Study about treatment of fresh leachate from MSW incineration plant with high strength using EGBC reactor (Dang *et al.*, 2013).	Methanosarcina (Archaea), Firmicutes (Eubacteria).	After fermentation, 86.7% of COD removal.
3	Study about the effect of using immobilisation technique to the bacteria for nitrification process(Isaka *et al.*, 2007).	*Nitrosomonassp.*	It shows that the rate of nitrification of ammonia is higher at temperature 10˚C for more than a year.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Gaseous Requirement

Gaseous environment is the most important requirement to influence the environmental condition of the bacteria. Condition of gases in the environment can be divided into three types; aerobic, anaerobic and facultative condition. An aerobic condition is a situation where the bacteria need oxygen for their growth and acts as its essential nutrient. Meanwhile, an anaerobic condition is the condition where some bacteria cannot tolerate oxygen at all (strict anaerobe). For facultative bacteria, the bacteria have the possibility to grow in both conditions.

Commonly, in poor oxygen environment like at the bottom of the sea or inside a swamp, anaerobic bacteria can easily be found. However, aerobic bacteria can also be found in this environment, where they still can probably survive in low oxygen or if it is facultative bacteria. Most of the common anaerobic bacteria can be found in poor oxygen environment like *Methylococcuscapsulatus*(Chistoserdova et al., 2005).These bacteria will reduce methane gases (normally producedby anaerobic bacteria from methanogenic group) by converting them into methanol and other products. Other aerobic bacteria are *Vibrio diabolicus* SF16, which are used to remove $NH_4^{\pm}N$ content (Duan et al., 2015). Alleman(1999) used b*acillus spp* in the thermophilic condition for biological treatment of wastewater.

Most strict anaerobic bacteria could not tolerate oxygen from outside but it can tolerate gases such as nitrogen or carbon dioxide. On the other hand, some of the bacteria cannot tolerate at a small amount of oxygen at all, even in salt form (Walter, 1969). Some examples of anaerobic bacteria are *Saccharomyces cerevisiae*, *Zymomonasmobilis*, *Escherichia coli* and *Clostridium acetobutylicum*(Singh et al., 2012). These bacteria are used in the production of bioenergy fuel like bio-ethanol and bio-buthanol.

Facultative bacteria, which could grow in aerobic and anaerobic conditions, have high possibility to isolate from the source of environment. However, their metabolite and production are probably a bit different, even if it comes from the same species of bacteria if it compares the culture from aerobic and anaerobic conditions (Walter, 1969).

Temperature

Most bacteria grow well at their optimum temperature. The common bacteria easily isolate from an environment within their range of optimum temperature between 37˚C to 45˚C. This type of bacteria is called mesophilic, which is mostly used in the biological treatment for heavy metal, carbon and nutrient removal. Bacteria in this group are also used in mining industries as a bioleaching that replaces the ordinary leaching technique that is expensive and environmentally unfriendly(Makita *et al.*, 2004). However some of the bacteria from this group also have the tendency and possibility to cause human diseases as they can grow well in human body temperature, especially from the pathogenic group (Sahlström, 2003).Thermophilic bacteria are bacteria that can tolerate a high temperature environment. The ranges of temperature for thermophilic bacteria are between 40˚C up to 80˚C. Basically, these kinds of bacteria can be found in places like volcano area, hot springs and a very hot place. The examples of thermophilic bacteria are *Thermoanaerobacteriumsaccharolticum*,*Thermoanaerobacteriumthermosaccharolyticum*, *Anoxybacillusspp* and *Geobacillusspp*(O-Thong *et al.*, 2011). These bacteria can be used in the industries for the production of bio hydrogen from cassava starch processing wastewater (CSPW).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Psychrophilic bacteria are bacteria that can survive at a temperature below 25˚C and usually, these kinds of bacteria can be found in cold weather places like the north and south poles. Usually, psychrophilic bacteria have names like 'arctic'. However, some psychrophilic bacteria that do not have the sign of their psychological condition on their name, like *Pseudomonas sp* CBZ-4, are used in the cold weather to degrade carbamazepine, that is contained in the pharmaceutical wastewater(Li *et al.*, 2013).

pH

pH is one of the indicators used to measure the acidity and alkalinity of the aqueous solution. pH of the solution is measured by referring to the concentration of hydrogen ion in the solution. Greater amount of hydrogen ion in the solution will lead to lower pH and vice versa. Many groups of bacteria can grow best in the pH range of 6 to 8. An example of bacteria that can grow in the solution within this pH and used for biological treatment is *Ganodermalucidum*. This bacteria is used in the industries to treat textile dye wastewater (Selvakumar *et al.*, 2012). Other bacteria like *Methylomirabilisoxyfera* is used in the wastewater treatment, where ammonium and residual dissolved methane can be removed at the expense of nitrite and nitrate (Luesken *et al.*, 2011).Several groups of bacteria can tolerate highly acidic and alkaline environment. Normally, these types of bacteria are known as halophilic bacteria. The advantage of these bacteria is that it can be used to treat wastewater in extreme conditions. For example, *Marinobacterhydrocarbonoclasticus* and *Halomonasspp*thatcan survive in high salt concentration and high pH of around 8 to 9, are commonly used in denitrification of wastewater (Li *et al.*, 2013).

Inhibition

Before biological system could be operated, identification types of culture need to cleared. Moreover, mixture or single cultures want to be introduced. If the mixture culture is selected, then the environment condition needs to be improved. For example, if aerobic bacteria have been chosen, the pH and aeration need to be studied. Lack of this factor could bring inhibition to bacteria. Normally, these inhibitory substances can be one of the factors for treatment failure. This inhibition can be traced by measuring the byproduct produced; for instance, in the anaerobic digestion, the byproducts are methane gas and organic acid. The lowest production from common rate means that inhibition is probably happening (Chen *et al.*, 2008).

For the treatment of waste water, mainly leachate, anaerobic treatment is preferable. This is because protein and carbohydrate are more efficiently degraded in anaerobic treatment. On the other hand, leachate also contains pollutants like ammonia; phosphate, nitrogen, and sulfur.In the aqueous solution, there are two forms of ammonia material like ammonium ion and free ammonia. The free ammonia can cause inhibition to the anaerobic treatment because it can passively diffuse into the cell and cause problems like proton imbalance and potassium deficiency. For the waste water treatment, ammonia inhibition can be controlled by lowering the ammonia content in the leachate at an acceptable level but not totally removed because ammonia is one of the sources of nitrogen to the anaerobic bacteria (Cheung *et al.*, 1997).

Sulphate can also become an inhibitor element. Sulphate is one of the common chemicals that can be found in the wastewater. In anaerobic treatment, sulphate will be reduced by using Sulphate Reducing Bacteria (SRB). These bacteria will degrade sulphate to become a simple compound. One of the major problems in applying SRB is the competition of common nutrients between SRB and other bacteria that will lead to the accumulation of sulphate. Other inhibition is the toxicity of sulphide, which affecting

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

other bacteria. During the process, SRB will degrade sulphate to a simple compound namely sulphide, which will inhibit the growth of SRB if it is above the acceptable amount. In addition, the increase of pH can also elevate the toxicity level of sulphide to the bacteria (Muyzer& Stams, 2008). In order to control the inhibition of sulphate for anaerobic treatment, several processes can be done, including diluting the landfill leachate. Recently, the removal of sulphide can be done by using physio-chemical and chemical techniques, which will be discussed later.

The third inhibitor is heavy metal. Heavy metal is a non-biodegradable material that can potentially become toxic to the bacteria and cause failure in anaerobic treatment of landfill leachate. The toxic effect of heavy metal can be seen in the disruption of enzyme function and structure by binding the metal to the group of protein molecule or replacing the material in the enzyme prosthetic groups. However, there are some heavy metals that are essential for the enzyme parts that contribute to the enzyme functions like iron, zinc, nickel, cobalt and etc. The inhibition of heavy metal to the bacteria is based on concentration, chemical form, process-related factors like pH and redox potential in the landfill leachate. Some of the heavy metals are used in many physio-chemical treatments of leachate, such as precipitation of sulphide, sorption of solid fraction, and formation of complexes in the solution (Chen *et al.*, 2008). To remove heavy metals from leachate, detoxification must be done by using several techniques such as adding sulphide, activated carbon, kaolin, bentonite, and diatomite in the treatment.

Even organic compound is food for bacteria but it can also become an inhibitor. Organic compounds inhibit the growth of bacteria if they are poorly soluble in the water. It may also adsorb to the surface of the bacteria and accumulate to high level in digesters. The nonpolar pollutant that accumulates in the bacteria membrane can cause the membrane to swell and leak. Some of the organic compounds that inhibit the growth of bacteria are benzene and its derivatives, phenol and its derivatives, alcohol, ether, ketones, and etc. Factors that affect the toxicity of organic compounds are toxicant concentration, biomass concentration, toxicant exposure time, cell age, feeding pattern, acclimation and temperature.

Pretreatment

Nowadays, rubbish is thrown into the landfill because it is the most cost effective way to dispose municipal solid waste (MSW). Every country has their own technology to manage landfill in order to make it less polluted and safe for the people. However, when using landfill as a method to dispose MSW production, leachate should be considered. Leachate is the water that comes from the landfill when the majority of soluble materials in the waste will come along with the water that comes out from the landfill. This contaminated water contains a lot of polluted material such as heavy metals, chemicals, organic materials and others that cannot be degraded by the bacteria. As a result, this leachate eventually pollutes rivers, lakes, and ground water severely. In addition, the production of leachate depends on the rate of rain fall onto the landfill that contributes to the rate of leachate production. A higher amount of leachate is produced during the wet season compared to dry season (Tränkler *et al.*, 2005).

Thus, to solve the leachate problem, treatments of leachate are required. To keep the treatment environmental friendly and cost effective, biological treatment is the best option. However, due to high content of a variety organic and chemical compounds in the leachate, several pretreatments are required in order to treat the leachate before going to the biological stage. Physical-chemical treatment has been suggested for use such as screening, flocculation, sedimentation, flotation, filtration, natural evaporation coagulation, precipitation, chemical oxidation, chemical reduction, disinfection, and carbon adsorption (Baig *et al.* 1940).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

However, due to high maintenance and non-environmental friendliness of the physical-chemical process, the reaction or removal that emerges from this treatment will be minimized sufficiently to prepare the leachate for biological stage. After that, microorganism becomes suitable to grow and consume nutrient, organic matter and significantly treat landfill leachate. Understanding the profile of the leachate is important to ensure that whether the leachate requires a pretreament or not. Biological treatments have some limitation. Generally, the amount of COD is greater than BOD, but if the ratio of BOD/COD is too small, it indicates that the leachate needs a pretreatment from physical-chemical process. High concentration of oil, grease, heavy metal and inorganic material isone of the factors that indicate the requirement of a pretreatment (Imen et al 2001).

Mechanism of Biological Process

Nowadays, wastewater treatment applies modern technologies and knowledge in order to upgrade the quality of treated water and also to reduce its operational cost. Each wastewater treatment is classified by their nature of the process involved, namely physical, chemical or biological treatment. For the mechanism of biological treatment process, bacteria are mainly used in the decomposition of biochemical matter in the wastewater to produce stable end product. The mechanism chosen for each treatment is based on the severity of pollutants contained in the waste water.

Nitrification and Denitrification

Ammonia is a compound of nitrogen and hydrogen that bonds together in the form of NH_3. Normally, ammonia is in the form of gas and it has a pungent smell. In the landfill leachate, ammonia is produced when the organic compound that contains nitrogen element breaks down to a simpler form. In general, nitrogen is the fourth most abundant element in the world. The landfill leachate contains a large amount of organic waste, which is mainly food waste. Due to that, the ammonia content in the landfill leachate becomes high, which could obviously cause harm and pollute the environment when it is discharged without undergoing proper treatment. Nitrification is the process where the ammonia will be converted into nitrite and eventually it will be converted into nitrate by biological treatment. The nitrification process occurs due to biological oxidation process that occurs between ammonia and oxygen. In the degradation of ammonia into nitrite, the ammonia will undergo nitrifying process by bacteria under aerobic condition to become nitrite (NO_2). Then, the nitrite will undergo another biological oxidation process where it will be nitrified by nitrifying the bacteria under aerobic condition to become nitrate (NO_3).After the nitrification process is done, the denitrification process will take place. In the denitrification process, the nitrate will be converted into other products through assimilatory and dissimilatory cellular functions. In assimilatory cellular function, the nitrate will be converted into nitrite and it will be further converted into nitrite, and eventually will become ammonia. These conversions will be done by specific bacteria under anaerobic condition (Yang & Zhang, 1995).

In contrast, dissimilatory denitrification occurs when the nitrate becomes the electron acceptor in energy metabolism and it will be converted into various gases such as carbon dioxide and nitrogen gas. There are several elements that are needed by the process to make the dissimilatory denitrification process become efficient, which are oxygen gas and carbon sources. The condition of the leachate is normally under anoxic condition when it can be considered that the oxygen level of landfill leachate is lower than in aerobic condition. Therefore, the leachate must be aerated properly to supply sufficient

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

oxygen to the leachate. The other element is carbon sources. The carbon sources become important due to their function to become an electron donor for the denitrification process to take place. The sources of carbon may already be contained in the leachate or will be added manually. The proportion of carbon to nitrogen and to phosphorus must be 100:5:1 in order for the process to occur (Yang & Zhang, 1995).

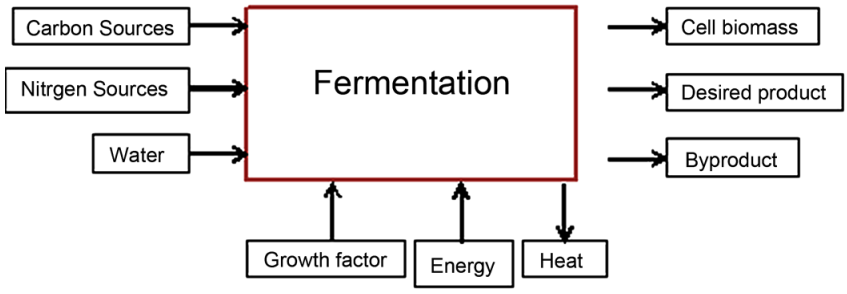
Digestion and Fermentation

Biological Oxygen Demand (BOD) is the amount of dissolved oxygen needed by the aerobic bacteria in the leachate or wastewater to breakdown the organic material that is present in the solution at a certain temperature over a specific period of time. Meanwhile, Chemical Oxygen Demand (COD) is one of the techniques to measure the amount of materials that can be oxidized in the presence of a chemical oxidizing agent. In landfill leachate treatment, the COD and BOD values become one of the indicators to the pollution level of the leachate. Basically, in the leachate, the value of COD must be larger than the value of BOD because the COD value is composed of materials that can be oxidized by chemicals and taken by biological material, while the BOD is a material that can be consumed by biological organism as carbon sources. Therefore, by referring to the value of COD and BOD removal, we can indicate the efficiency of the leachate treatment based on these two indicators (Ghosh *et al.*, 2014).

In anaerobic digestion, degradation and fermentation will occur in the same digester. The bacterial will degrade carbon and nitrogen sources to produce specific products under fermentation (anaerobic condition). Process in the anaerobic digestion can be divided into four stages. Hydrolysis process will start from beginning. In this stage, enzyme will degrade complex organic matter to simple organic matter such as protein to amino acid, carbohydrate to simple sugar and lipids to fatty acids. Enzyme from this stage is produced by bacteria, which are available in the digester. Then acidogenic or fermentation bacteria will take part and convert simple organic matter to other products such as acetic acid, simple fatty acids and gases such as hydrogen and carbon dioxide. Then, this is followed by acetogenic bacteria to degrade complex fatty acids to acetic acid. Finally, bacteria from the methanogenic group will take part and convert acetic acid and hydrogen to methane and carbon dioxide. Figure 6 shows the schematic diagram for fermentation process.

From the figure above, we can see the requirement of the bacteria for the treatment of landfill leachate. The carbon sources come from the organic material in the leachate. The measurement of organic material that can be consumed by the bacteria can be done by referring to the BOD value as it indicates the organic carbon that can be utilized by the bacteria.

Figure 6. Schematic diagram for bacteria fermentation process (Zacharof & Lovitt, 2013)



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Most of the landfill leachates contain a lot of other materials like sulphur, ammonia and organic matter. These materials can be degraded in the leachate by altering the bacteria fermentation by introducing specific types of bacteria that can consume the material as food sources. For example, *Nitrobacter* bacteria can convert ammonia content into nitrate (Sun *et al.*, 2015).

Metal and Nutrient Removal

Usually, leachate is contaminated with high concentrations of a variety of heavy metals, solvents and chemicals, which come from dumped waste in the landfill or reaction between all of those components. Table 4 lists the MSW composition in Pulau Burung Landfill Site (PBLS), Penang.

Table 4. shows the variety of waste dumped at the landfill. The highest percentage of waste composition in PBLS comes from food waste followed by plastic, others and paper. This is because Penang state has one of the highest populations per square meter after the capital city of Malaysia (Kuala Lumpur). It is also due to a lot of industrial parks located in Penang that contribute the variety of solid waste. As a result, numerous chemicals, heavy metals and compounds will be contained in the leachate. The leachate components of PBLS are shown in Table 5.

Based on the composition of leachate, there are several treatments that are required to reduce these compounds to an acceptable amount before being discharged into the environment. For example, if the leachate from landfill has frequently identified high contents of ammonia, then it is reduced by using the nitrifying and denitrifying techniques that have been discussed in subtopic 3.1. For the heavy metal removal, numerous pretreatments are used and the removal efficiency of metal is quite high. In previous researches, fly ash made from coal was used as an adsorbent to trap heavy metal ions such as zinc, lead, cadmium, manganese, copper and etc. (Cho *et al.*, 2005; Mohan & Gandhimathi, 2009;Cetin & Pehlivan, 2007). There is also heavy metal removal from leachate using biological treatment as presented in Table 6.

Table 4. Composition of MSW from PBLS (Yusoff, 2012)

Waste Components	Weight (%)
Organic Food	57.4
Paper	8.56
Plastic	13.93
Rubber	2.8
Textile	2.79
Glass	2.28
Ferrous	1.3
Other	10.94

STABILIZATION PONDS AND BIOREACTOR

Stabilization ponds and bioreactors are most important for biological treatment. The performance of biological system depends on this matter. Table 7 shows the types of ponds and bioreactors that are commonly using for leachate treatment.

Stabilization pond is a pond that consists of one or more shallow ponds in a series for treatment and the natural process of algae and bacteria occurs in a mutually dependent relationship (Indah Water Konsortium, 2014). Meanwhile, a bioreactor is a vessel specifically designed to grow and maintain the microorganism in which the condition inside the vessel can be controlled.

Aerobic Ponds and Bioreactor

Aerobic treatment is the treatment of leachate in the presence of oxygen. In this process, the microorganisms will generate energy through enzyme-mediated electron transport using molecular oxygen as electron acceptor (Environmental Protection Agency, 2000). There are many types of aeration treatments, such as activated sludge reactor, rotating biological contactor (RBC) and aerated lagoons.

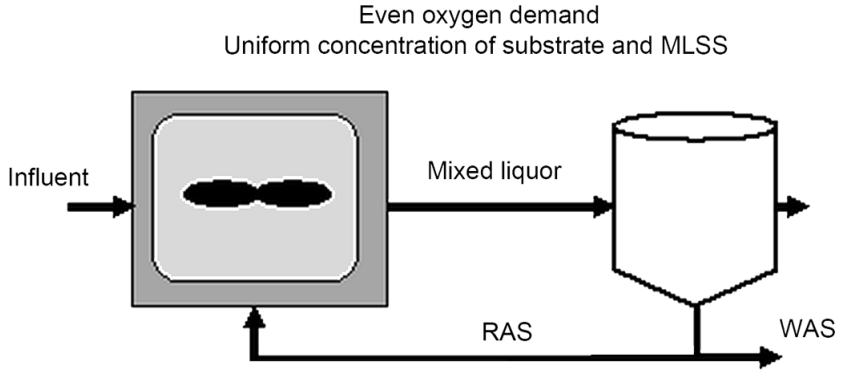
Activated Sludge

The principal that appears in activated sludge process is that it uses a community of microorganisms in a reactor that is constantly supplied with organic matter and oxygen (Wiszniowski *et al.*, 2006). The microorganisms will consume the organic matter in a leachate and undergo metabolism to produce new cell and products, which consist of water, carbon dioxide and minerals (Wiszniowski *et al.*, 2006). Instead of using pure culture, the activated sludge consists of bacteria, yeast, fungi, protozoa and higher organisms which interact with each other (Wiszniowski *et al.*, 2006). According to the Environmental Protection Agency (2000), in activated sludge process, diffusion or surface aeration is used to maintain aerobic condition in a reactor. After some time, a mixture of new and old cell is passed through into a settling tank, but a portion of the settled cell is recycled to maintain the desired cell concentration in a reactor and the rest are sent to sludge handling facility. The schematic diagram of activated sludge process is shown in Figure 7.

In a landfill site designed by the Environmental Protection Agency, which was published in 2000, emphasizing the aerobic process such as activated sludge, there will be a residue of 0.1 to 0.6 g of sludge generated per g COD removed at about 1.0% solids concentration. Activated sludge process strongly depends on several parameters, which are concentration of feed, sludge retention time (SRT), hydraulic retention time (HRT), biomass concentration in aeration tank (MLSS, Mixed Liquor Suspended Solids), organic

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 7. Schematic diagram of mixed activated sludge process (Environmental Protection Agency, 2000)



loading, food to microorganism ratio (F/M ratio), sludge wastage rate, and sludge settling characteristics in sedimentation tank (Setiadi & Fairus, 2003).However, this method has some disadvantages, such as:

A. If the production of sludge is high, large areas are required (Setiadi and Fairus, 2003)
B. Inadequate sludge settling ability and needs longer aeration times (Zouboulis *et al.*, 2001)
C. High energy demand and excess sludge production
D. Microbial inhibition due to high amount of ammonium-nitrogen strength (Renou *et al.*, 2008)

The performance of conventional activated sludge process is significantly affected by several parameters such as concentration of feed, sludge retention time, hydraulic retention time, biomass concentration in aeration tank, organic loading, food to microorganism ratio, sludge wastage rate and sludge settling characteristics (Setiadi & Fairus, 2003). In the past century, basic activated sludge process has been modified depending on various purposes such as complete-mix activated sludge that allows more uniform aeration in the tank, step-aeration activated sludge, which distributes the influent to several points in aeration tank, contact-stabilization activated sludge, which allows high concentration of biomass to be in contact with the influent for a period of time, tapered aeration process that loads organic influent at the head of aeration tank and pure oxygen activated sludge, which is based on the rate of oxygen transfer. Furthermore, to enhance the performance of activated sludge process, many researchers suggested integrating membrane technique in the leachate treatment (Setiadi & Fairus 2003; Renou *et al.*, 2008; Yamamoto *et al.*, 1989).

Aeration Lagoon

The idea that lies behind aeration lagoon is very simple. The retention time of the leachate is long enough so that many microorganisms can grow per time as the leachate is transported out of the lagoon. Long retention time is necessary in order to oxidize ammonia nitrification. The cost for the operation and maintenance of aerated lagoon is relatively low (Stegmann *et al.*, 2005).The advantages of aerated lagoon are that it can cope with various leachate strength, flows and the most flexible type of leachate treatment. However, it also serves many disadvantages such as large area requirement, odor and aerosol formation, low energy efficiency and high heat loss due to surface and mechanical aerator (Environmental Protection Agency, 2000).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Rotating Biological Contactor (RBC)

RBC consists of a series of circular plastic discs (polyethylene, polyvinyl chloride or polystyrene) mounted on a common horizontal shaft. It is approximately 40% submerged in a leachate and slowly rotates either by a mechanical or a compressed air drive. It usually rotates at 1-10 revolutions per minute (RPM) (Wiszniowski*et al.*, 2006). Figure 8 shows the schematic diagram of RBC.

Microorganisms from the leachate will adhere to the plastic disc and within 1-4 weeks, it will form a biofilm ranging from 1 to 2 mm thickness. This biofilm will be exposed to air when the plastic disc rotates out of the leachate. After some extent of thickness, the biofilm will be sloughed off the plastic disc (Wiszniowski *et al.*, 2006). Generally, RBC is used for weak leachate.

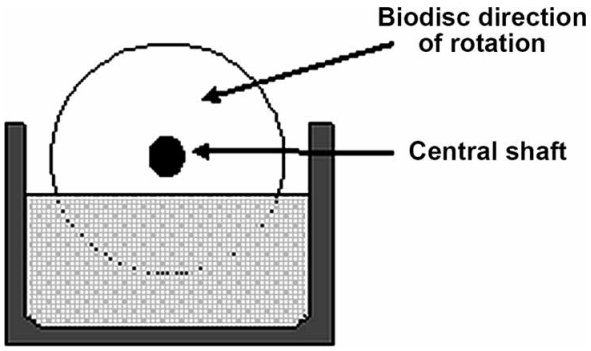
Anaerobic Ponds and System

Anaerobic process is slightly different from the aerobic process where no oxygen is required. Electron acceptors in this process are inorganic compounds such as nitrate, sulphate and carbon dioxide (Environmental Protection Agency, 2000). The EPA (2000) stated that anaerobic process provides several benefits such as lower sludge production, lower energy demand (no oxygen required) and recovery of methane may provide energy. Anaerobic process is an effective process, but the remaining of BOD and COD are still high and at the end, it still needs to be treated to meet the effluent standard with means of aerobic process (Stegmann *et al.*, 2005). Normally, anaerobic treatment is required if the production of leachate is too high or the landfill is huge and has been operated for a long period of time. Many kinds of anaerobic bioreactors have been introduced for leachate treatment such as AF (Anaerobic Filters), ASBR (Anaerobic Sequencing Batch Reactor) or UASB (Up-flow Anaerobic Sludge Blanket) (Wiszniowski*et al.*, 2006).

Anaerobic Filters

Anaerobic filters (AF) is filled out with a support material arranged in sheet, ring or sphere configuration, which will provide the best attachment place for microbial in the form of biofilm and can be operated in upflow or downflow feed mood(Bodik *et al*., 2000).

Figure 8. The schematic diagram of rotating biological contactor (RBC) (Environmental Protection Agency, 2000)



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

AF is a high rate system that gathers all disadvantages of anaerobic system and thus minimize the disadvantages (Renou *et al.*, 2008). Henry *et al.* (1987) reported that the removal of COD from landfills with different ages was at 90% with a loading rate of 1.26-1.45 kg COD m^{-3} d^{-1}.

There are several advantages of AF, which are, this system is suitable to treat low strength leachate, the produce sludge is in minimal quantity, and the maintenance and handling are easy. The disadvantages of the AF system is dead zone formation as a result of sludge compaction and it tends to clog because of poorly designed distribution system (Bodik *et al*., 2000).

Anaerobic Sequencing Batch Reactor

Anaerobic sequencing batch reactor (ASBR) consists of four steps, which are feeding, reaction, settling and liquid withdrawal (Zaiat *et al.*, 2001). This system is not suitable for low-strength leachate since the low gas production will result in insufficient turbulence, which will lead to stagnant zone in a reactor and/or external mass-transfer resistance (Brito et al., 1997).

ASBR can eliminate the use of clarifier because it can achieve solid capture and removal of organic in one vessel (Timur & Özturk 1999). According to Timur and Özturk(1999), the COD removal effeciencyrate was between 64-85% and net daily biomass conversion yield was about 0.1g volatile suspended solids (vss) per g of COD removed.The removal of nutrient (COD, NH_4-N, PO_4-P) from landfill leachate by using SBR was investigated by Uygur & Kargi (2004), who reported 75% COD, 44% NH_4-N and 44% PO_4-P removals after 21 hours of operation. This high removal was achieved when the investigator combined the anaerobic reaction with aerobic and anoxic reaction in SBR.

Up-Flow Anaerobic Sludge Blanket

Up-flow anaerobic sludge blanket (UASB) is a modern anaerobic process which have high treatment efficiency but short hydraulic retention time (HRT) (Lin *et al*., 2000). UASB performs more preferably at higher organic loading rate compared to other anaerobic treatments (Govahi *et al*., 2012). The author also emphasized that UASB is suitable to treat leachate with a COD value higher than 800 mg/L and BOD/COD value ratio higher than 0.3.

UASB offers very good treatment, which can remove 77-91% COD but leachate that was treated by UASB is not suitable for direct discharge of leachate into sewerage system, thus further treatment is required (Kennedy & Lentz, 2000). Kettunen *et al.*(1996) reported that UASB treatment can be done on leachate that hasa temperature of as low as 11ºC. Thus, this will minimize the need of heating up leachate prior to treatment especially in cooled weather country, which will provide more cost effective treatment (Renou *et al.*, 2008). The main disadvantage of this treatment is its sensitivity to toxic substances (Sung *et al*., 1997).

FACULTATIVE SYSTEM

Another system is facultative, which normally runs in the lagoon and has already been introduced for a long time as the treatment of leachate. Facultative lagoon is not mechanically agitated or aerated. From wastewater technology fact sheet that was published by United Sates Environmental Protection Agency in 2002, it is clearly stated that a facultative lagoon is separated by two layers, which is aerobic and an-

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

aerobic. Aerobic layer is located near the surface of pond, while anaerobic layer is a layer at the bottom of the pond where the sludge deposits. The advantage of this system is that the maintenance cost is very low due to the system that is designed to make use of gravity flow. It is also easy to operate. According to the fact sheet, the performance of this system is partially reliable even though the BOD removal is up to 95%,and the total suspended solid exceeds 150mg/L (United Sates Environmental Protection Agency, 2002).

Advanced Bioreactor

Recently, membrane reactor technology found its way in treating the landfill leachate. According to Ahmed & Lan (2012), membrane bioreactor (MBR) is an advanced biological treatment process that can replace traditional secondary clarifier of an activated sludge process using a membrane separation unit. The authors also suggested that MBR is more advantageous in treating old leachate, which shows better effluent quality, process stability, smaller footprint, and increased biomass or mixed liquor suspended solids (MLSS) retention. Meanwhile, Laitinen *et al.* (2005) mentioned that membrane bioreactor can achieve high quality of treated water in a reduced sludge production. In general, MBR can be separated into two parts; biological unit,, which is responsible for biodegradation and membrane module, which is responsible for the separation. This membrane model normally uses ultrafiltration (UF) or microfiltration (MF) in the configuration of hollow fiber, plate and frame, flat sheet or tubular (Ahmed & Lan, 2012). They also added that the common design of bioreactor includes continuous stirred tank reactor (CSTR), plug-flow reactor (PFR), sequencing batch reactors (SBR) and upflow anaerobic sludge blanket (UASB) reactor. There are two types of MBRs, which are categorized by the position of the membrane; submerged or external reactor and submerged system becomes more attractive due to the more compact system (Bohdziewicz*et al.*, 2007).An article published by Ahmed &Lan in 2012 can be classified as a complete review on MBR technology in treating landfill leachate. In their article, it is reported that the COD removal was as high as 90% using MBR. In addition, Bohdziewicz*et al.* (2007) also reported that the COD removal was 90% for landfill leachate treatment using MBR.

Table 8. Effluent quality from SBR and MBR from the previous work done Laitinenet al. (2005)

Parameter	SBR Effluent	MBR Effluent
pH	8.2 ± 0.3	8.4 ± 0.2
Conductivity, mS/m	320 ± 90	350 ± 40
Suspended solids, mg/l	290 ± 210	1.2 ± 0.9
BOD_7, mg/l	190 ± 140	8.3 ± 9.6
COD_{Cr}, mg/l	500 ± 110	340 ± 30
Total P, mg/l	16.9 ± 4.2	0.77 ± 0.37
Soluble P, mg/l	10.89 ± 0.35	0.75±0.37
NH_3+NH_4 –N, mg/l	1.84±0.39	2.4±2.2
NO_3+NO_2 –N, mg/l	150±60	140±40
Alkalinity, mmol/l	8.5±3.5	12.0±4.3
Turbidity, FNU	250±210	0.9±0.31

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

SBR is a form of activated sludge process in which aeration, settlement, and decanting can occur in a single reactor. The process employs a five-stage cycle: fill, react, settle, empty and rest (Environmental Protection Agency, 2000). According to Laitinen *et al.* (2005), SBR system seems suitable for the treatment of landfill leachate in which the volumes and concentrations of the water produced can vary with time. However, some problems arise when using SBR system, such as high deviation values and bulking problems in the system, and also leakage of the sludge. There is a lot of improvement that can be done in SBR system in order to make it more efficient and reliable. Table 8 clearly indicates that the SBR system fluctuates so much. Laitinen *et al.* (2005) also concluded from their studies that both systems, i.e., SBR and MBR, removed total ammonia nitrogen effectively.

Integrated Biological Process

Sometimes, the combination of two types of biological system will lead to high performance for leachate treatment rather than using only one system. Im*et al.* (2001) reported the use of aerobic and anaerobic treatment process in treating leachate. They carried out denitrification and methanogenesis in anaerobic reactor, while organic removal and nitrification of NH_4^+-N were carried out in an aerobic reactor.

Im *et al.* (2001) emphasized the use of this combined reactor that can treat old and new leachate, and the removal rate of COD and BOD was also high. This system can be used for a longer time once installed in a leachate treatment facility. Figure 9 shows the schematic diagram of anaerobic-aerobic system.

Figure 9. Schematic diagram of anaerobic-aerobic system (Im et al., 2001)

Natural and Ecosystem Treatment

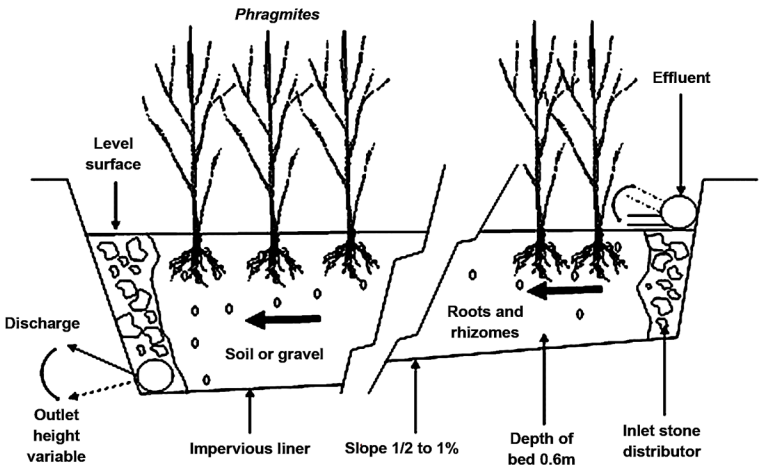
Respect to green environment, manipulation resource of natural and ecosystem without disturbing their chemistry and physically are widely useful. Wetland is one of the natural ecosystem resources that had been applied for treating polluted water through human simulation. In the United Kingdom, this system is called "reed beds" or "reed bed treatment systems" (RBTS), but internationally they are called constructed wetland (CW) (Sector Guidance Note IPPC S5.03, 2007). This system will reduce COD and BOD, oxidize ammoniacal-N, remove suspended solids, and also reduce concentrations of nitrate and phosphorus.

This system depends on the reed to transfer oxygen to their rhizomatous root system, which will stimulate the growth of bacteria in the surrounding soil and in turn will break down the organic substances in the root zone (Environmental Protection Agency, 2000). This treatment system is considered as 'green' and low in capital cost operation because real plant is used. Besides, the system is more natural and can provide habitat for animals. It can be constructed horizontally or vertically. Figure 10 shows the schematic diagram of horizontal RBTS.

Downstream

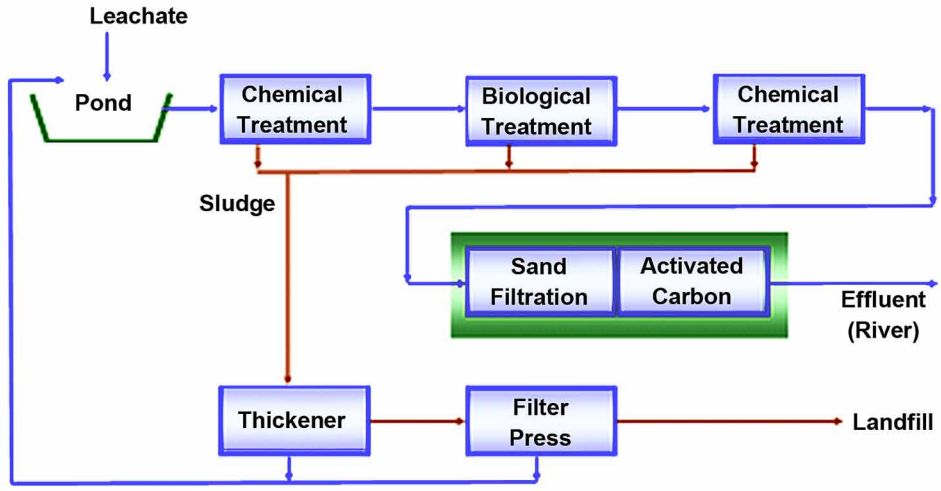
After complete the upstream process for pretreatment, treatment or additional treatment, leachate cannot directly discharge to river or return back to landfill but it need going to downstream system. The main concern of downstream system is to sort out any components not allowed to river. From the figure 11, the downstream unit operation would be physical processes where sludge will be thickened and filter pressed, and lastly will be dumped into landfill. The treated liquid will be filtered through sand filtration and activated carbon bed to ensure that the effluent released in the river stream follows the discharge standard from legal authority.

Figure 10. The schematic diagram of horizontal reed bed treatment systems (RBTS) (Sector Guidance Note IPPC S5.03, 2007)



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 11. Flow scheme of leachate treatment plant (Damieckiet al., 2007)



There are some rules that need to be followed for the place to discharge the leachate in Malaysia. The point of discharge must be within the boundary of landfill, immediately after the final unit of leachate treatment system. Second, the location must be easily accessible and does not pose any safety hazards to the personnel for inspection side and leachate sampling. The discharged leachate must be through pipe, conduit or channel. Fourth, the discharge point can be physically identified by installing a metal identification sign "Final Discharge Point". Lastly, the point of discharge and its surrounding must be properly maintained in order to be free from any obstruction and hazards during site inspection or leachate sampling (Environmental Quality act and Regulations, 2014).

Although biological treatment methods are known to be simple, cost effective and reliable, there are several limitations to that such as high concentration of ammoniacal nitrogen which is known to inhibit the biological degradation by microorganism, biological treatment gives good performance for treating young landfill leachate but cannot treat old leachate which mainly consists of recalcitrant matters and many substances that inhibit biological activity and low concentration of substrate such as phosphorus which is required by microorganism activities thus required addition of substrates (Tugtas *et al.*, 2013). Therefore, in general, biological treatment is used in combination with physical and chemical processes in order to achieve an effective leachate treatment.

Other alternative method integrated in the downstream system for leachate treatment is photocatalytic oxidation by titanium dioxide (TiO_2) which is widely used as photocatalyst because of its non-toxicity, photochemical stability, and low cost (Chemlal *et al.*, 2014). Using TiO_2 advanced oxidation method has resulted a stabilized leachate treatment, complete refractory fractions mineralization, 90% and 87% reduction of initial BOD_5 and COD for leachate treatment in Oued Smar landfill, Algeria (Chemlal *et al.*, 2014). In addition, techniques such as membrane treatment, bio-electrochemical treatment, ozone treatment, electro coagulation and electro-fenton oxidation were also implemented to increase the effectiveness of leachate treatment (Abu Amr *et al.*,2014; Cheml al *et al.*, 2014; Iaconi et al, 2011; Lin and Chang, 2000; Kashani *et al.*, 2012; Robinson 2005; Tugtas *et al.*, 2013). Using membrane bioreactor for treating leachate was proven to be the most efficient technique, but membrane fouling will be the biggest issue among operators (Robinson 2005; Ahmed and Lan 2012). Using bio-electrochemical

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

treatment via microbial fuels cells (MFC) produced high removal of volatile fatty acids (VFA) that can be exploited as polishing step for pre-treated landfill leachate (Tugtas *et al.*, 2013). In addition, it was reported that using Fenton oxidation for mature landfill leachate has achieved 60-86% of COD removal (Socias *et al.*, 2015). Also, ozonation process is also effective for landfill leachate treatment due to high oxidative power that will enhance fragmentation of organic compounds to carbon dioxide (Abu *et al.*, 2014). However, these treatments are not economically acceptable for large scale applications. Hence, strategies based on integrated chemical-physical-biological processes must be further studied to obtain the most feasible system.

Handling and Disposal Activated Sludge

Activated sludge exhibits wide mixture of properties depending on origin and previous treatment step. Thus, before handling or disposing the activated sludge, characterization parameters such as dry matters and volatile solids must be known in order to select the best method to be adopted for further applications. The selection of sludge handling and disposal should also include the energy requirements, cost efficiency of sludge thickening and dewatering, staffing requirements, sludge digestion or stabilization requirements (includes toxic effects of heavy metals or other substances), treatment of side-stream flow (i.e. digester and thickener) and sludge storage. The goal of treatment is to reduce sludge volume and make it suitable for ultimate disposal and also utilizing gas generated if biological treatment involved in the process. Table 9 shows the list of parameters used, their relation to the treatment and disposal steps (Brester*et al.*, 1997).

From Figure 11, the established method for sludge handling and disposal in Malaysia via sludge thickening and filter press method. Thus, only these methods will be described briefly in this part. Sludge thickening is employed to reduce the volume of sludge. There are two basic types of thickeners work by gravity or floatation and use either continuous or batch process. Gravitational thickeners use settling tanks with or without mechanical thickening devices. The design is basically on hydraulic surface loading and solids loading. Sometimes, the use of chemical additives such as lime or polyelectrolyte promotes higher loading rate. Floatation thickening causes sludge solids to rise to the surface where they can be collected via dissolved air floatation process. This process is suitable for activated sludge treatment where solids content of 4% or higher will be obtained. Sludge dewatering reduces the moisture content (60-80%) of the sludge so that it can be more easily disposed of by landfill, incineration, heat drying or composting. Sludge dewatering can be done using several techniques such as belt press filtration, sludge drying beds, vacuum filtration, centrifugation and filter press. Filter press is a plate and frame batch device that has been used for difficult process to dewater the sludge. It has the ability to produce a very dry cake and clear filtrate that makes it favorable for sludge handling. The advantages and disadvantages of filter press are listed in Table 10 (Joint Departments of Army and Air Force USA, 1998).

There are also several methods to dispose activated sludge such as land filling, agricultural use, composting and incineration. For land filling, sludge can be disposed using two method either mono deposits where only sludge is disposed of or mixed deposits where the sludge from municipal waste water treatment plant is disposed of together with the municipal solid waste. Selection of the feasible site has to be fulfilled especially safety distance from residential areas, public roads, river dikes and others. The important point is that the site should not cover even temporarily by inland waters or near to the area of water bases (aquifers). Re-cultivation of the sludge deposit has also been taken into consideration when selecting land filling method (Bresters *et al.*, 1997).

*Table 10. Advantages and disadvantages of filter presses **

No.	Advantages	Disadvantages
1	High solids content in cake	Large quantities of inorganic conditioning chemicals are commonly used for filter press
2	Able to dewater hard-to-dewater sludge, although very high chemical conditioning dosage or thermal condition may be required.	High capital cost especially for diaphragm filter presses.
3	Very high solids capture	Noise level caused by feed pumps can be very high
4	Only mechanical device capable to producea cake dry enough to meet landfill requirements in some locations.	Requires grinder or pre-screening equipment on the feed.

Risk of Untreated Leachate to Biological Life

Landfill leachate constitutes a very wide range of serious pollution hazards namely metals and toxic organics that can create environmental problems. It also can be a threat to both groundwater and surface water (Mendoza & Izquierdo, 2008). Various compounds can be found in landfill leachate such as dissolved organic matter, volatile fatty acids, heavy metals and organic xenobiotic micro compounds such as chlorinated solvents, petroleum products and pesticides, making them immediate treatment imperative (Mendoza & Izquierdo, 2008, Zainol*et al.*, 2013; Tugtas *et al.*, 2013; Xie *et al.*, 2014; Lema *et al.*, 1988). Many factors may contribute to the characteristic of landfills leachate, i.e., age, precipitation, climatic conditions, type and composition of waste (depending on the surrounding population) (Zainol *et al.*, 2013; Tugtas *et al.*, 2013; Xie *et al.*, 2014). For example, large amount of biodegradable organic matter contained in young landfills will promote rapid anaerobic fermentation resulting in the production of volatile fatty acids (VFA). In matured landfill, methanogenic microorganisms will convert VFA to biogas such as CH_4 and CO_2 (Renou *et al.*, 2008; Tugtas *et al.*, 2013).

Chemical pollutants contained in the leachate could be absorbed by aquatic species and may pass through the food chain and bio accumulate over long-term exposure if the leachate is not treated effectively (Sanchez-Chardi & Nadal, 2007; Sanchez-Chardi *et al.*, 2007; Long *et al.*, 2010). For example, mercury as contaminants may be stored in specific organ in which will accumulate over time known as bioaccumulation. This substance has the potential to pass on to the next level of consumers known as biomagnifications (Mulamoottil *et al.*, 1999). An understanding of leachate composition and an integrated strategy for risk assessment are crucial and necessary on long term impacts especially on possible adverse effects on human and ecosystem health (Isidori *et al.*, 2003; Baderna *et al.*, 2011). Previous studies

Table 11. Acceptable conditions for discharge leachate (Ministry of Natural Resources and Environment, 2010)

Parameter	Unit	Standard	Parameter	Unit	Standard
Temperature	°C	40	Manganese	mg/l	0.20

reported that ammonia plays an important role in leachate composition and toxicity both for human and ecological because it is a reducing agent with long term persistence (Isidori *et al.*, 2003; Baderna *et al.*, 2011). In vitro study showed that leachate inhibits cell proliferation at low doses probably inducing a reversible cell-cycle arrest at high doses that can lead to death (Baderna *et al.*, 2011). Leachates also have been previously shown to induce abnormal sperm morphology (Bakare *et al.*, 2005) and chromosomal abnormalities in bone marrow of mice, indicating that landfill leachate is genotoxic in mammalian cells (Sang & Li, 2005; Koshy *et al.*, 2007). Furthermore, the involvement of oxidative stress in municipal landfill leachate has induced toxicity in boar sperm (Adedara *et al.*, 2013). Therefore, precaution steps must be taken when dealing with landfills leachate to prevent unnecessary contacts that can cause severe injury to living organism. The risk can be either in the form of acute or chronic toxicity or subtle effect that will accumulate in the body of the exposed organism (Mulamoottil *et al.*, 1999). Therefore, this contaminated liquid must be treated before safely disposed to prevent contamination of water resources. Table 11 shows the specification of leachate discharge standards in Malaysia.

CONCLUSION

Even application of biological process for leachate treatment is not new technology but improvement especially in technical part about of this process is required. Integrated biological process or combination with new technology is needed to be explored due of possibility to increase quality and quantity of leachate treatment. Besides that, understanding about principal, mechanism and reaction of microorganism to leachate are advantages to design great system.

ABSTRACT

Adsorption techniques are widely used for the removal of various classes of pollutants from water due to their mild and facile operating conditions. The operations involved in the adsorption techniques are environmentally friendly, economical, highly selective on pollutants, highly efficient and easily operative. However, the adsorption of heavy metals from water using biomaterials (biosorption) is a relatively new and interesting technique which holds a great potential. Its effectiveness in lowering the heavy metals concentration to sub-ppb levels is appealing and has attracted increasing attention. The technique is believed to replace the existing technologies in the near future. This chapter discusses the prospects of biomaterials in the removal of heavy metals from waste water, the modification techniques that can enhance biosorption efficiency, and the factors influencing the biosorption processes.

1. INTRODUCTION

The increase in population, advances in technology and excessive use of resources have disturbed the ultimate existence of human beings. Water is the platform from which lives evolved and on which life exists. Notwithstanding, the amount of fresh water necessary to sustain the geometric rise in population is limited. More than one billion people live in a shortage of drinking water, and the figure is expected to reach four billion by 2025 (UNEP 2008). The available fresh water that is unevenly distributed within nations is faced with the problems of climate change, pollution, and inefficient management strategies. No denial, the world is seriously facing water crisis.

The presence of heavy metals (cadmium, mercury, lead, arsenic, chromium, nickel, zinc, and selenium) in the aquatic environment due to industrial, agricultural and domestic activities has confounded the existing problems of water scarcity with pollution. Heavy metals are widely known for their toxicity, bioaccumulation, and their propensity to pose serious threats to the ecosystem (Saleh and Gupta 2012). The conventional methods of removing heavy metals from effluents include flotation, coagulation, chemical precipitation, reverse osmosis, ion exchange, electro-dialysis, ultrafiltration, nano--filtration, *etc*. (Gupta *e*t *a*l., 2012). However, the conventional methods have several disadvantages such as lack of specificity to the metal ions, relatively expensive, and generate excessive sludge as a by-product (Lakherwal 2014).

The use of adsorbents is an efficient way to isolate heavy metals and other pollutants from industrial, agricultural, and domestic effluents (Saleh *e*t *a*l., 2016; Gupta *e*t *a*l., 2013). It has become the most preferred method of heavy metals removal because it is inexpensive, versatile, simple, and highly effective. Despite its advantages over the conventional methods, the pursuit for more efficient, cheap and environmentally-friendly adsorbents has been the focus of researchers in recent years (Ngah *e*t *a*l., 2008; Hua *e*t *a*l., 2012). Biosorption is an emerging technique in this regard, possessing a tremendous scope, especially in the developing countries where potable water has limited accessibility. Biosorption is the technique of utilizing living and non-living biological materials specifically for the purpose of removing contaminants such as heavy metals from aqueous solutions and effluents (Salam *e*t *a*l., 2011; Feng *e*t *a*l., 2011; Demirbas 2008). This chapter, therefore, discusses the application of modified and non-modified biomaterials for efficient heavy metals removal.

The first section of the chapter reviews the pollution and toxicity of heavy metals. The second section of the chapter discusses the adsorbents in use for heavy metals isolation, including activated carbon, nano-materials, biomaterials, and low-cost adsorbents. The application of non-modified and modified biomaterials for the removal of heavy metals is also reviewed in this section. The last section, which is the heart of this chapter discusses the modification strategies associated with biosorbents for efficient adsorption, possible biosorption mechanisms and the factors affecting the biosorption process.

2. POLLUTION AND TOXICITY OF HEAVY METALS

Heavy metals pollution is caused by natural and artificial sources. The volcanic eruptions, erosion of metal deposits and unavoidable atmospheric pollution are the major points of entry of heavy metals naturally into the environment. Nevertheless, nature has an inherent capacity to curtail the impact of natural pollution. Artificial sources of heavy metal pollution are mainly from agricultural activities, tannery operations, mining operations, metal plating activities, production activities of commercial products (*e.g*.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

batteries, paints, pigments, glass, ceramics), leachates from landfills and contaminated groundwater, *etc*. (Förstner and Wittmann 2012). Since the survival and comfort of human beings are directly linked to the above activities, the continuous release of heavy metals into the environment is inevitable.

Cadmium, mercury, lead, arsenic and chromium (even at low concentrations) are regarded as the most toxic heavy metals due to their significant impact on the environment (Tchounwou *e*t *a*l., 2012). They are systemic toxicants classified by the international agency for research on cancer (IARC) and the US EPA as "known or probable" carcinogens with the potential of inducing organ damage. These heavy metals are very much denser than water and the water laden with these heavy metals turns very toxic. The microbial population, which grows on this toxic water also turns toxic. When the water bodies flow into the seas, the polluted microbial population accumulates in the sea bed through which the heavy metals largely enter into the overall food chain of many organisms.

It has been proven that heavy metals affect cellular components and organelles such as the mitochondria, nuclei, cell membrane, lysosomes and enzymes involved in detoxification, metabolism and damage them (Wang and Shi 2001). They interact with cell components such as nuclear proteins and DNA and introduce significant changes to cell cycle leading to carcinogenesis or programmed cell death (Beyersmann and Hartwig 2008). Heavy metals are directly linked to the increased production of reactive oxygen species (ROS) and oxidative stress affecting master regulatory protein and the guardian of the genome p53, thereby increasing susceptibility to cancer and other diseases (Patlolla *e*t *a*l., 2009).

2.1 Cadmium

Cadmium is a heavy metal with environmental and occupational concerns. The anthropogenic sources of cadmium into the environment include the production of nickel-cadmium batteries, pigments, nuclear reactors and alloys. The routes of exposure to cadmium are mainly inhalation and ingestion (ASTDR 2008). Cadmium is a severe gastrointestinal and pulmonary irritant, which can be toxic and poisonous when ingested or inhaled. Acute exposures to cadmium are associated with symptoms such as abdominal pain, pulmonary, hepatic or renal injury, muscle cramps, vertigo, convulsions, shock, burning sensation, and nausea (Baselt and Cravey 1995). The chronic exposure to cadmium is associated with hormonal imbalance and pulmonary adenocarcinomas (Waalkes *e*t *a*l., 1996).

2.2 Mercury

Mercury exists in three different forms in the environment (elemental, organic and inorganic) having varying degrees of toxicity. The most frequently encountered organic species in the environment are the methyl mercury formed by the microbial methylation of the inorganic mercury in soil and water (Dopp *e*t *a*l., 2004). Mercury is a widespread environmental pollutant which causes severe alterations in body tissues and induces a range of adverse health effects. The major routes of exposure to mercury are inhalation, skin absorption, ingestion, skin/eye contact. Mercury is a carcinogen that affects the kidney, eye, nervous and reproductive systems (Leaner *e*t *a*l., 2007). The anthropogenic activities leading to the release of mercury into the environment include the industrial production of electrodes, thermometers, barometers, fluorescent lamps and amalgams (Tchounwou *e*t *a*l., 2003).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

2.3 Lead

Lead occurs naturally in the environment, but the anthropogenic activities such as mining, burning of fossil fuels and manufacturing of pigments, lead acid accumulators and antiknocks in petrol contribute significantly to the release of lead into the environment. The routes of exposure are mainly inhalation, ingestion, and skin/eye contact (ATSDR 1999). Lead is the most systemic toxicant that affects several organs in the body, including the liver, kidney, central nervous system, haematopoietic system, reproductive system and endocrine system. Children are the most vulnerable to lead poisoning and are prone to nervous system breakdown and mental retardation. The reason is that children absorb lead from contaminated water significantly higher than adults (ATSDR 1999). Decreased sperm count in men and spontaneous abortions are the major effects of lead exposure in the adult population (Hertz-Piccioto 2000).

2.4 Arsenic

Arsenic is found in low concentrations in almost all environmental matrices (ATSDR 2000). It exists in organic form as methylated metabolites and in inorganic form as trivalent arsenite and pentavalent arsenate respectively. Arsenic compounds have a wide application in the medical field for the eradication of many diseases (Centeno *e*t *a*l., 2005). However, the anthropogenic sources of arsenic have serious health consequences. The route of exposure of arsenic compounds to our body system includes inhalation, ingestion, skin and eye contact. Arsenic targets organs such as skin, kidneys, liver, gastrointestinal tract and lungs. It affects our respiratory, nervous and reproductive systems (Tchounwou *e*t *a*l., 2003). The major anthropogenic sources of arsenic into the environment include the industrial production of herbicides, insecticides, fungicides and algicides for agricultural purposes.

2.5 Arsenic

The chemistry and toxicology of chromium are complex and interesting. For example, chromium poses detrimental as well as beneficial properties. It exists in two different states in the environment, Cr (III) and Cr (VI) with contrasting toxicities, bioavailability, and mobility. Cr (III) is not mobile and is required for the normal functioning of our body system. Chromium released into the environment from anthropogenic sources is mainly in hexavalent form. It is a toxic pollutant classified as a human carcinogen by many agencies (USEPA 1992). It moves readily through the soil and aquatic environment and is a strong oxidizing agent capable of being absorbed into our body tissues (Park and Jung 2001). The industries with the largest contributions to chromium release into the environment include tannery facilities, metal processing, chromate production, welding, and pigment production.

3. ADSORBENTS

The increase in the density of a fluid within the vicinity of an interphase is termed as adsorption. Adsorption is mainly controlled by physical forces (such as dipole, dispersive forces, or polarization forces) and chemical forces (such as the interaction of electrons between solid particles and the atoms of the liquid or vapour phase) (F. Rouquerol *e*t *a*l 2014). Adsorption on commercial and industrial scale depends solely on the type, quantity, the economic cost and effectiveness of the adsorbent material. The

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

substances used as adsorbents can either be of organic or inorganic origin. Regardless of the origins, each adsorbent material should be: mechanically and thermally stable, highly porous, possessing a high surface area with the balance between the micro and macro-pores, easily regenerative, and high affinity for the adsorbate (Czaja *e*t *a*l 2009).

In recent years, adsorptive removal of heavy metals from effluents primarily uses conventional adsorbents such as activated carbon, polymers, activated alumina, silica and zeolite (Mouni *e*t *a*l., 2011; Haladu *e*t *a*l., 2016; Aguado *et al.*, 2009; Motsi *e*t *a*l., 2009). However, of late, the use of modified and non-modified carbon nanotubes (CNT), magnetic nanoparticles (MNP) and metal organic frameworks (MOFs) has received increasing attention for the removal of heavy metals from contaminated water (Gupta *e*t *a*l., 2011; Zagoosh *e*t *a*l., 2013; Khan *e*t *a*l., 2013). The fibrous shape, large external surface area and established mesopores of CNTs are offering higher adsorbing capacity for them. MNPs are very effective and easy to operate; hence they are widely used for the removal of heavy metals. On the other hand, MOFs offer a great potential as their porous surfaces can be easily modified which ultimately leads to the improved selectivity of certain functional groups.

3.1 Activated Carbon

The large surface area and microporous nature of activated carbon, which can be modified by sulfuration, ammonification, oxidation, and coordinated ligand anchorage, has made it a suitable adsorbent for the removal of heavy metals from aqueous solutions (Rivera-Utrilla *e*t *a*l., 2011). Activated carbon produced by carbonizing organic materials is the most widely used adsorbent. Yet, the high cost of the activation process limits its use in wastewater treatment applications. Numerous studies have focused on enhancing the oxygen-containing functional groups on the surface of activated carbon by physical and chemical treatment (Saleh and Danmaliki 2016 [a,b]; Danmaliki and Saleh 2016). Activated carbon is less specific and ineffective in isolating heavy metals from solution when the concentration of heavy metals is too high.

3.2 Nanomaterials

Development of cost-effective and novel nanomaterials for heavy metals treatment is gaining wide interest in recent years. Nanocarbon materials, nanometal particles, and polymer-supported nanoparticles have unique properties that provide high adsorption capacities and selectivity. Nanosized metal oxides, including nanosized cerium oxides, manganese oxides, magnesium oxides, ferric oxides, zinc oxides, aluminium oxides, and titanium oxides provide high surface area and specific affinity for heavy metal removal from aqueous solutions (Hua *e*t *a*l., 2012). Iron oxide nanoparticle based nanomaterials are widely used adsorbents for the remediation of contaminated water due to their favourable physiochemical properties. The removal of chromium was monitored using polypyrrole/Fe_3O_4 magnetic Nano composite. The magnetic nanocomposite was prepared by in situ polymerization of pyrrole monomer and it was tested for its effectiveness in the removal of toxic Cr (VI). The initial concentration of chromium was 200 ppm and there was 100% removal efficiency at pH of 2. Ion exchange and the reduction of the surface of the adsorbent were proposed as the possible mechanism of adsorption (Bhaumika *e*t *a*l., 2011).

The removal of Cd^{2+}, Pb^{2+}, Zn^{2+}, and Cu^{2+} was monitored using a polymer modified magnetic nanoparticles. Fe_3O_4 magnetic nanoparticles modified with 3-aminopropyltriethoxysilane and copolymers of acrylic acid and crotonic acid were evaluated for the removal of heavy metals from aqueous solution.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

The magnetic nanoparticles removed the metal ions efficiently with high maximum adsorption capacity at pH 5.5 (Ge *e*t *a*l., 2012). Nano zerovalent iron particles have been used as an effective adsorbent for the removal of cadmium in the concentration range of 25-450 ppm. The maximum adsorption capacity and activation energy of the adsorbent were 769.2 mg/g and 54.8 kJ/mol at 297 K respectively (Boparai *e*t *a*l., 2011). The major drawback with nanomaterials is that they are expensive and they require a considerable amount of time for their preparation and functionalization. Additionally, for treating large quantities of waste water an enormous amount of nanomaterials is required.

3.3 Low Cost Adsorbents

Apart from industrial by-products and natural materials, agricultural residues or wastes can also serve as the sustainable source for low-cost adsorbents. Some agricultural residues such as rice husk, wheat bran, sawdust and peanut shell are discarded into the environment as they are available in plenty and having little commercial value (Abdel *et al,*. 2011). Hence, these residues were attempted by researchers as an absorbent for the removal of heavy metals from effluents. Ricordel *et al.* (2001) successfully sequestrated heavy metals from aqueous solutions using activated carbon made from peanut husk and rice husk. The work by Periasamy and Namasivayam (1996) studied employing peanut shell carbon (PHC) for the removal of Cu (II) from waste water. It was interesting to note that PHC exhibited 18 times greater adsorption capacity than commercially available granulated activated carbon (GAC).

Examples of Low-Cost Adsorbent

Activated carbon, Algae, Aragonite shells, Bagasse, Blast furnace slag, Bone chars, Charcoal, Clinopyrrhotite, Coconut coir, Cow-dung ash, Eggshell, Geothite, Immobilised biomass, Lignite, Natural zeolites, Olive stones, Orange juice residue, Peanut husk, Peat, Rice husk, Saw dust, Sepiolite (Orera), Waste straw dust, Waste tea leaves, Bacteria and Fungi.

3.4 Biomaterials

With the advent of adsorption as a waste water treatment technique, the need to match water treatment efficiency with cost effectiveness and environmental sustainability became paramount. Although a variety of adsorbents are already in use, the lookout for novel adsorbents that meet the above three requirements has resulted in enormous research works. Most commercially available adsorbents are either of coal origin or artificially synthesized. The sudden needs to be environmentally conscious have pushed most of these adsorbents unfit for use. It was in the wake of these needs that the application of biological materials as adsorbents was thought of.

The use of biomaterials as adsorbents is a new, but promising and alternative concept, especially in the removal of heavy metals from water. Biosorption and bioaccumulation have sometimes been used interchangeably to describe the removal of contaminants using materials of biological origin. However, while biosorbents involves the use of passive biomaterials, bioaccumulation describes the removal of the contaminants by metabolically active organisms. Phytoremediation and bioremediation also involve treatment of contaminants using biological organisms. Phytoremediation describes living plants ability to sequester contaminants and degrade them to less toxic elements during their metabolic activity. Conversely, bio-remediation is the process of introducing a microorganism into an effluent as to remove its pollutants.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

The scope of this write-up will be limited to the use of biosorbents in the sequestration of heavy metals from water non-metabolically. Biosorption has shown high efficiency in the removal of heavy metals from water especially at low concentrations. The use of readily available, inexpensive biological materials has made it widely accepted. It also results in the generation of low quantity biological sludge. Biosorbents can also be regenerated. The advantages of the use of biomaterials for heavy metals treatment are illustrated in Figure 1.

Similar to any adsorption process, the use of biosorbents in the adsorption of heavy metals requires a solid phase and a liquid phase. The liquid phase is made up of the contaminants to be sequestered unto the biosorbents. The passive removal of metals from water by biomaterials requires that the substrate shows high metal uptake, suitable mechanical properties, and selectivity (Davis *et al.*, 2003). Biosorbents removal of heavy metals also depends on its composition of proteins, lignin and carbohydrates that make functional groups such as carboxyl, hydroxyl, and amines available for metal sorption (Kuyucak and Volesky, 1988). In recent times, efforts have been directed towards screening efficient biomaterials, investigating different preparation/modification possibilities and the mechanisms involved in the adsorption of heavy metals on biomaterials and the application of biomaterials in water treatment at large scale (Wang and Chen, 2006). Biosorbents can be used directly or after modification. The following section explains the use of biosorbents with and without modification.

Examples of some biomaterials:

Aloe, Bagasse, Beat sugar sludge, Chitosan, Coconut shell, Coconut coir, Coffee, Corn cobs, Cottonseed hulls, Distillery waste, Green tea, Japanese coarse tea, Jute stick, Kelp and seaweed, Molasses, Newspaper, Nutshells, Palm tree cobs, Pulp-mill waste, Rice hulls, Sunflower seeds, Tea, Wheat straw and Yuzu.

4. APPLICATION OF BIOMATERIALS IN THE REMOVAL OF HEAVY METALS

4.1 Non-Modified Biomaterials

Biomaterials used with little or no further treatment, alteration or change in their physical or chemical properties is referred to as 'non-modified biomaterials'. It is important to reduce the size of the biomaterials before they can be used as sorbents. As such, within these contexts, grinding biomaterials to powdered form is not referred to as modification because it does not affect its chemical structure. Non-modified biomaterials have been given a particular interest because of their easy availability and application. Despite being untreated, they have adsorption capacities suitable for the removal of different heavy metals. Non-modified biomaterials can be further classified into cellulose or plant materials and animal wastes.

4.2 Plant Waste

Plant cells are made up of cellulose, lignin, hemicellulose, protein, pectic substances, lipids, proteins and other chemical materials (Heredia *et al.,* 1995). These materials provide functional groups that have a high affinity for heavy metals and form chelates or metal complexes, useful for heavy metal adsorption. Cellulosic materials are the most abundant and renewable organic resource on earth (O'Connell, *et al.,* 2008). They are considered inexhaustible because of the huge quantity produced. Photosynthesis aids the production of 10^{11} -10^{12} tons of pure cellulose materials, yearly (O'Connell, *et al.,* 2008). The properties and reactions of cellulose are influenced by factors such as intermolecular interactions, the isolation process employed, chain lengths, cross-linking reactions, crystallinity, distribution of chain-length, functional groups along polymer chains and repeating glucose units (Klemm *et al.,* 2005, Poletto and Zattera, 2013). These factors contribute to the uniqueness of cellulose materials. Cellulose is poly-functional possessing high chain stiffness and is very sensitive to hydrolysis and oxidation of acetal groups (Klemm *et al.,* 2005). This determines its chemistry and method of handling (Klemm *et al.,* 2005). Different cellulosic materials have been used for the removal of heavy metals from aqueous mediums with less modification. In most cases, applying washed, dried and ground wastes of these cellulose materials can be effective enough for the treatment process.

Even micro-organisms such as algae, bacteria, and fungi have been found to adsorb metal ions from solution, forming metal complex effluents. The removal of heavy metals using biomass of dead microorganisms has been given much research attention because of their chemical composition. The sequestration of chromium, lead, and copper from industrial effluents using microorganisms was studied by Illhan *et.al* (Illhan *et al.*, 2004). The influence of pH, temperature and initial concentration on the removal of metal was studied. It was reported that the bacteria *Staphylococcus saprophytics* effectively removed lead and chromium from the effluent. The investigation on the removal of heavy metal from aqueous solution employing *Schizosaccharomyces pombe* (Fission yeast) in free and alginate immobilized cells was performed by Subhashini *et al*. (Subhashini *et al.*, 2011). The parameters such as pH, temperature, and initial concentration were studied. 73% heavy metals removal were achieved using this fungus. The study reported that immobilized cells remove heavy metals better than free cells.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

4.3 Animal Waste Biosorption

Animal waste adsorbents are a low-cost option for the removal of heavy metals from solution. The use of animal waste for heavy metal removal from water presents an alternative waste management opportunity. Animal bones (Al-Asheh *et al.,* 2002, Banat *et al.,* 2002, Al-Asheh *et al.,* 1999), chicken feathers (Al-Asheh *et al.,* 2003, Aguayo-Villarreal *et al.,* 2011) and animal horns (Banat *et al.,* 2002) have been successfully applied in removing different heavy metal from aqueous solution. For instance, chicken feathers with minimal treatment were used in the removal of Pb from water (Rosa *et al.,* 2008). Water and ethanol mixed in the ratio of (5:1) were used to rinse the chicken feather and was subsequently dried. When applied in the heavy metal adsorption process, it yielded about 8.3mg/g adsorption capacity at optimal treatment conditions.

The huge generation of animal wastes makes them readily available sorbent for water treatment. Chicken feather for instance constitute about six percent of a bird's total weight (Mittal *et al.,* 2007) while egg shell represents about 11% of an egg's total weight (Ishikawa *et al.,* 2004). They are thus largely generated as waste in poultry industries. The high heavy metal sorption capabilities demonstrated by these materials have been attributed to their keratin content (Banat *et al.,* 2002). They are also hydrophobic as a result of the presence of sterol and biomolecular triphosphate ester layers (Gao *et al.,* 2007). Keratin is a fibrous protein material that forms the main structural components of animal parts such as hooves, teeth, bones, and hair. The structure of Keratin and their corresponding elements that make up the functional groups are shown in Figure 2. Keratin monomers are arranged in bundles forming intermediate, tough filaments. They have high tensile strength, high surface area and are insoluble (Suyama *et al.,* 1996). They are particularly rich in carboxyl, hydroxyl and amines functional group which make them readily made for use as an adsorbent in water treatment. Avian keratin fiber; a keratin protein type contained in bird feathers showed high stability and removal efficiency over a wide pH range in the removal of copper, chromium, lead, uranium and mercury from water (Kar *et al.,* 2004).

Figure 2. The α-helix and β-pleated sheet structure of Keratin and their corresponding elements (Belamino et al., 2012)

4.4 Modified Biomaterials

Numerous factors affect the suitability for use and adsorption capacity of unmodified biomaterials. The presence of the different functional group, heterogeneous/irregular surface areas, pore size distribution and other physical or chemical factors may influence the removal efficiency of a biosorbent (Gautam *et al.,* 2014). In order to increase their sorption properties and enhance their metal selectivity, biomaterials irrespective of their source (plant or animals) are modified (Gautam *et al.,* 2014). Several adsorbents are derived from the modification of biomaterials. This involves the treatment and subsequent alteration in the physical or chemical structure of the materials.

The reason for biomaterial modification has been supported by different researchers that compare the removal efficiency of modified and non-modified biomaterials in heavy metal sorption. For instance, in the removal of copper and zinc from waste water, chicken feathers treated with alkaline solutions showed higher adsorption capacities than those treated with anionic surfactant and untreated chicken feathers (Al-Asheh *et al.,* 2003). The findings of the work are illustrated in Figure 3. and 4 respectively.

Modified and non-modified (native) sugar beet pulp showed similar results in the removal of nickel and copper from water (Reddad *et al.,* 2002). Raw sugar beet pulp was modified by saponification and acid-base extraction. An evaluation of the resulting effect of these modifications on the biosorbents binding properties revealed that that base extracted pulp and saponified pulb displayed higher metal sequestration compared to the raw pulp. The study also showed that the functional group contained in the biomaterials has a tremendous impact on their sorption capacity. The above fact suggests that when biomaterials are modified, different functional groups are added which in turn increases the number of active sites available for metal binding (Lu *et al.,* 2009).

Figure 3. Sorption capacities of alkaline treated, anionic surfactant treated and untreated chicken feather in the removal of Cu from waste water (Al-Asheh et al., 2003)

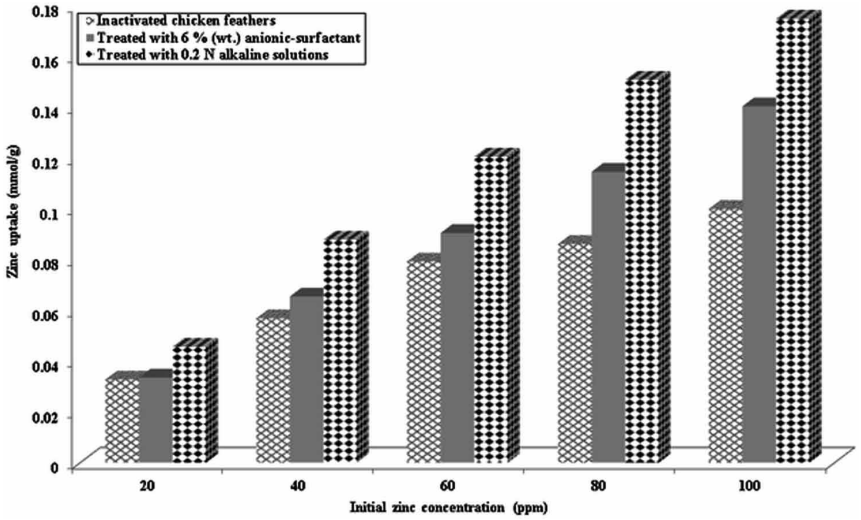
Figure 4. Sorption capacities of alkaline treated, anionic surfactant treated and untreated chicken feather in the removal of Zn from waste water (Al-Asheh et al., 2003)



5. MODIFICATION OF BIO-SORBENTS

The objective of the modification is to improve the surface area of biosorbents thereby increasing its sorption capacity. Modification is a kind of pre-treatment on bio sorbents. The modification discards the impurities on the surface of the biosorbents thus converting the surface into active sites readily available for sorption (Huang and Huang, 1996). It also imparts adequate structural stability and improves the adsorption potential of bio-sorbents. Modification can be accomplished either by physical or chemical methods. However, before going for any modification it is necessary to understand the parameters which influence the adsorption capacity of biosorbents.

5.1 Physical Modification

Physical modification of biosorbents involves the activation of the sorbent capability or increase in the adsorption capacity of biosorbents by heating or drying at optimum temperature.

5.2 Chemical Modification

Chemical modification of biosorbents can be broadly classified into two categories. The first one is monomer-grafting, in which specific groups are attached to the substrate. The grafting is again classified into, photografting, high energy radiation grafting and chemical initiation grafting. The other one is a direct modification where the functional groups are attached to the hydroxyl groups of substrate through chemical reactions. The chemical reactions involved in the modification are esterification, etherification, halogenations, oxidation, alkali treatment and silynation (Hokkanen, *et al*., 2016).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

5.3 Surface Functionalization

Surface modification is the process of modifying the surface of biomaterials such that its physical, chemical and biological characteristics are entirely different from its original state. The surface characteristics such as roughness, hydrophilicity, surface charge, surface energy, biocompatibility, and reactivity are altered on the surface of the biomaterials. Surface functionalization is a kind of surface modification. It is the phenomenon of introducing specific functional groups onto the surface of biosorbents to increase the removal efficiency of metal ions (Ihsanullah *et al.*, 2015)

5.4 Nanoparticle Functionalized Biosorbents

Nanoparticles are nano-sized particle possessing very large surface area. The atoms on the nanoparticles are unsaturated and can attach to any atoms (Farnad *et al*., 2012). Nano-particles due to their surface functionality and high surface area to volume ratio display very high adsorption capacity and efficiency (Fei *et al*., 2012). It's because of that there is a widespread interest among the researchers to employ nanoparticles in the adsorption of heavy metals from effluents. Of late, the surface of nanoparticles is functionalised to improve their selectivity of metal ions from effluents. Since the selectivity and efficiency are extremely high, there is a growing need for nanoparticle functionalised biosorbents for heavy metals sequestration in aqueous solution.

6. FACTORS INFLUENCING BIOSORPTION

The predominant factors that affect the biosorption processes are pH, temperature, initial metal ion concentration, biomass concentration, contact time and particle size.

6.1 pH

pH is the most important parameter that can significantly influence the biosorption process. It affects the solution chemistry of the metals and disturbs the functional group of the biomass (Das *et al.*, 2008). pH should be neither too high nor too low. It has been found that at a high acidic medium of pH close to 2, the adsorption of metal ions is almost nil. Therefore, the pH should be close to neutral (Ojedokun and Bello, 2016).

6.2 Temperature

The increase in temperature increases the adsorption potential of biomaterials. This could be due to the diffusion of metal ions through the solution as the viscosity of the solution reduces owing to the increase in temperature. It has been reported that at a temperature range of 25-35˚C, temperature does not have an influence on biosorption process (Das *et al*., 2008).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

6.3 Adsorbent Concentration

The binding sites for the metal ions are offered by the adsorbent. Hence, the concentration of absorbent has a profound influence on adsorption. Adsorbent concentration in the solution influences the specific uptake. The increase in adsorbent concentration can either increase or decrease the adsorption of metal ions. For some metal ions increase in the biomass favors adsorption whilst for other metal ions decrease in adsorbent concentration supports adsorption (Ihsanullah *et al*., 2015).

6.4 Ionic Strength of Metal Ions

The Ionic strength of metal ions also can affect the adsorption of heavy metal ions onto the biomass substrate. In general, an increase in ionic strength of metal ions has a negative effect on the sorption process. The detrimental effect could be due to two facts. Firstly, increasing ionic strength reduces the activity coefficients of metal ions, thereby reducing the transfer of metal ions onto the biomaterials. Secondly, at the high ionic strength (metal ions) formation of electrical double layer occurs between cations and biomass substrate hindering adsorption. The adsorption process is also affected by the contention of different metal ions which are trying to accommodate the limited active sites of the substrate (Ihsanullah *et al*., 2015).

6.5 Contact Time

The contact time also can affect the adsorption of metal ions onto the biomass. For batch adsorption process, it is very important to define the optimum contact time to attain maximum removal of heavy metal ions (Ojedokun and Bello, 2016). At large, longer contact time increases the chances of removal of metal ions from the effluents. However, this holds good until an equilibrium is achieved. The equilibrium is highly determined by the initial concentration of metal ions. By and large, when the initial strength of metal ions is low, the attainment of equilibrium is very rapid. Nonetheless, in few studies, it has also been reported that concentration of metal ions has no effect on adsorption.

6.6 Particle Size

The decrease in particle size of biomaterials increases its adsorption capacity as a reduction in particle size increases the surface area of the substrate (Somasani, 2012).

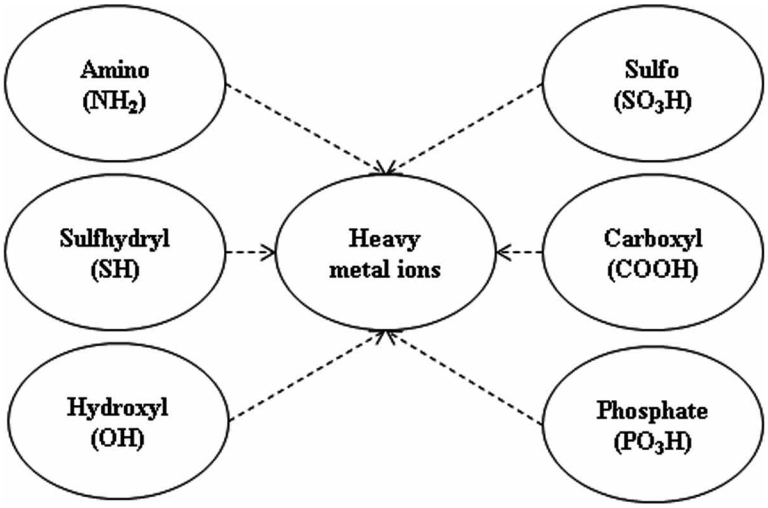
7. MECHANISM OF HEAVY METAL ADSORPTION BY BIOMATERIALS

Biosorption is the process of removal of metal ions from aqueous solutions by employing certain biomass. The metal biosorption by biomass mainly depends on the functional groups it possesses.

The most important functional groups are carbonyl (ketone), carboxyl, sulfhydryl (thiol), sulfonate, thioether, amine, secondary amine, amide, imine imidazole, phosphonate, and phosphodiester. The possible binding combination between functional groups and heavy metal ions is presented in Figure 5 (Zhang, 2014). Biomass involved in the biosorption can be living or non-living (Prabhakaran, 2006). The use of living organisms is called bio-accumulation. There are some operational difficulties while

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 5. The possible binding combination between functional groups and heavy metal ions



using live biomass. The industrial effluents, in general, carry toxic metals of high concentration. The pH of the effluents is either too high or low where living organisms cannot sustain. Also, living cells require nutrients and increase the BOC and COD of effluents. Hence, bioaccumulation is not viable for all cases of adsorption of heavy metals. On the other hand, the non-living organisms are not affected by the concentration of heavy metals ions or by the pH of the effluents (Al-Qodah, 2006). Further, dead cells are inexpensive and need less maintenance. Above all, dead cells can be easily regenerated and reused. However, it is a developing technique and is seen as a potential process of removal of heavy metals from industrial effluents.

It is well known that the biosorption is an interaction between a sorbent and sorbate. The sorbent also termed as bio-sorbent or bio-material or substrate is in the solid phase. The sorbate, which is metal ions, in this case, is dissolved in the liquid phase. The liquid phase solvent is water here. The sorbate gets attracted to the sorbent due to the higher affinity between them when they come into contact with each other. The sorption process continues till an equilibrium reaches between sorbent and sorbate. The extent of sorbent affinity for the sorbate decides the sorbate distribution between solid and liquid phases (Das *et al.*, 2008).

The process of metal biosorption in living cells (bio-accumulation) is a two-step phenomenon. In the first step, the metals ions are adsorbed onto the surface of cells by interactions between metal ions and functional groups present on the surface of cells. The metal ion comes across the cell walls. The cell comprises of a wide range of polysaccharides and proteins and hence offers a number of active sites capable of attaching metal ions. Microorganisms *viz.* algae, bacteria, fungi display different adsorption capacity. The variance in the adsorption potential of microorganism is due to the variance in the cell wall composition of them. Algal cells are cellulosic. The metal binding groups in the microbe are carboxylates, amines, imidazoles, phosphates, sulfhydryls, sulfates and hydroxyls. Among them, amines and imidazoles are positively charged, when protonated they show an affinity towards negatively charged metal ions. The cell walls of bacteria are mainly comprised of peptidoglycans. Chiton and chitosan make up the cell walls of fungi. Of the two steps, the first step passive biosorption is independent of metabolism. The step takes place rapidly by a single or a combination of the below binding mechanism: coordination,

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

complexation, ion exchange, physical adsorption (*e.g.* electrostatic) or inorganic micro precipitation. The second step is the active biosorption, where the metal ions penetrate the cell wall and enter into the cells.

Metal uptake by non-living cells is mainly in passive mode. The metal uptake takes place in two steps; passive uptake which takes place rapidly and active uptake which happens slowly. The first stage is more of physical adsorption where adsorption is at the surface of the cell. The adsorption reaches equilibrium within 30-40 min. The passive step is mainly due to the functional groups on the surface of the cell walls. The active mode is dependent on the metabolism and is associated with metal transport and deposition.

8. SUMMARY AND OUTLOOK

Thus, the chapter elaborated on the scope of biomaterials in the context of heavy metals removal from waste water or effluents. The chapter also discussed the modification of biosorbents and parameters influencing the biosorption process. The conventional method of heavy metal removal from effluents is inefficient, non-selective, expensive and time-consuming. On the other hand, the non-conventional techniques are highly efficient and selective. There are numerous non-conventional modes of heavy water removal from effluents. Biosorption is one such alternative method which has been gaining interest recently because of its simple operation, high efficiency, and economics. Also, biosorption offers the flexibility of trying out with different biomass as there is a wide variety of biomaterials availability. Further, a number of modification techniques are available to improve the adsorption capacity of biomaterials. As stated in the article, biosorption is a developing technology and a lot of augmentations are underway to make the technique more dependable. There is no doubt that the technology would be more established in the near future.

Chapter 38
Waste Disposal:
Sustainable Waste Treatments and Facility Siting Concerns

ABSTRACT

Through the human municipality growing and industrialization process, productions of municipal solid waste have been growing in parallel line. The properties and composition of municipal solid waste as the main solid waste produced by human has cultural, regional, social habits and behavior, beside the economic condition, influences the properties and compositions of waste disposal, which contains process that start after collecting and transporting MSW to landfill site. After site selection, the process of recycling, waste composting and incineration will be assessed as intermediate disposal methods. Our final goal in waste disposal focused on environmental protection. This chapter will have a review on recycling merits and as effective ecofriendly methods for disposing municipal solid waste (MSW) for saving greenhouse gases (GHGs). Incineration as a commercial waste disposal will also be reviewed. Making decision about waste disposal is a multi-criteria issue because of MSW mixture, climacteric of area, cultural and economic condition, technical support, and environmental impact.

INTRODUCTION

Civilization and industrialization cause to produce of municipal solid waste (Parfitt, Barthel et al. 2010, Lim, Chen et al. 2013). Global solid waste production was 1636 million tons per year(Robinson 2009), meanwhile (Soltani, Hewage et al. 2015) indicate that ten years ago global MSW production was 0.6 billion tones /year, so it equal 0.64 kg of MSW / person /day and nowadays MSW generation had been reached to 1.3 billion tones /year which is equal to 1.2 kg /person/day. For the year of 2025 municipal solid waste production is estimated to reach 2.2 billion tons per year (Soltani, Hewage et al. 2015). Most common waste disposal methods are incineration, composting, recycling and landfilling (Magrinho, Didelet et al. 2006, Narayana 2009).Nevertheless some literatures indicate to recycling and landfilling as final waste disposal(Demirbas 2011). As a matter of fact, municipal solid waste (MSW) has mutable composition, with the main ingredients being; (40–60%) edible waste Products; (20%) paper and cardboard; and up to 40% glass plastic and metal (Costa, García et al. 1991). Meanwhile, Zhang et al. (2015) presented their waste disposal research on long term manned spacecraft and(Tanabe & Hoshino 2015)concentrated on secondary waste generated from wastewater treatment and as well as these issues should be added to our waste disposal subject, but we will concentrate on the ground side of waste disposal . With considering specification and characteristic of MSW, process of waste disposal should be planned. A fundamental activity, which should be in the first level of importance, is the site selection. Following siting process is another critical basic; managing recycling metals (mostly iron), plastic, paper and glass will be carried out. Other disposal methods that are the same as incineration and composting, decrease the volume of MSW and increase the suitability of application in other industry such as filler in construction (incineration ash) or agricultural nutrient (compost). Based on the local, national, and global limitation, merit of this chain of managing waste system may be arranged in different respect. Managing system for waste disposal mainly depends on the composition of MSW and the rate of development has the most critical effect on mixture of solid waste as well as social and regional factors (Denafas, Ruzgas et al. 2014).

SITE SELECTION

One of the most important parts of waste disposal process is site selection, which nowadays going on to be converted as critical factors by countries such as China(Zheng, Song et al. 2014), Brazil (Kannan, de Sousa Jabbour et al. 2014) and India(Suthar & Sajwan 2014) These countries are improving their standards to tackle this issue. Also Swartzbaugh (1993) mentioned that site selection is one of the three major phases in his presented method in USA, and the strategy and planning of waste disposal starts after site selection .

Critical Factors

There are many effective elements, which normally considered for site selection. Ekmekçioğlu et al. (2010) compared four alternative locations in Turkey for selection of best site for waste disposal. They carried out the study considering elements such as hydrology, topography and soils, adjacent land use, climate, flora and fauna, site capacity, road access and cost of the land. Some of the related elements and their relationship is presented based on obtained data from researches. The following points are related researchers on above-mentioned factors in siting issues:

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

- Generally, sites with slopes exceeding 1:5 are not considered good, as there might be a risk of soil erosion (Tadros 2009).
- The leaching process has critical impact on the environment, depends on two factors: The landfill hydrology and, the geochemistry of landfill material (Johnson, Richner et al. 1998). Hydrological factor is the major factor that should be considered for subsequent treatment of leachates beside the leachate quantity data (Tatsi & Zouboulis 2002).
- Site capacity is considered as the key in deciding factor in fuzzy method of Turkey (Ekmekçioğlu, Kaya et al. 2010), for selecting waste disposal site between four nominated locations.
- The efficiency of municipal solid waste (MSW), depends on two major factors, transport capacity and manpower availability(Sharholy, Ahmad et al. 2008).
- Public health and environmental protection are the fundamental consideration for site selection (Önüt and Soner 2008).
- Flora and fauna and human health are reported as most important environmental risk in recycling solid waste (Pappu, Saxena et al. 2007).

Software and Analyzing Technique Application in Site Selection

During recent decades, there has been a rapid growth of attention in the application of computer base program for managing environmental problems (Ijäs, Kuitunen et al. 2010). As previously mentioned, many factors affect site selection. Furthermore, these elements also have internal and external correlation and limitation so application of mathematical and technical software will be suitable in the selection process. Recently, a mixture of these techniques have been used in various researches to show a more clear and trustworthy picture. Önüt and Soner (2008) used AHP, TOPSIS and MCDA, Şener et al. (2011) applied GIS and AHP, Shahabi et al. (2014) used from AHP and GIS. These techniques are notused specifically only for waste disposal method or site selection but also are widely applied in many sides of knowledge body. Some of these techniques are mathematical and usually subjective considerations or may ignore qualitative. Decision maker can easily use linguistic terms to describe a value as an alternative. Some of the well-known methods (abbreviation) are presented and defined As follows (Soltani, Hewage et al. 2015); AHP (analytical hierarchy process)

- TOPSIS (technique for order preference by similarity to ideal solution)
- MCDA (multiple criteria decision analysis)
- MILP (mixed integer linear programming)
- RIAM (rapid Impact Assessment Matrix)
- WLC (weighted linear combination)
- GIS (geographic information system)

Fuzzy Multiple Criteria Analysis (FMCA)

Based on the fundamental of this method, user should find the main criterion and then assess multi criteria through proposed methodology. The weights for selection criteria can be determined by fuzzy pairwise comparison matrices of Analytic Hierarchy Process (AHP). Furthermore, relative importance of the selection criteria could be determined by a fuzzy AHP procedure. This method had been used

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

successfully by Önüt and Soner (2008), and Ekmekçioğlu et al. (2010) in Turkey .They reported that MCA method is a suitable assessment system for both site selection and disposal method.

Geographic Information System (GIS)

In a general sense, Geographic Information System (GIS) or spatial management of risk (Brugnot 2010), is a computer base information system, which designed to relate unrelated information of which key index variable is location. GIS had been applied to the water management, land researches and environmental risk assessment. GIS is also considered powerful decision supportive tools capable of performing spatial engineering analysis in different environmental modeling applications(Lukasheh, Droste et al. 2001). GIS had been used successfully in landfill siting by using vehicle routing and scheduling in the collection of solid waste(Chang, Lu et al. 1997).Nowadays, GIS is also being used at biogas plant sites in Finland(Höhn, Lehtonen et al. 2014), landfill site at Saqqez city in Iran(Shahabi, Keihanfard et al. 2014), and air pollution mapping in urban area(Kumar, Mohan et al. 2015).

Mixed Integer Linear Programming (MILP)

This is an optimizing program that is used for subjects, in which all or some of the variables are integers only (Sawik 2011). After collecting all related information about feasibility or optimization of linearly varying single or multiple variables, it can be applied as an engineering tool for waste disposal (Balaman & Selim 2014., Vadenbo, Hellweg et al. 2014). The adaptability of this system makes it suitable for various researches such as determining optimal recycling program (Baetz and Neebe 1994), environmental impacts(Chang, Yang et al. 1996), recycling waste(Louis and Shih 2007) rivers logistic activities.

Rapid Impact Assessment Matrix (RIAM)

Many traditional methods, which are usually applied for environmental impact assessment (EIA), produce a lot of data and information (quantitative and qualitative). Judgment on the same basis and giving a clear picture for permanent judgment are the main objectives in these issues. The computerized rapid impact assessment matrix (RIAM) can show enhanced graphical and clear pictures of matrix information. Furthermore, it gives the opportunity to evaluate development options(Pastakia & Jensen 1998). The original rapid impact assessment matrix has five evaluation criteria(Pastakia & Jensen 1998) contain: A1: Impact importance, A2: Magnitude, B1: Permanence, B2: Reversibility, and B3: Cumulatively .Depending on the environmental impact assessment(EIA) the matrix can be adjusted. Some of the real studies, which were carried out with above mentioned computer base method, are presented in Table 1.

MUNICIPAL SOLID WASTE RECYCLING

According to the report of Ang (2008), which was carried out about economic development, in the long run, of energy consumption and pollutant emission in Malaysia. Pollution and energy usage have positive relation. Malaysia as a leading country in tropical tourism have more than 261 active landfills (Kamaruddin, Yusoff et al. 2014)and previous report showed that the number of landfills was 230(Alkassasbeh, Heng et al. 2009). In five years there was 11.87 percent of growth, which gives a clear picture

(De Feo & De Gisi, 2014)	Italy	MCDA,GIS	Minimizes the wasting of space for the siting	Better results in Combination model

about the future scenario of waste disposal. Increasing maintenance cost on one hand and lack of land on the other hand are the factors for finding another alternative method for waste disposal(Zia, Bhatti et al. 2007). Waste disposal together with in homogenous nature of municipal solid waste puts more pressure on effective disposal methods, when considering socio-economic criteria is a multi-environmental project(Soltani, Hewage et al. 2015).Installation of incineration facilities is surrounded by serious challenge. Meanwhile, recycling opportunities and organic material treatment are available as replacements. Furthermore, recycling contain GHGs saving merit(Mohareb, Warith et al. 2008).

Literature Review

Waste disposal is considered as a social and political issue all around the globe . Recycling is a major section of waste disposal and could be considered as a valid response to a critically catastrophic environmental crisis (Beal 2012). More than 90% of municipal solid waste (MSW) in Indian cities, disposed of, unscientifically in open damp and landfilling method (Sharholy, Ahmad et al. 2008).In order to earn sustainable conversion of MSW to useful products, improving recycling process is the key (Read 1999). Also for most municipalities, recycling had been proved costly in compare with landfilling(Lave, Hendrickson et al. 1999). Meanwhile, in economic assessment of literature, cost of landfill disposal is lower than recycling. However, after considering the externalities, recycling could be presented as economically efficient(Lavee 2007). Affluent countries (mostly developed countries) provide substantial financial and supervisory capitals for recycling waste fractions, such as metals, glass, plastics, and paper. In contrast,

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

for developing economies, recycling is an economic activity in certain sectors of the society(Sanneh, Hu et al. 2011).Survey results for population estimation of the cyclists in various slums shows that, in 90,000 population area 1500 cyclists are there(Agarwal, Singhmar et al. 2005) and their income is sufficient for food and accommodation for a day. In developed countries or some parts of developing countries, social charity groups are working on recycling in living complex(Council & Hawkins 2014). To sum it up, social aspect of waste disposal is highly correlated to economic condition and developing rate of civilization area. On the other hand, land availability for waste disposal plays a critical role in waste disposal policy. Currently, zero waste strategy is reviewed by(Cole, Osmani et al. 2014). England (Read 1999) and Japan (Sakai 1996, Lim, Chen et al. 2013) are suitable samples for recycling care, methods and strategies . There are different reports on recyclable percentage of municipal solid waste such as 25%(Metin, Eröztürk et al. 2003), 50%(Holloway 1989) and based on a questioner study carried out by (Lavee 2007) shows that recycling ranges from 10% to 80%. In the light of this, prediction of the recyclable component should be made by studying the percentage composition of each material in MSW, such as plastic, paper, metals and glasses (Saeed, Hassan et al. 2009). Normally, Volume % of recyclable material in MSW is many times higher than weight %. This could be a fundamental reason of importance for recycling in waste disposal especially on the medium and large sized municipalities(Lavee 2007). Electricity consumption in material recovery facility ranges from 4.7 to 7.8 kWh for each metric ton of solid waste impute (Pressley, Levis et al. 2015). Consequently, in any site with comparing global price of raw materials and recovery cost, efficiency of recycling can be calculated. International standard organization (ISO) published two specific environmental standard (Standardization 1997, Standardization 2006) for life cycle assessment, which are widely applied for MSW management process(Diaz & Warith 2006). Environmental justifications of recycling are mentioned by Daskalopoulos et al. (1997) are as follows:

- Move towards sustainable economies by conservation of non-renewable resources
- Energy consumption due to production process will decrease
- Significant decrease in cost of waste management
- Increasing the landfill life
- Pollutant emissions due to production and waste disposal will decrease
- Benefits of participation in environmental education

Recyclable materials are divided into sub materials, which depend on industrialization rate and packaging in food industry. Sub materials for plastic, paper, glass and Aluminum presented by Agarwal et al. (2005). According to Palmer et al. (1997) the least expensive of the policies for waste disposal (aluminum, paper plastic and steel) is deposit/refund.

Recyclable Plastic Materials

Plastics are widely used in humankind's life. Furthermore, plastic production in society is higher than steel, and is increasing year by year(Yoshioka & Grause 2015). Percentage of plastic solid waste in MSW is also increasing (Al-Salem, Lettieri et al. 2009). Recycling is the best method for treatment of plastic materials considering stable chemical and physical characteristic(Li, Wu et al. 2015) . Specially assessment case study in Spain shows that high-density polyethylene (HDPE), low density polyethylene (LDPE), polyethylene terephthalate (PET), polyvinylchloride (PVC), expanded polystyrene (EPS), poly-

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

styrene (PS), liquid packaging board (LPB), and material recover facility(MRF) are detected in MSW (Bovea, Ibáñez-Forés et al. 2010). Major plastic sources are PVC and PET(Yoshioka & Grause 2015). According to Holloway (1989), steam separation method in municipal solid waste recycling have higher efficiency in recycling of plastic materials. Quality of recycled plastic vary widely in terms of color, mixed materials and density meanwhile, through the different types of plastic materials, PET recycling framework can also be considered as an acceptable method for preparation of raw material. High quality recycled PET cab be used as a raw material in different industries (Yoshioka & Grause 2015). According to Scheirs and Kaminsky (2006)and Al-Salem et al. (2009), higher quality and process of separation in recycling plastic such as tertiary and quaternary treatment scheme following primary and secondary treatment technologies and schedules, could be considered as a robust, worse scientific and traditional investigation. Preliminary researches such as (Yoshioka, Sato et al. 1994, Paszun and Spychaj 1997) tried chemical treatment for recycling. Manufacturing high quality carbon for phenol adsorption was carried out by Parra, Ania et al. (2004). Recent researches are focused on hydrocyclonis separation (Yuan, Fu et al. 2015), froth flotation as recycling technology (Wang, Wang et al. 2015), and using waste PETs as filler in phenolic resin mold (İyim & Orbay 2015) . Worldwide plastic production and power application for producing in plastic manufactories consumes 8 percent of total oil production. In Europe and USA, plastic recycling has reached to 26% and 9% respectively, which clearly shows that recycling industry have great scope for improvement (http://www.worldwatch.org 2012).

Recyclable Paper Materials

The domestic per capita consumption of board and paper in South Asia and India is 53kg,11kg and 6.5 kg respectively (Pati, Vrat et al. 2008). Paper as a renewable source material, is the major part of municipal solid waste such as white paper, mixed shredded paper, fresh newspaper, carton and brown packing paper, tetrapack (Agarwal, Singhmar et al. 2005). Based on the three years case study carried out by Metin et al. (2003) on 60 municipalities,in Turkey ;paper including cardboard is recognised as the main constituent in MSW. The savings of recycling for the paper products are smaller than non-renewable materials in the case of GHGs emission (Björklund and Finnveden 2005). On the other hand, paper quality, energy source at the mill and energy avoided by incineration process are the most effective elements in ranking between incineration and recycling method selection for paper (Figure 1).

Recyclable Aluminium and Glass

Aluminium production process consumes a majority source of power in society. In commercial area, aluminium and paper are the most recyclable solid waste. Nevertheless, in tourism area, putrescible material, such as aluminium and paper should be recycled(Diamadopoulos, Koutsantonakis et al. 1995). In municipal solid waste incineration, more than 90% of the aluminium and cooper is transferred to slag(Wäger, Eugster et al. 2005). This slag cab be used for cement production (Kikuchi 2001, Ferreira, Ribeiro et al. 2003). In many countries, zeolite is recognized as suitable absorbent for pollutant removal in environmental treatment process. However, this natural absorbent is not available in some countries. Therefor production of zeolite through the recycling process could be an acceptable opportunity for a win-win term. Zeolite synthesis (Yang and Yang 1998, Penilla, Bustos et al. 2003, Terzano, D'Alessandro et al. 2015), when compared to energy application and GHGs saving, the recycling is highly recommended. Bear and cold drink cans, deodorant scent cans and aluminium foils are the most commontypes of alu-

minium products in MSW (Agarwal, Singhmar et al. 2005, Wäger, Eugster et al. 2005). Glass recycling in material refinery facilities(MRF) consumes a much larger fraction of electricity (28%) when compared to other material recycling, which only consumes 10% of total electricity (Pressley, Levis et al. 2015). Amortized cost for each metric tone of waste input to MRF in ranges from 19.8 to 24.9 USD(Pressley, Levis et al. 2015) (Figure 2).

Recycling, Greenhouse Gas (GHG) and Global Warming

Greenhouse Gases

Greenhouse gases (GHG) contain carbon dioxide (CO_2), methane (CH_4),nitrous oxide(N_2O) and fluorinated gases. USA total emission of greenhouse gases in 2013 reach to 6.673 mllion tones CO_2 equivalent (USEPA 2013).

- **CO_2:** Coal, natural gas and oil burning, waste and cement manufactoring are some major sources for Carbone dioxide emission to atmosphere. Absorbtion by plant is the main removal mechanism for CO_2.
- **CH_4:** Production and transporting process of natural gas, coal and oil causes the emission of CH_4. Municipal solid waste landfilling and agricultural activities are other two major sources of CH_4.
- **N_2O:** Agricultural livestock, combustion of solid waste and fossil fuels are main sources of N_2O.
- **Fluorinated Gases:** The smallest quantity in emission but still is a powerful greenhouse gas that is emitted from industrial process. Figure 3 present main sources of GHGs emissions. Industrial processes, transportation and electricity consumption can be considered as the main sources of GHGs emission through various waste disposal methods.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 2. Worldwide evaluation of recycled and primary Aluminium (http://www.world-aluminium.org 2010)

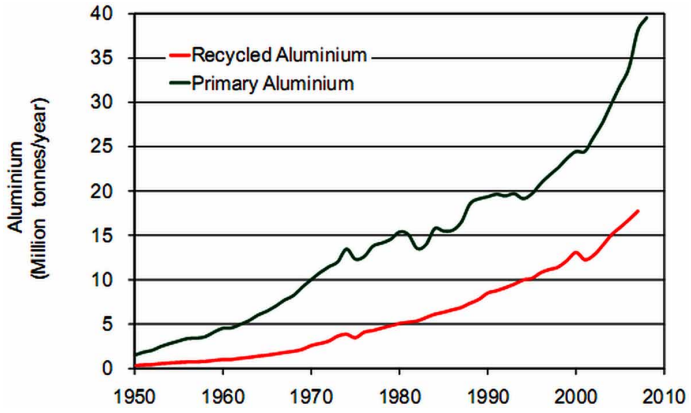

Figure 3. Sources of Greenhouse Gas Emissions (USEPA 2013)

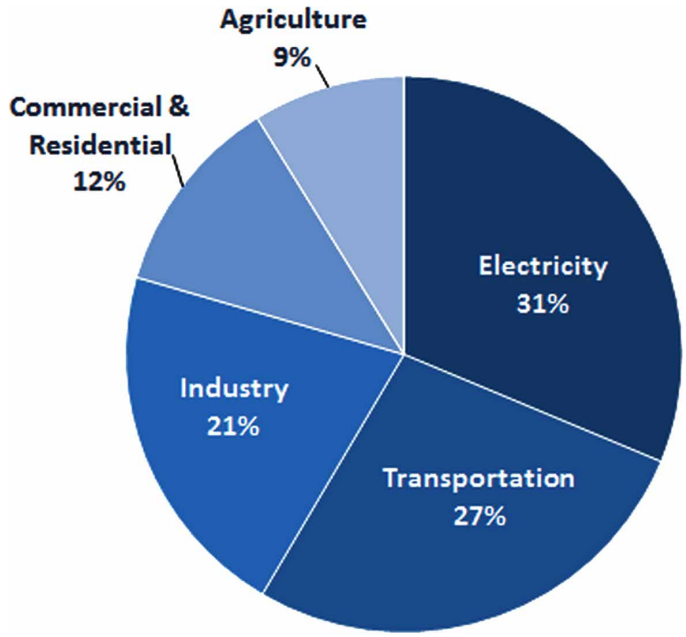
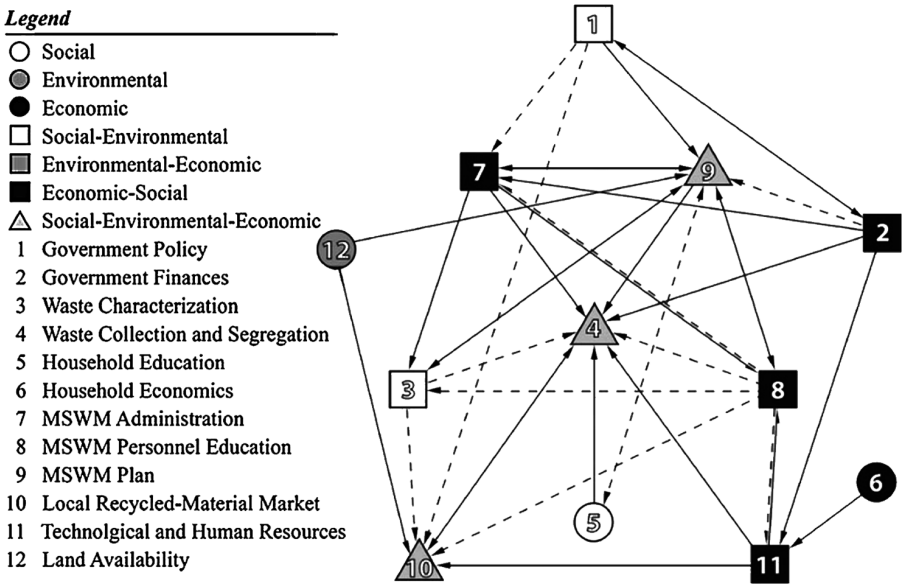


Some of the important researches related to GHG, global warming and recycling indicate that recycling is an effective method for decreasing CO_2 gas emission and hence reducing global warming. Other researches were carried out by Astrup et al. (2009) on plastic recycling, Larsen et al. (2009) on glass recycling,Damgaard et al. (2009) on metals recycling, Laurijssen et al. (2010) on paper recycling and Kim and Song (2014) on wood recycling. Nowadays, most of the developing countries are not setting their municipal solid waste management system with specific view on energy recovery from waste in different process of MSW management, especially in disposing methods. This policy does not only allow us to produce energy, but also we can follow green technology in waste disposal, which saves us from greenhouse gases(Kothari, Tyagi et al. 2010, Nakata, Rodionov et al. 2010). Greenhouse gases

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

contain carbon dioxide(76.7%), methane(14.37%) and nitroxide (7.9%), which are normally produced from anaerobic biodegradation of disposed wastes in landfill(Zuberi & Ali 2015). Based on Fotovat et al. (2015) and Yoshioka and Grause (2015), concentration on refuse drive fuel (RDF) production from landfill disposal system, incineration facilities or recycling process can be considered as suitable GHGs reduction method. Furthermore, Tan et al. (2014) researches show that integration landfill gas recovery as major waste-to-energy strategy and incineration as the minor WTE strategy could reach to comfortable GHGs reduction and energy potential. Another research carried out in African weather by Oyoo et al. (2014) also suggested that integrating resource recovery, anaerobic digesting, sewerage and landfilling is the best method for all environmental impact categories in comparison to traditional methods, maximizing landfilling and finally combining composting, landfilling, sewerage and resource recovery. In other words, recycling gives new life to material as well as save GHGs. According to Schott and Andersson (2015), 35% of food waste in municipal solid waste are avoidable. Consequently, this amount of food waste avoidance can help in reduction of GHGs. Based on the report ofVergara et al. (2015), textile informal reuse save largest GHGs and landfilling leads to highest emission of GHGs. Municipal Solid Waste disposal is not only a multi-complex process including MSW collection, transfer station locations, treatment policy, location of treatment plants, and recovering energy by waste to energy (WTE) system (Consonni, Giugliano et al. 2005), but also an effective ecofriendly sustainable GHGs reduction method (Cheng & Hu 2010). Global attention to air pollution and GHG caused establishment of national and continental regulars for prohibiting environmental impacts of incineration plants. Recently, Cheng and Hu (2010) presented emission limits of air pollutant materials from municipal solid waste incineration system in USA, EU and China in their review paper. Municipal solid waste disposal is a multi-complex process including MSW collection, transfer station locations, treatment policy, location of treatment plants, and recovering energy by waste to energy (WTE) system (Dewi, Koerner et al. 2010).This issue presented in **Figure 4** as a schematic plan of management.

Figure 4. Collaboration web illustrating relationships among the 12 factors influencing sustainable recycling in developing countries (Troschinetz & Mihelcic 2009)



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

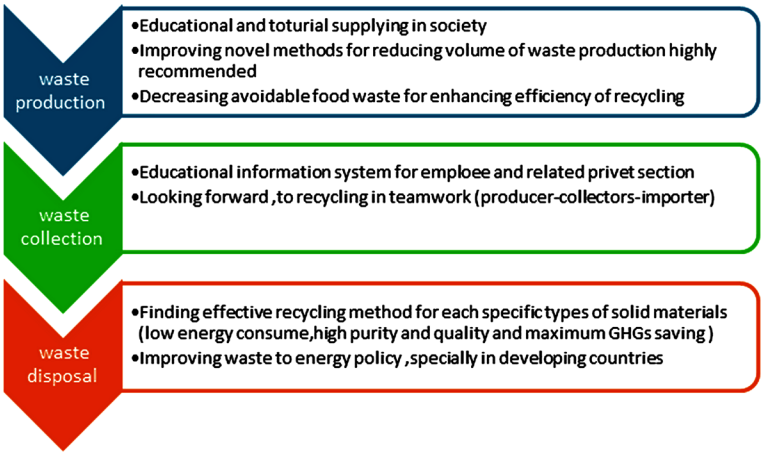
Recycling Efficiency

As opposed of the agricultural or industrial homogenous waste, municipal solid waste is the most complex stream (Wang & Nie 2001). For avoiding counterproductive results, establishing the new formal recycling method should have a clear picture from drawback and merits of informal recycling methods which already exist (Wilson, Velis et al. 2006). Informal recycling environmental impact as GHGs had been assessed in compare with industrialized and modernized formal recycling by Vergara et al. (2015) and their results indicate that informal recycling emit far fewer GHGs than formal system. A questioner study carried out by Lavee (2007) shows that recycling ranges from 10% to 80% . Other efficiency study carried out on 23 cases by Troschinetz and Mihelcic (2009) shows that average of recycling recovery in developing countries are 5% - 40%, in this research the average of MSW generation rate was 0.77 kg per person per day. Consequently, between about 40-300 grams of daily MSW could be recycled (Figure 5).

WASTE INCINERATION

One of major process of waste management is waste incineration, which can reduce approximately 90% of waste volume. Japan, Germany, France, Sweden, Switzerland and Denmark are the countries in which 50% or more of the un-recycled waste goes to incineration process (Hjelmar 1996). This kind of waste disposal is carried out in developed countries. Furthermore, limited available and cost effective land for landfill or transporting system are critical elements in waste disposal by incineration method (Hjelmar 1996, Quina, Bordado et al. 2011). Developing countries are also going to be major operators of incineration. In China, there were 109 MSW incinerators till 2011 and treatment capacity of these plants reaches to 94414 (Yao, Kong et al. 2015). Taiwan as a developing country combined sanitary landfilling of MSW with incinerated residuals as a specific method (Gau & Chow, 1998). On one hand, based on the world bank report by Daniel and Perinaz (2012), MSW production will reach 2.2 billion tones in 2025. On the other hand, incineration technology is going to be the second most important means of MSW management strategy because of increasing MSW and merits of this method of waste disposal (YAN & WU 2003).

Figure 5. Diagram of critical effective elements in waste disposal (recycling)



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Incineration Drawback and Solution

Some kind of hazardous residues that are produced by incineration systems are boiler ash, fly ash, air pollution control (APC) and bottom ash. Heavy metals (Zn, Cr, Pb, Ni, As, Hg and Cu) and high amounts of soluble salts (K, Na, Ca and Cl) are specific characteristic of incinerated residues, which normally form leaching solutions. Incineration residues should also be considered as an air pollution source (Tu, Yu et al. 2010). Air pollution control (APC) residues, generated from municipal solid waste incinerator(MSWI), are classified as hazardous waste since they contain a lot of leachable metallic elements, soluble salts and organic compounds, hence should be disposed carefully (Reijnders 2005, Quina, Bordado et al. 2010). Furthermore, as a thermal treatment, incineration may produce polychlorinated dibenzo-p-dioxins and polychlorinated dibenzofurans, which are highly toxic compounds(Fiedler 1996). MSW residues obtained from waste incineration should also be categorized as a hazardous waste and waste management in this part of waste disposal should be properly carried out (Li, Xiang et al. 2004). Based on the report of (Quina, Santos et al. 2008), solubility of APC in water is 24% higher than in 1/10 ratio of solid to liquid ratio which is the cause for its reduced utilization. For metal carbonation of APC residues which originate through natural aging from MSW incinerator, water content plays a critical role (He, Cao et al. 2006). There was a positive effect of pre-washing in chemical stabilization of MSW incineration by-products (APC) as reported by Quina et al. (2010). Also, water washing presented by Lin et al. (2011) as a suitable way for removing odor and environmentally apprehensive organic materials. Due to high content of soluble salts air pollutant control (APC) residues have been classified as "not allowed as building material" (Quina, Bordado et al. 2011). Therefore, pretreatment for removing soluble salts absolutely should be carried out. Aerobization of metallic elements which reach residues is possible, furthermore it doesn't lead to much dramatic increase of metallic elements in the leachate (Inanc, Inoue et al. 2007). Presence of high quantity of nitrite in municipal solid waste incinerator (MSWI) bottom ash was reported by Belevi and Moench (2000). Nowadays, Islam and Patel (2011) and Yang et al. (2014) have indicated that high concentration of metallic (Fe and Al) hydroxides and layered double hydroxides, which have high capacity for nitrite absorption, can solve the problem of nitrite in MSWI. Controlling pH will be an effective factor in removing organic matter but it has the disadvantage of nitrite reduction. Hence, using additive assistance (PO_4^{-3}), will be suitable for nitrite retention by formation of apatite(Yao, Kong et al. 2015). Dioxin contained in MSWI residue is another drawback, which makes it a hazardous potential waste. Humification of municipal solid waste incineration residue has high positive effect in decreasing dioxin content and it can be carried out through biological activities(Kim & Osako 2004).

Incineration Bottom and Fly ash Application

- Road construction in Denmark(Birgisdottir, Bhander et al. 2007).
- Ceramic tile body(Andreola, Barbieri et al. 2001).
- Incineration ash can use as co landfilling with cellulose for alkaline degradation of cellulose(Svensson, Berg et al. 2007).
- Geotechnical or construction offered by Tu et al. (2010) for incineration slag since structure of slag can immobilized heavy metals .
- Residual carbon of incinerator used for formation of dibenzofurans by using $Na^{37}Cl$ in USA(Addink & Altwicker 2001).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

- Suitable for use as secondary constructional issue or applied in landfill disposal process with MSW(Youcai, Lijie et al. 2002).
- Applied as the liner, leachate drainage layer and protection layer in place of natural mineral such as till, gravel, sand and clay(Travar, Lidelöw et al. 2009, Su, Guo et al. 2013).
- Prohibitory application for nitrite immigration in the landfill(Yao, Kong et al. 2015).

There have been some researches, such as Lisk (1988), Durlak et al. (1997, and Hellweg (2001) on optimum operation management system and technical supplying through incineration process in thermal plants for decreasing hazardous emission. Nevertheless, environmental impact of fly/bottom ash is a concern for many researches. Table 2 presents related studies to environmental impact through incineration ash application.

Heavy Metals

Batteries are the main source for zinc, cadmium and nickel. Meanwhile, mercury content in batteries is nearly zero. So they could be found in sludge and incinerator ashes (Lemann, Walder et al. 1995). In the process of waste incineration, rare metals like Ag, Ga, Bi, In, Sb, Te, Sb, Pd and TI are volatilized in gaseous and/or chloride form. In the next step at melting furnace, fly ash goes to condensing while, Zr, Cr, Ni, Ta and V remain in the molten sludge (Jung & Osako 2007). Based on the report of Jung et al. (2004), a considerable amount of heavy metals have been distinguished to be lost as waste material in the land-filling of incineration residues. Due to the volatility of Pb and Zn, these low metallic elements are found in the bottom ash up to a third amount of these metals in the incinerator. Cd will be found in the fly ash, where as Fe, Cu, Al, and Cr will be found in the bottom ash (Jung, Matsuto et al. 2004). Shimaoka et al. (2007) researched on determining the alterations due to weathering in 2-10 years old landfill site in which MSW incineration residues have been applied as landfill. Based on the research, not only did Al, Mn and Fe increased by depth of landfill, but also in 8-10 years old landfill, concentration of Al, Zn, Pb and Fe in pH 6-10 was lower than the fresh residues. Hydration was presented as the reason for stabilization of these elements. Figure 6 show the XRF composition of MSWI residues in fresh and land-filled residues.

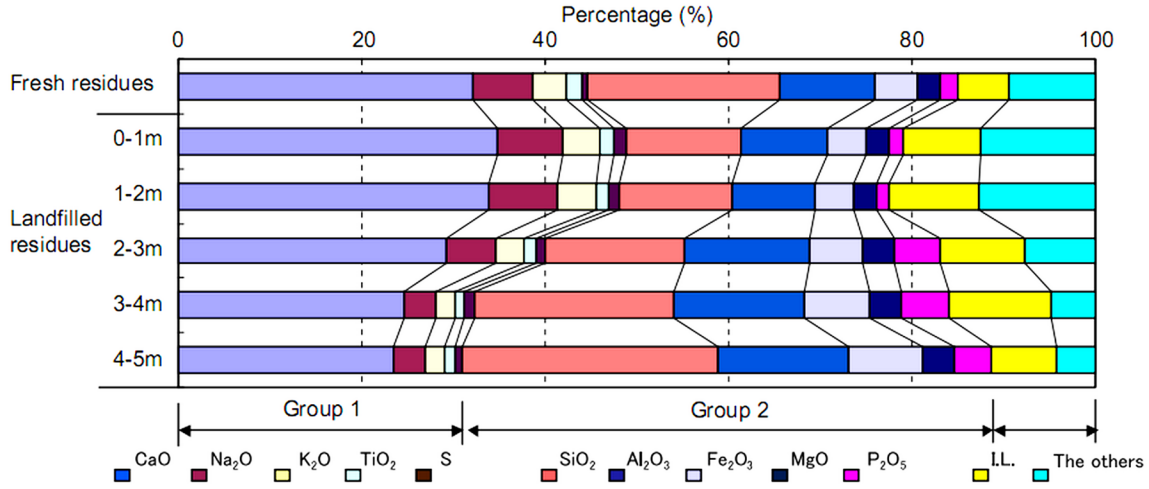
Figure 6. Major compositions (>1%)in the fresh and landfilled MSWI residues determined by XRF (Shimaoka, Zhang et al. 2007)



Dissolved Organic Matter

Organic carbon in waste incineration process is converted to CO_2 (98-99%) or transferred to bottom ash (1-2%) or (0.1-0.4%) to boiler ash APC residues(Ferrari, Belevi et al. 2002). Based on the research of (Seo, Kim et al. 2007) fluorophores, an aromatic amino acid in dissolved organic matter fraction, could be considered as an important effective factor in the complexation process with the pollutant materials. Residual organics have received far less attention in comparison to metallic elements as counterpart. Aromatic amines, antrhracene, carboxylic acid diethylamide, bromo–N-(4-bromo-2-chlorophenyl)-propanamide) and other aromatic compound are major odorous compounds in incinerator bottom ash (Lin, Yen et al. 2010; Ferrari, Belevi et al. 2002).

MUNICIPAL SOLID WASTE COMPOSTING PROCESS

Municipal solid waste is by far the largest source of human made organic waste, which has the capacity of composting, based on the document presented by (Epstein 2011). According to the research, there was a publication of report on compost application in year of 1888. Composting process is a natural process in our environment. In fact, industrial composting is an expert of advanced copy of natural biodegradation of organic material, which is specialized by mechanical and electronic equipments. After recycling process, edible waste which has high quantity of organic matter, could be used in the composting system; an intermediate disposal method, which converts high quality of organic manure. Furthermore, this process could decrease the volume of MSW (Stentiford 1996, Epstein 2011).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Microbial and Thermal Characterization

Composting is a microbiological singularity that highly depends on temperature fluctuation within the windrows. The temperature through a composting mass regulates the rate at which many of the biological procedures, play a specific selective role on the advancement and the succession of the composting microbiological communities (Hassen, Belguith et al. 2001, Epstein 2011). Controlling the process of composting fundamentally depends on the Oxygen rate, which has to be kept at optimum level. Generally in biological terms, operating temperature should be more than 55 ° C for highest sanitation, 45 to 55 ° C for achieving maximum biodegradation ratio and 34 to 40 ° C for the lowest diversity of microbial communities (Stentiford 1996) . Three major steps, which can be distinguished in a schematic aerobic composting process, are: (i) mesophilic phase, (ii) thermophilic phase and finally (iii) a cooling phase. Thermophilic and mesophilic are basically effective temperature regime throughout the composting process. Thermophilic condition could control herb seeds and pathogen. Mesophilic situation is prepared to finally reach mature stable compost. Mesophilic condition provides optimum temperature for rapid and suitable biological decomposition of organic materials(Epstein 2011). Nowadays, compost plant construction and management are well developed and there are many advanced composting system for operation and application. The future of this technique was presented as organic fiber production from unsorted MSW (Quirós, Gabarrell et al. 2014),producing higher agronomic value compost (Awasthi, Pandey, & Khan, 2014). Meanwhile, composition of municipal solid waste plays a major role in the management of waste. In **Table 3** composition of MSW in some parts of the world, USA, China, Malaysia, and Gambia are presented.

Organic Fertilizer Production for Agricultural Application

Composting is growing as a green technology and the application of MSW compost as organic manure in different agricultural system has a historical background, same as the composting of municipal solid waste. These two parallel lines are going fast together. The quality of municipal solid waste compost highly depends on the waste composition, which usually correlated to the economy and developing factors of the production origin. **Figure 7** shows the composition of MSW in developed countries and average of 19 developing countries.

Table 3. MSW composition in New York (MacBride 2014), Hangzhou China (Chi, Dong et al. 2014), (Sanneh, Hu et al. 2011) and Kuala Lumpur Malaysia (Saeed, Hassan et al. 2009)

Component	New York USA	Hangzhou China	Greater Banjul Area Gambia	Kuala Lumpur Malaysia
Food waste	26.54%	58.15%	32.44%	57%

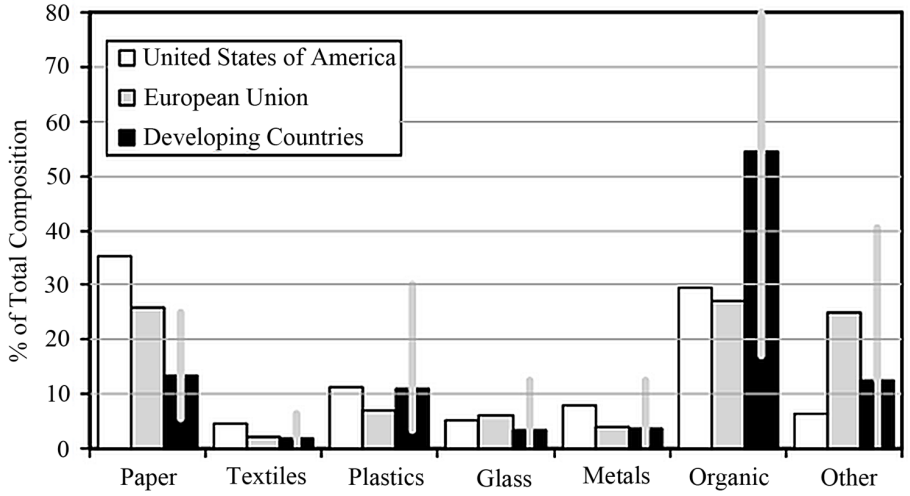
Figure 7. Comparison of MSW composition of United States and European Union in compare with the average of 19 developing countries (Troschinetz & Mihelcic 2009)



Horticulture science is a well-known part of agriculture, which has many operations and applications in human society and environment such as landscaping, floriculture parks, grass area for playground and countryside vegetable and fruit garden. This could be considered as the main applier of municipal solid waste compost. Different kinds of compost application in horticulture are presented by (Stoffella & Kahn 2001). (Hargreaves, Adl et al. 2008) present a review on agricultural application of MSW compost. Based on the research of (Garcıa-Gil, Plaza et al. 2000), for long term application of MSW compost, heavy metal content and other toxic material should be considered as an aspect of quality control. Some of the positive effects of MSW compost are mentioned in the following points:

- Improving soil biochemical and biological properties (Garcıa-Gil, Plaza et al. 2000)
- Increasing total N and C, furthermore enhancing nitrate reeducates and de-hydrogenase activities in soil (Crecchio, Curci et al. 2001)
- Improving physical and chemical properties of soil (Shiralipour, McConnell et al. 1992, Giannakis, Kourgialas et al. 2014)
- Increasing yield of vegetables comparing chemical fertilizers (Mkhabela & Warman 2005).
- Better seedling emergence for tomato, pepper and cucumber comparing commercial peat (Roe, Stoffella et al. 1997)
- Suitable effect on adjusting plant hormones for cultivation of some forage species (Ouni, Albacete et al. 2014)

In fact, due to the materials departure and waste string as well as lack of nutrients and high level heavy metals, composting dropped to <4% in present time from 17% in 2001(YAN & WU, 2003). Composting of municipal solid waste has some drawback as follows:

- This kind of waste disposal needs size reduction and waste separation before starting
- Volume of produced organic manure is disproportionately large and quality is low

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

- This organic fertilizer may cause many pathogens and heavy metals in soil(Ayari, Hamdi et al. 2010).
- Since compost is bio manure so application in public area of cities and landscape may cause to odor and bioaerosol problem
- A product should be marketed (Epstein 2011).

ENVIRONMENTAL IMPACT

Waste disposal is one of the most important parts of waste management, which has a critical effect on our environment. On one hand, waste disposal methods reduce the volume and hazardous effects of our municipality (agricultural, industrial and municipal) waste, on the other hands, this part of waste disposing will produce other byproducts which are hazardous or may cause higher environmental impacts(Smith, Brown et al. 2001). Some of the environmental impacts of waste disposal are presented in GHG emission explained in (Palmer, Sigman et al. 1997, Williams 2005). It reports odor, noise, traffic congestion, emission of carbon dioxide and other pollutions from all kinds of waste disposal. Report of (Hjelmar 1996) indicates that landfilling incineration bottom ash is less problematic in comparison to air pollution control residues. Based on the researches of Japanese team (Mendes, Aramaki et al. 2004) in Brazil, landfilling have higher environmental impact in comparison to incineration.

During Waste Incineration

- A complete overview carried out on incineration environmental impact by scientist team from Denmark, Australia, Germany, and Italy (Sabbas, Polettini et al. 2003) and they concentrated on salts, metals and greenhouse gases emissions in their studying.
- Odor, litter and dust problem during discharge, handling and transportation.
- Sub-micron particles contain heavy metals and metallic compounds.
- Nitrogen oxide which can form at the flame temperature.
- Incompletely combusted pyrolysis products may produce volatile organic compounds and carbon monoxide (Daskalopoulos, Badr et al. 1997).

During Waste Composting

As an organic fertilizer, municipal solid waste compost is usually applicable manure for enhancing soil's physicochemical properties. According to Hargreaves et al. (2008), MSW compost could be applied in agriculture as a safe fertilizer. Meanwhile, application of urban waste compost for humans and its environment hazards, were reviewed by Déportes et al. (1995) .Furthermore Lou and Nair (2009) reviewed the effect on greenhouse gases emission in application of MSW compost. Following notes are some of the specific researches on environmental impacts through composting MSW:

- Dust and aerosol particles, some microbes and odor to air (Iranpour, Cox et al. 2005)
- Leachate, from high content of moisture (60%- 65%) in compost, to water resources (Daskalopoulos, Badr et al. 1997).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

- Volatile organic compounds (VOC) production in composting process(Brinton 1998).
- Emission of NH_4-N through the composting process(Komilis & Ham 2006, Pagans, Barrena et al. 2006).

During Waste Recycling

Recycling process take a place by construction, transportation, washing, chapping all of which needs electrical energy application and causes production of GHG as a specific industrial activity. Among all environmental impacts of recycling, one of the most important issues is direct human hazard or injury as following:

- Health risks for sorting and recycling process and de-inking recycled materials (Rigamonti, Grosso et al. 2009).
- Hepatitis B and C prevalence during the separation process (Tsovili, Rachiotis et al. 2014).
- Respiratory disorders throughthe recycling MSW (Abou-ElWafa, El-Bestar et al. 2014).
- Gastrointestinal, skin, musculoskeletal and respiratory problems observed in Municipality operators worker (El-Wahab, Eassa et al. 2014).

SOLUTIONS AND RECOMMENDATIONS

Civilization and industrialization are related and correlated to waste production in municipals. Waste disposal has many aspects and relationships to other parts of waste management. The processes of waste management start withthe waste generation and end with final landfilling. On one hand, municipalize going on to produce higher volumes of waste; while on the other hand, industrialization has another effective point in waste composition. Selecting an effective method for treatment or disposing MSW could give novel improvement in saving energy and reducing the drawbacks of produced waste. Meanwhile, concentration on decreasing volume of waste production with the educational system and promoting on the cultural background of any society will assist the sustainable environment. Not only, the economic circumstances, but also cost effective properties will have a significant effect on selecting favorite waste disposal method. Protecting the environment in green way method needs to avoid the production of hazardous waste or environmental impacts. Governmental policy is the most effective element as well as private section cooperation could lead us to eco-friendly methods of waste disposal. In other words, recycling is a major concern of waste disposal and is an important requirement for today. Nevertheless, in the next decades, there will be critical imperative activity. To sum it up, our future worlds are mostly going to incineration of municipal solid waste and land filling disposal method, so eco-friendly aspects of these methods will be the key to reaching green way of waste disposal. Meanwhile, professionally engineered, cost effective green technologies for specific recycling method have high value in researches.

Chapter 39
Assessment of Available Technologies for Hospital Waste Management:
A Need for Society

ABSTRACT

Modern hospital practices with galloping growth in medical technology facilitate increase human life span, decrease mortality rate and increase natality rate. Life supporting health services generates potentially hazardous and infectious hospital wastes like pharmaceuticals, cottons, food, paper, plastics, radionuclide, sharps, and anatomical parts etc. These wastes are complex in nature with maximum part of municipal solid waste and small part of biomedical waste (anatomical parts, body parts etc.). Improper conduct and management of hospital waste create several problems and nosocomial diseases to human beings and harms environment. Traditional practices included for management are open burning, mixing waste, liquid discharge and waste disposal without treatment normally. Hence, this issue comes in lime light and several guidelines come to sort out this problem. Thus, challenges associated with traditional hospital waste management techniques and modern techniques for management are assessed in general and association with human society in particular in this chapter.

INTRODUCTION

With rapid growth of human population and urbanization there is increase in quantity of waste generation. Most developing and develop part of the world is facing challenges of waste. Waste is the substances which have resource but not value. Waste is classified by their source of generation, process by the wastes is produced, and also by its composition. According to literature, there are several attempts to define waste, enlisted in Table 1. Similarly, source of generation, compositional structures, and regulatory framework also supports and defines waste, given in Table 2, in Indian context only.

Among the varieties of waste, as listed in Table 2, Bio-medical waste (BMW) has a serious thought, because inappropriate treatment and final disposal of the wastes directly shows the negative impact on human health and local environment. Thus, bio-medical waste, which consists of pathological and hazardous healthcare wastes, included as a major part of study in this chapter. In general wastes generated from

Table 1. Definitions of Waste

Agency	Definition	Reference
BASEL Convention	"Wastes" are substances or objects which are disposed of or are intended to be disposed of or are required to be disposed of by the provisions of national law.	BASEL Convention, 1989
OECD	Wastes are materials other than radioactive materials intended for disposal, for reasons specified.	OECD, 1994
World Bank	Unwanted materials left over from any human activity. or, Refuse from places of human or animal habitation. Waste may be generically defined as heterogeneous mixture of material which is discarded as superfluous and has no further use or value to its owner.	World Bank, 2000
EU	Any substance or object which the holder discards or intends or is required to discard.	European Commission, 2012

Table 2. Different type of wastes according to Indian regulatory framework

Rules	Definition
Hazardous Wastes (Management and Handling) Rules- 1989	Hazardous waste means any waste by reason of its physical, chemical, reactive, toxic, flammable, explosive or corrosive characteristics causes danger or is likely to cause danger to health or environment, whether alone or when in contact with other wastes or substances.
Bio-Medical Waste (Management and Handling) Rules - 1998	Bio-Medical Waste (BMW) means any waste, which is generated during the diagnosis, treatment or immunization of human beings or animals or in research activities pertaining thereto or in the production or testing of biological.
Municipal Solid Wastes (Management and Handling) Rules- 2000	Municipal Solid Waste (MSW) includes commercial and residential wastes generated in municipal or notified areas in either solid or semi solid form excluding industrial hazardous wastes but including treated bio-medical wastes.
E-Waste (Management and Handling) Rules- 2011	E-Waste means waste electrical and electronic equipment whole or in part or rejects from their manufacturing, refurbishment and repair process which are intended to be discarded as waste.
Plastic Waste (Management and Handling) Rules- 2011	Plastic waste means any plastic products such as carry bags, pouches or multilayered packaging, which have been discarded after use or intended life is over.
Solid Waste Management Rules-2015*	Solid Waste means and includes solid or semi-solid domestic waste including sanitary waste, commercial waste, institutional waste, catering and market waste and other non-residential wastes, street sweepings, silt removed or collected from the surface drains, horticulture waste, construction and demolition waste and treated bio-medical waste and e-waste generated in an area under urban local body.

*(It is in draft stage. It will come into force on the date of their final publication in the Gazette of India.)

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

households and industries can be managed through using conventional and advanced treatment methods. But, bio-medical waste technically not ease to handle, it requires relatively adequate managing skilled workers for proper management. Often, it has been noticed that the management and handling of these types of wastes is taken over by poorly educated or untrained workers, who perform the management steps without proper guidance and self-protection. Hence, the objective of this article was to study the document existing resources, management practices related to bio-medical waste in general and a city specific study in particular.

Patient and hospital staffs during the service of humanity release large quantity of waste which is rising in its quantity and composition, due to advances in scientific knowledge its impact is also increasing. We are unaware about the bad effects of the waste generated by hospitals on human body and environment (Sharma et al., 2013; Sanjeev et al., 2014; Patil et al., 2013). Cleanup costs for medical wastes are extremely high (Johnson et al., 2013; Brichard, 2002), so hospitals avoid following BMW management practices. It is complex type of waste hence, there is not a particular method of BMW treatment or disposal that completely eliminates all risks to humans and environment. Untreated Bio-medical waste deposits have health risk to the public due to potential for pathogen release to harm human beings epidemically or endemically; acutely or chronically. Main target of this waste are:

- Doctors,
- Nurses,
- Paramedical personals,
- Hospital workers,
- Waste management workers,
- Transporters,
- Hospital visitors etc. And this type of infection is known as noscomial or hospital acquired infections (HAI).

Some time it has been also seen that staffs dealing with BMW and rag pickers are badly affected, because unknowingly or unwittingly, they search through all kinds of hazardous material while trying to recover items which they can sell for reuse. Some hospitals and laboratory waste may contain hazardous chemicals, biohazards, radioactive materials, papers, metals as well as sharps like (hypodermic needles, knives, scalpels, etc.). About 75-80% of the waste produced in hospitals is non-risk waste and comparable to domestic waste and usually called “non-hazardous” or “general health-care waste” (Mosquera et al., 2014). The remaining 10–25% of health-care waste is considered as “hazardous” and may cause a variety of environmental and health risks (Chartier et al., 2014). There is temporal and spatial variation in BMW generation during different parts of world (Table 3). Mixing of BMW to general waste contaminate the general waste also.

There is not adequate public understanding of BMW management (Singh & Nath, 2013; Yong et al., 2009). There is no segregation of waste starting from generation to disposal, need of awareness among the sweepers and cart drivers about personal protection, no separate committee for the management of the hospital waste, and no proper cover during transportation of waste, incinerated ash is found thrown on the area nearby the incinerator (Kungu et al., 2016; Athvale et al., 2010), polychlorinated dibenzo-p-dioxins and furans (PCCD/Fs) in the fly ash and air (Chen et al., 2015) and concerned people are explored to the danger of such wastes (Hassan et al., 2008). Handling and proper disposal of BMW have very high risk to cause injury or infections in healthcare personnel and there are also risk to general public through the

India	0.5-2.0	-	Patil et al. (2001)

spread of pathogenic micro-organisms from healthcare facilities to the environment (Babanyara et al., 2013; Hossain et al., 2013; Brichard, 2002; Mohee, 2005). To minimize these problems many efforts have been done at international level but proper management of BMW is still infancy all over the world (Athvale et al., 2010; Altin et al., 2003). There is lots of confusion among generators and operators about the safe management of BMW (Athvale et al., 2010). For scientific and secure management of BMW, handling, segregation, mutilation, disinfection, storage, transportation, and final disposal are essential steps for any health care institution (Isaacs & Dhakkal, 2015; Altin et al., 2003). In developed countries these vital steps are in process of adopt. While in India and other developing and poor countries it is an intractable problem. The management of BMW has received little attention despite their potential environmental hazards and public risks (Thakur and Ramesh, 2015; Hassan et al., 2008).

WHO stated that 85% of hospital wastes are comes under the category of non-hazardous, approximately 10% is infectious and only 5% is non-infectious but hazardous wastes. In USA, only 15% of the hospital waste comes under the category of infectious waste. Whereas, in India this could range from 15% to 5% of the total quantity of hospital waste generated (Chandra et al., 1999). Table 3 summarizes the amount of hospital waste generated from different countries, according to data available, while Table 4, enlists the different sources of BMW generation, its treatment options and harmful effects associated with the sources in general.

There are several technological options available for handling and treatment of BMW at traditional and modern scale (Thakur and Ramesh, 2015).

- Autoclaves are generally used for sterilization of infectious reusable materials such as sharps, surgical instruments, surgical gloves, aprons *etc.*

Table 4. Sources of bio medical waste generation, treatment options and harmful effects

Waste category	Source of generation	Color code bins	Treatment options	Harmful effects
Human Anatomical Waste	Human tissues, organs, body parts	Yellow	Incineration/ deep burial	Foil smell, enhance microbiological activity, risk to diseases
Animal Waste	Animal tissues, organs, body parts carcasses, bleeding parts, fluid, blood and experimental animals used in research, waste generated by veterinary hospitals, colleges, discharge from hospitals, animal houses	Yellow	Incineration/ deep burial	Bad odor, enhance microbiological activity, risk to disease
Microbiology & Biotechnology Wastes	Wastes from laboratory cultures, stocks or specimens of micro-organisms live or attenuated vaccines, human and animal cell culture used in research and infectious agents from research and industrial laboratories, wastes from production of biological, toxins, dishes and devices used for transfer of cultures	Yellow	Local autoclaving/ microwaving/ incineration	Risk to allergy, skin and other infections, Biochemical, anatomical, and Physiological alterations, Capable to reach inner part of body through inhalation
Waste sharps	Needles, syringes, scalpels, blades, glass etc. that may cause puncture and cuts. This includes both used and unused sharps	Blue/White	Disinfection (chemical treatment/ autoclaving/ microwaving and mutilation/shredding	Physical damage, Subcutaneous infections, Virus associated blood infections such as HIV, Hepatitis B and C, etc.
Discarded Medicines and Cytotoxic drugs	Wastes comprising of outdated, contaminated and discarded medicines	Black	Incineration/destruction and drugs disposal in secured landfills	Potential carcinogens, Abortions, water contaminations, Antibiotic resistant
Solid Waste (Infectious)	Items contaminated with blood, and body fluids including cotton, dressings, soiled plaster casts, lines beddings, other material contaminated with blood	Yellow	Incineration autoclaving/ microwaving	Communicable Diseases such as: Cholera, Tuberculosis, Diphtheria, Flue, etc.
Solid Waste	Wastes generated from disposable items other than the waste (sharps) such as tubing, catheters, intravenous sets etc.	Red	Disinfection by chemical treatment, autoclaving/ microwaving & mutilation/shredding	Physical damage, environmental pollution
Liquid Waste	Waste generated from laboratory and washing, cleaning, house-keeping and disinfecting activities, dialysis		Disinfection by chemical treatment and discharge into drains	Water and land contamination
Incineration Ash	Ash from incineration of any bio-medical waste	Black	Disposal in municipal landfill	Hazardous
Chemical Waste	Chemicals used in production of biological, chemicals used in disinfection, as insecticides *etc*.	Black	Chemical treatment and discharge into drains for liquids and secured landfill for solids	Children malformation, Abortions, Antibiotic resistant, Reaches through inhalation in lungs and other body parts
Radioactive waste	Radiotherapy Units of Cancer ward	Special containers	Send to Atomic labs	Headache, dizziness and vomiting, Tissue destruction, fatal

(Source: Modified from Schedule I and II of Bio-Medical Waste Management and Handling Rules, 1998, India; Pruss et al., 1999; Chartier et al., 2014)

- Incineration is considered as a best alternative for treatment with high temperature for burning of BMW.
- Chemical disinfection and sterilization has been done generally with iodine-povodine solution, 1% Sodium hypochlorite solution etc., whereas, floors and bins are cleaned with phenol and bleaching powder with other many more market based chemicals.
- Sharps and needles are shredded onsite with shredder.

Some places where modern technologies are not available for BMW treatment due to limitations to reach to remote areas or absence of proper skilled manpower, encapsulation and deep burial is suggested by researchers and policy makers. Some other technological options are also available in literature, properly discussed in next section of chapter.

TREATMENT OPTIONS FOR HOSPITAL WASTE MANAGEMENT

Among the different treatment options, according to source of generation, some common methods utilized for management of infectious wastes at worldwide level (Table 4), are:

Physical Methods

In physical processes, autoclave, hydroclave, incineration are frequently used and suggested technologies, discussed here as:

Autoclave

Autoclaves are mainly of two types-

- Gravity flow and
- Vacuum, Gravity flow autoclave.

Gravity flow autoclaves operated at 121ºC temperature, 15 psi pressure for 60 minutes or 135ºC temperature, 31 psi pressure for 45 minutes or 149ºC temperature, 52 psi pressure for 30 minutes. While, vacuum autoclaves are operated at 121 ºC temperature, 15 psi pressure for 45 minutes or 135ºC temperature, 31 psi of pressure for 30 minutes. Steam is used for temperature and pressure.

Hydroclave

Another steam based technology is hydroclave, it has a double walled container, inner chamber contains waste and steam is injected to outer jacket which transfer heat to inner chamber. Moisture content of waste creates pressure of about 35- 36 psi (if waste is dry then steam is injected) at 132°C with residence time of 20 minutes. To process one complete cycle, it takes time of 50-60 minutes including start up, heat up, sterilization, venting, depressurization and dehydration. These mentioned technologies have chances to little infection and not minimizes waste.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Incinerator

Complete destruction of waste is done by incinerators only at high temperature, mainly two chambered incinerators are preferred, primary chamber have about temperature of 800 ±50 ºC while secondary chamber have temperature of 1050 ±50ºC.

Others

Other technologies like microwave and plasma pyrolysis are still in infancy stage used for BMW treatment. Microwave is also steam based technology in which water contained waste is rapidly heated by microwave energy at frequency of about 2450 MHz. (Emmanuel, 2001). While, plasma pyrolysis uses extremely high temperature of about 1200ºC, in this technology, BMW is converted into simpler forms like CO, Hydrogen and hydrocarbons. It is better than incinerator because of there is no need to segregation of chlorinated compounds.

Chemical Methods

Mainly reusable and recyclable BMW like used gloves, instruments, masks etc. needs chemical treatment before disposing. These types of materials are generally treated with 1% -Sodium hypochlorite solution for minimum one hour. Use of super critical water with hydrogen peroxide is a good stabilizer of metals in incinerated ash (Bo et al., 2009). Cement has capacity to immobilize incinerated ash in form of bricks (Anastasiadou et al., 2012) which stable in buildings and roads. Use of super critical fluids like CO_2 (SF-CO_2) is also a good option for sterilization of wastes (Goddu et al., 2007) and make process easier for waste handlers. For the treatment of liquid wastes Effluent Treatment Plants, Microbial Fuel Cells (MFCs) are good option of liquid waste treatment. Fenton Treatment also a very good option for BOD_5 and COD and bacteria removal (Berto et al., 2009).

Biological Methods

There are not well developed methods available for BMW, but a very few documented in literature. Cotton, bandage and other degradable matter when soiled or inoculated with white rot fungus such as *Periconiella sp.* are capable to degrade them (Pandey et al., 2008). Vermi composting is also a good method for it use of epigenic earthworms is a good alternative. Dinesh et. al., (2010) used polycultures of three earthworms, *Eisenia fetida*, *Eudrilus eugeniae*, and *Perionyx excavates,* and reported that union of several earthworms is better way due to hazardous environment.

Therefore, all the above said categories for biomedical waste can be managed through below enlisted options:

- Autoclaves and retorts;
- Microwave disinfection systems;
- Chemical disinfection;
- Combustion, and
- Disposal on and beneath the land.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Whereas, residues of syringes and needles also a major part of this wastes, and generally managed through:

- Burial in covered pits;
- Encapsulation by cement/concrete materials;
- Point-of-use needle destruction technologies and size reduction with mechanical type destruction appliances.

Each treatment options for medical waste from hospitals have its limitations in different respects, which were highlighted in Table 5.

HOSPITAL WASTES IN VARANASI (UTTAR PRADESH), INDIA

With increasing awareness in public regarding hazards of hospital waste, a survey based study was conducted including questionnaire as a tool to support the findings of observations regarding process route of waste from generation to its disposal. The study area selected was the most populous city of eastern Uttar Pradesh i.e. Varanasi, with a population density of 2,395 people per square kilometre. Therefore,

Table 5. Comparisons of treatment technologies for medical wastes

Treatment systems	Autoclave	Hydroclave	Microwave	Incinerator	Chemical
Description	Steam sterilization (Direct heating)	Steam Sterilization (indirect heating) simultaneous shredding and dehydration	Microwave heating of Pre-shredded waste	High temperature waste incineration	Mixing pre-ground waste with chemicals, such as chlorine
Sterilization efficacy	Medium	Medium	Medium	High (total destruction of micro-organisms)	Dependent on chlorine strength and dispersement through the waste
Capital cost	Low	Low	High	High	Moderate
Operating cost	Low	Low	High	High	Low
Operator maintenance skills	Low skill level required	Low skill level required	Automated, but highly complex and high level maintenance skill required	High level operator and maintenance skills required	High level required for chemical control and grinder
Air emissions	Odorous but non-toxic	Somewhat odorous but non-toxic	Somewhat odorous but non-toxic	Can be highly toxic	Some chlorine emissions
Water emissions	Odorous, may contain live micro-organisms	Odorous but sterile	Negligible	None	None
Treated waste characteristics	Wet waste, all material recognizable	Dehydrated shredded waste, unrecognizable material	Shredded but wet waste	Mostly ash, may contain toxic substances	Shredded wet waste, containing chemicals used as disinfectants

Source: (Babu et al., 2009)

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

to evaluate the actual scenario of hospital/bio-medical waste in Varanasi (Uttar Pradesh), three specific funding partners i.e. Central, State, and Private hospitals taken as a study site, enlisted in Table 6, with coded abbreviations used for them.

This figure of population density is higher than national (382 people per square Km) and state level (Uttar Pradesh, 829) of population density. Gender wise population distribution indicates to have 1, 921,857 male and 1,754,984 female populations. Varanasi seems to be centralized place for various facilities such as commercial, education, health etc. with wider coverage area including eastern Uttar Pradesh and neighbor state (Bihar). Varanasi is identified as zone for centralized treatment facility from out of the ten selected zone under the World Bank (2011) funded project (Uttar Pradesh Health Systems Strengthening Project). Hospitals from Varanasi district were selected by following a pre short survey of health care facilities present in the city. Six healthcare facilities and one Common Bio-Medical Waste Treatment Facility (CBMWTF), Varanasi were selected to assess the waste as given in Table 6.

After selecting hospitals for waste management study, a questionnaire was developed for cross sectional study and given to key personals of hospitals (Table 7). A structured questionnaire was developed to ask the questions from respondents/stakeholders. The questionnaire was designed to obtain respondents awareness towards the waste management and to know the practices being implemented in those hospitals. Thus, a simple framework of questionnaire having binomial variables with a scale of either 1 or 2 (Yes or No) was used to conduct interview in selected hospitals. Whereas, on qualitative scale, a descriptive study was designed to explore the current hospital waste management practices by interviewing with key personals like directors, medical superintendent, deputy medical superintendent, chief matrons, housekeeping in-charges, medical officer and persons related to waste management processes. Focus was done on:

- National rules,
- Internal policies,
- Monitoring and awareness,
- Personal protective equipment's,
- Solid and liquid waste,
- Handling practices,
- storage facilities,
- training of hospital staff related to hospital waste management, and
- new technologies using by them.

Table 6. Study sites for assessment of BMW at Varanasi city (U.P.)

Type of Funding Hospitals	Name of Study site (Code)	Remarks
Central Government	Sir Sunderlal Hospital (SS1)	Tertiary care Hospital
	Central Hospital DLW (SS4)	Railway Hospital
	Indian Railways Cancer Institute and Research Centre (SS5)	Railway hospital for cancer patients
Private	Heritage Hospital (SS2)	Specialty care Hospital
	Apex Hospital (SS3)	With charitable blood bank
State Government	Pt. Deen Dayal Upadhyay Rajkiya Hospital (SS6)	Super specialty Hospital

(SS means survey site)

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

After questionnaire survey study, only 2 out of 6 selected hospitals were found to have data related to waste generation and management practices. Hence, these 2 hospitals were finalized for the detailed survey study plan i.e. SS1 and SS5 with CBMWTF.

Major Observations and Findings

Before detailed study plan, it has been observed that all the six study sites of Varanasi are required to handle hospital waste in a specified manner or in general way. Thus, total findings of the study are divided into different subsections, to easily understand the way to waste management practices and awareness among workers to officials at three major funding partners in Indian context i.e. Central, State and Private Hospitals.

Table 7. Questionnaire and key findings of survey sites

S. No.	Questions	SS1	SS2	SS3	SS4	SS5	SS6
A. Solid Waste							
1	Do you properly segregate your waste?	Y	Y	Y	Y	Y	Y
2.	Does your hospital has color coded waste containers and they are properly labeled? (Biomedical Waste & accumulation start date)	Y	Y	Y	Y	Y	N
3	Do departments have waste accumulation areas away from reach of peoples?	Y	Y	Y	Y	Y	Y
4	Does your hospital have a separate waste collection area for BMW?	Y	Y	Y	Y	Y	Y
5	Do your staffs who handling with waste receive BMW management training?	Y	Y	Y	Y	Y	Y
6	Do your staffs use Personal Protective Equipments for waste handling?	Y	Y	Y	Y	Y	Y
7	Does your hospital keep record of the amounts of BMW generated per month?	Y	N	N	N	Y	N
8	Does your hospital use a CBMWTF, for transport, & dispose of BMW?	Y	Y	Y	Y	Y	N
9	Does your hospital follow which of the following						
A	Off- site incineration	Y	Y	Y	Y	Y	NC
B	Through on- site incineration	N	N	N	N	N	N
C	Through autoclave	N	N	N	N	N	N
D	Through Chemical Disinfection						
E	By other processes	N	N	N	N	N	N
B. Liquid Waste							
1	Do you discharge wastewater in followings:						
A	Sewer	Y	Y	Y	NC	Y	Y
B	Septic system.	N	N	N	NC	N	N
C	Surface water.	N	N	N	NC	N	N
2	Does your Hospital keep records about amount of waste water discharge per day?	N	N	N	N	N	N
4	Have you ever sampled your waste water for water quality analysis?	N	N	N	N	N	N
5	Do you have a diagram of your waste water discharge system to sewer?	N	N	N	N	N	N

*SS means survey site, Y=Yes, N=No and NC=No Comments

Questionnaire Based Findings

Here, questions were clustered into two major divisions i.e. solid waste generated from hospitals and liquid waste generated from the source sites, which were further categorised into different questions. It has been found that a significant portion of solid waste including bio-medical waste generated from study sites in hazardous in nature. Similarly, there is also a difference noticed between data from questionnaire and self-observations during site visits i.e., SS4 and SS6 claiming that they have well labelled coloured containers with biohazard symbols/category wise labelling but these all findings were missing during self-visits. On the other hand, SS1 and SS2 show the match between claims and practical awareness.

The awareness for The Bio-medical Waste Management rule, 1998 and status of policy implementations among study sites also followed through question items. The status of management was alarming at state funded hospital (SS6) in comparison to central and private funded hospitals, because of no segregation facility and biomedical and general waste were. Thus, this indicates a requirement of major inputs for the improvement in segregation facilities, whereas, SS6 has a well separated accumulation area away from main building for collection of waste from several departments. While, SS2, SS4 and SS5 were found better in position for management of waste generated.

It has also been noticed that all the staff and working professionals have training on handling of BMW, but only two study sites have the data records on BMW generation i.e. SS1 and SS5 and other study site's members shows unawareness regarding to the records on data generation. Although, use of CBMWTF for waste treatment and disposal has been declared by 5 study sites i.e. SS1 to SS5 except SS6 (State government funded hospital).

Assessment of Solid and Liquid Waste from Study Sites: Generation and Treatment Strategies

Solid and liquid waste treatment systems were also not showed a promising for clean environment during study sites. In the case of solid waste treatment, all the study sites depend upon the CBMWTF, which is the only unit, managing the BMW of about 260 health care centres of city nearby districts of Uttar Pradesh. Collection and transportation of waste from different sites was done on daily basis from Varanasi and on alternate days from other districts. It is established by a private firm and charges for treatment and disposal of BMW is decided on the basis of beds present in hospitals. This unit have a treatment options i.e. Incineration, Autoclave and Shredders. Ash forms of BMW go to secure landfills or common Hazardous Waste Treatment Facility at Kanpur. Mixed waste is the biggest problem here, which increases the cost of treatment plant and rest of the study sites discharging wastewater directly into sewer system. Lack of proper wastewater management is also noticed during the study of sites.

SS1 and SS5 showed an awareness for treatment of BMW. Survey site 1, one of the biggest tertiary care hospital of city and eastern, U.P. There were about 1,181 beds, on which 47, 610 indoor patients, admitted with 1,027,134 out patients, 84,966 emergency outpatients investigated in year 2011 (according to data from hospital records of 2011). During treatment and caring of patient there were about 101167 Kg BMW generated. Hence, there were about 0.2346 kg/bed/day and about 0.0058 kg/patient/day BMW generated (Figure 1 and Figure 2). Similarly, survey site-5, biggest cancer hospital and research centre of eastern U.P., of about 107 beds, from which 8308 Kg of BMW generated. So, there was ratio of waste generation is 0.1945 Kg/bed/day (Figure 2). Collection of these waste materials was done accordingly

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

to colour codes declare by the policy framework i.e. yellow, red, blue/white translucent and black. Segregation of waste materials generated at source, and reducing the risks for contamination and cost of handling waste segregation according to colour coding was found in both study sites.

Cleaning practices were also found appropriate and according to the regulations at both sites (SS1 and SS5). Personal Protective Equipment (PPE) was also used by waste handlers, which shows the awareness towards safety and handling practices.

Lack of resources and poor processes were noticed due to rotation working policy of waste handlers is noticed. Similarly, on-site treatments of BMW in premises of both study sites were absent. All the treatment of waste was compiled at CBMWTF only, with daily transport to the facility centre. Thus, BMWM is a serious sector among various waste management practices. Improper procedures and lack

Figure 1. Generation of bio-medical waste (Kg) on yearly basis and their collection in colour coded bins for study site -SS1

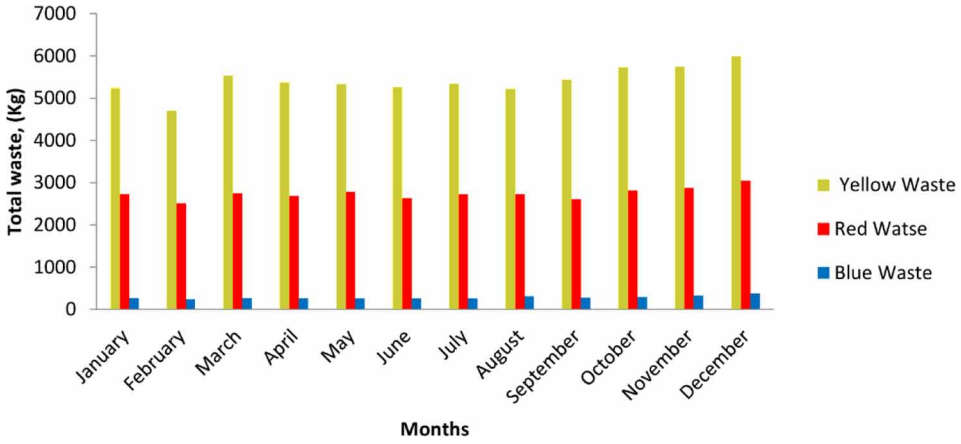

Figure 2. Generation of bio-medical waste (Kg) on yearly basis and their collection in colour coded bins for study site -SS5

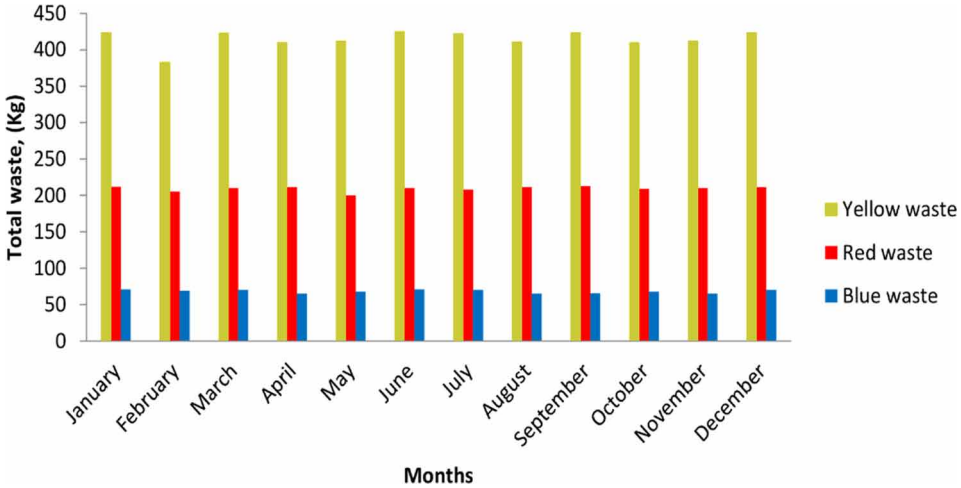

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

of awareness among officers-in-charge of BMW management at hospitals and nodal district officers at SPCB and CPCB requires an urgent need to solve the problem of BMW. Among all study sites, provides a bad picture of BMW management/ hospital waste management in general central, state or private funded in nature. Although various alternative options for BMW also noticed i.e. replacement of traditional BMW containers, trolleys, etc., use of microwave, hydroclave and biological agents (Thakur & Ramesh, 2015; Pandey & Gundevia., 2008; Dinesh et al., 2010) for clean-up of bio-medical waste provides a new insight for such type of waste practices. Similarly, Plasma pyrolysis with high temperature provides an energy recovery options and reduces the volume of organic matter (Tanksali, 2013; Nema & Ganesh Prasad, 2002). Many authors described the reasons for bad system/improper management as lack of sensitivity and awareness, concerning human health risks of BMW and economic constraints (Da-Silva et al., 2005). Other studies from India have also reported similar situations (Pandit & Choudhary, 2008; Shafee et al., 2010).

CONCLUSION

Hospitals are the place where humanity is serving from birth to last breath including treating several fatal diseases, abnormalities, immunization and rehabilitations etc. Its gives society to healthy life and maintain human population. During this process lot of several types of waste generated which are infectious in nature which has great potential hazard to human beings as well as natural environment. These waste creating several diseases, soil, air and water pollution also. Complex natures of Bio-medical waste are creating several problems during waste management. There is no single cleaner technology present to handle this complex type of waste so there is need to adopt good segregation practices. Hence, in concluding remark we can say that biomedical waste management is lacking proper implementation way in Indian context. Thus, handling, disposal and treatment options needs urgent involvements to improve the systems at all the three sectors-central, state and private funding hospitals, with specific focusing on awareness, policy reformation with responsive governance.

Chapter 40
Mystery of Recycling:
Glass and Aluminum Examples

Yasin Galip Gencer
Bogazici University, Turkey

ABSTRACT

Recycling is a key component of modern waste reduction and is the third component of the "Reduce, Reuse and Recycle" waste hierarchy. Recycling and/or waste minimization is a prerequisite for sustainable value and green environment. Recyclable materials include many kinds of glass, paper, metal, plastic, textiles, and electronics. The composting or other reuse of food is also considered recycling. This chapter starts with an expanded definition of recycling; afterwards, the recycling processes of glass and aluminum are examined in detail. Besides recycling, for a green environment the necessity for reducing and reusing of waste is also considered. Another topic will be the myths of recycling-unknown realities about recycling process. Furthermore, types of recycling and cost-benefit analysis will be explained. Ultimately, the chapter will be concluded by criticisms about recycling, and potential areas for further discussion.

RECYCLING

Definition and Scope

Recycling and/or waste minimization is a prerequisite for sustainable value and green environment. This chapter starts with an expanded definition of recycling; afterwards, the recycling processes of glass and aluminum are examined in detail. Besides recycling, for a green environment the necessity for reducing and reusing of waste is also considered. Another topic will be the myths of recycling-unknown or misknown realities about recycling process. Furthermore, types of recycling and cost-benefit analysis will be explained. Ultimately, the chapter will be concluded by criticisms about recycling, and potential areas for further discussion.

Recycling, mainly driven by economic and regulatory factors, is performed to retrieve the material content of used and nonfunctioning products (Srivastava, 2007). Recyclable materials include many kinds of glass, paper, metal, plastic, textiles, and electronics. The composting or other reuse of food is also considered recycling. Materials to be recycled are either brought to a collection center or picked up from the curbside, then sorted, cleaned, and reprocessed into new materials bound for manufacturing. Recycling can also be defined as a process to change waste materials into new products to prevent waste of potentially useful materials, reduce the consumption of fresh raw materials, reduce energy usage, reduce air pollution and water pollution by reducing the need for conventional waste disposal, and lower greenhouse gas emissions as compared to plastic production.

Many types of waste can be retrieved by recycling material. Among the diverse types of waste, glass is one of the most valuable recycling materials because it can be revived and recycled completely and hardly decomposes. Recycled glass can be used for porcelain, building material, sidewalks, and asphalt roads. Glass recycling has many advantages such as the preservation of natural resources and minerals, reduction in energy consumption, and reduction in air pollution. If glass can be recycled effectively, the environment can be greatly improved (Furlani et al., 2010; Ismail & Al-Hashmi, 2009).

Recycling is a key component of modern waste reduction and is the third component of the "Reduce, Reuse and Recycle" waste hierarchy. Aluminum is also another product that is mostly recycled and reused. Aluminum recycling has a number of key environmental and economic benefits. Compared to other high volume materials, aluminum production has one of the largest energy differences between primary and secondary production: 186 MJ/kg for primary compared to 10–20 MJ/kg for secondary (Green, 2007). With energy and cost savings in mind, many producers now have targets of increasing their usage of secondary materials (2002; Alcoa, 2006). However, the accumulation of impurities in these recycled material streams provides a significant, long-term compositional barrier to these goals (Liu, 2003).

On the other hand, these processes have also important quality standards. The examples for such standards related to recycling are ISO 15270:2008 for plastics waste and ISO 14001:2004 for environmental management control of recycling practice. These standards are needed for more efficient and effective processes in terms of recycling.

Continuously increase in world population and changes on the habits of consumption demand on the materials leads to rapid decrease on natural resources. It ıs inevitable that these resources will be run out shortly by the high consumer demand. In order to use effectively the limited resources, some of countries have taken a number of decisions, contributing the effective consumption on the resources. One of the most important ways of preserving the resources has been recycling, which is a process of reusing the materials used before and waste materials which have no use. In order to preserve the resources for the future generations and crises on energy leads the countries to take some radical action on energy and resources consumptions. All the material which can be reused such as asphalt, concrete, timber, paper, glass etc. has been reused for the same purposes or different. Especially construction industry has been a major resource for recycling to preserve and protect the environment. Unfortunately all this kind of preservation policy has no effective implementation. This chapter will underline the preservation policies and recycling carried out around the world.

Waste management has received in the last decades increasing attention. This is mainly due to the growing volume of waste produced, the scarcity of disposal areas and environmental protection. Lately, due to the harmful environmental effects of disposal, the emphasis has been shifting towards recycling. (Barros et al., 1998) Recycling is the process of remaking materials from ones that have already been

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

used. It also means using the used materials as raw material. If a product is described as "recycled", it means that it contains material that has been reprocessed. Most common materials recycled are paper, aluminum, plastic and glass (Go Facts Environmental Issues, 2006).

There is increasing pressure on waste managers, planners and waste regulators to deliver a sustainable approach to waste management and to integrate strategies that will produce the best practicable option for the environment. To aid evaluation and selection of the "best option(s)" for the management of wastes, guidelines were produced by the EC in 1989. These highlighted the potential resource conservation and pollution benefits available through developing solutions that focused on minimizing waste, on reusing and recycling unavoidable waste and rendering unusable wastes and residues safe for disposal. This so-called "waste hierarchy" has become the bedrock of strategy development for waste management throughout Europe. (Barton et al., 1996)

Recycling reduces waste, reduces consumption of new raw materials, reduces energy utilization, reduces air pollution (from incineration) and water pollution (from landfill) and reduces greenhouse gas emissions from the production of new goods from raw materials. Recycling is a key part of modern waste management and the third component of the "Reduction of waste, Reuse, Recycle "waste hierarchy (Lyons & Burford, 1993). The material can be recycled, including most types of glass, paper, metal, plastic, textiles, and electronics.

Life Cycle Assessment (LCA) has been defined by SETAC as "an objective process to evaluate the environmental burdens associated with a product, process or activity, by identifying and quantifying energy and materials used and waste released to the environment, and to evaluate and implement opportunities to effect environmental improvements". LCA is normally considered to involve the following stages:

- Goal definition (i.e. study objectives) and scope.
- Preparing the inventory of burdens (e.g. resources used, pollutants emitted).
- Assessment of the environmental impact of these burdens.
- Improvement analysis.

In practice the process is iterative as the results from subsequent stages will often require previous assumptions about system boundaries, required data, data quality, etc. to be modified. Approaches to setting the goal and scope of a LCA study and developing the inventory of burdens have been subject to much debate and a consensus has been reached within the LCA community. The inventory procedure provides a fingerprint for the defined activity by quantifying the mass of raw materials and consumption of energy. This encompasses the extraction from the earth of all raw materials used both directly by the activity and indirectly through provision of raw materials used to supply energy and finished/semi-finished products demanded by the system. It includes emissions to air, discharges to water and generation of solid waste. (Barton et al., 1996)

People are producing more waste. Developed countries mostly in Europe and North America produce far more waste than most other countries. The least amount of waste is produced in several countries as Zimbabwe, Sudan and Gambia in Africa. In back, people were more likely to repair something rather than throw it away, and therefore goods lasted much longer. Nowadays, people tend to throw something away when it goes wrong, frequently because it is cheaper to buy something new than to have repairs done. This brings the increase in the amount of waste material and at the same time the increase in the potential for recycling them.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

A report by Imperial College London concluded that recycling one tonne of steel saved 970 kg of carbon emissions, however recycling one tonne of aluminum saved 3.54 tonnes (Grimes S. et al., 2008). Recycling aluminum is much more critical than many other products because of its environmental effects. This reality is shown by many reports in academic literature.

There is a report of OECD. Some of the outcomes of the report are that:

- Global extraction of material resources goes on to grow, in spite of significant improvements in countries' resource productivity, i.e. the amount of material resources that is used per unit of output.
- Per capita consumption in G8 and OECD countries remains at high levels and is about three times that of the rest of the world.
- Within the G8, Canada, Germany, Italy and Japan have succeeded in decoupling material consumption from economic growth in absolute terms, i.e. to make smaller the amount of material resources that they use.
- If indirect material flows associated with trade are taken into account, i.e. material flows that are not incorporated into traded products such as materials for resource extraction and processing, progress in countries that are net resource importers is more modest.
- While G8 countries offer a mixed picture on all annual waste generation, with some countries indicating a decrease and others an increase, a generally not negative trend can be observed in municipal waste management (representing roughly 10% of total waste).
- Further progress can only be achieved through more integrated policy approaches that take account of the full life-cycle of materials and are designed according to the principles of Sustainable Materials Management developed by the OECD.

Comprehensive efforts towards increasing recycling combined with the relatively stable waste generation observed after 2008 across Europe have led to an upsurge in combustion Waste-to-Energy (WtE) overcapacity in countries like Austria, Germany, the Netherlands, Belgium, Sweden and Denmark (Friege & Fendel 2011; Sora, 2013).

As we mentioned, the generation of waste is increasing within the European Union. The 2008 EU Waste Framework Directive (WFD) introduced some important changes to the European waste market. Most importantly, the evaluation of needs for incineration capacity can now be assessed at the European level, as non-hazardous combustible waste can be traded between countries more freely. As a result, shipments of combustible waste from countries with treatment under-capacity towards countries with treatment over-capacity have increased significantly in the last few years and are expected to continue increasing, especially if fuelled by favorable economic conditions created by national authorities. (e.g. the UK) (Dubois, 2013) It has therefore become of prime importance to specify basic notions such as recovery and disposal, so as to better organize waste management activities. It is also essential to reinforce measures to be taken with regard to prevention as well as the reduction of the impacts of waste generation and waste management on the environment. Finally, the recovery of waste should be encouraged so as to preserve natural resources.

This Directive also establishes a legal framework for the treatment of waste within the Community. It aims at protecting the environment and human health through the prevention of the harmful effects of waste generation and waste management. It applies to waste other than: gaseous effluents; radioactive elements; decommissioned explosives; faecal matter; waste waters; animal by-products; carcasses of

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

animals that have died other than by being slaughtered; elements resulting from mineral resources. In order to better protect the environment, the Member States should take measures for the treatment of their waste in line with the following hierarchy which is listed in order of priority: prevention; preparing for reuse; recycling; other recovery; notably energy recovery; disposal. Member States can implement legislative measures with a view to reinforcing this waste treatment hierarchy. Furthermore, they should ensure that waste management does not endanger human health and is not harmful to the environment.

Any producer or holder of waste must carry out their treatment themselves or else must have treatment carried out by a broker, establishment or undertaking. Member States may cooperate, if necessary, to establish a network of waste disposal facilities. This network must allow for the independence of the European Union with regard to the treatment of waste. Dangerous waste must be stored and treated in conditions that ensure the protection of health and the environment. They must not, in any case be mixed with other dangerous waste and must be packaged or labelled in line with international or Community regulations.

On the other hand, any establishment or undertaking intending to carry out waste treatment must obtain a permit from the competent authorities who determine notably the quantity and type of treated waste, the method used as well as monitoring and control operations. Besides, any incineration or co-incineration method aimed at energy recovery must only be carried out if this recovery takes place with a high level of energy efficiency.

Lastly, the competent authorities must establish one or more management plans to cover the whole territory of the Member State concerned. These plans contain, notably, the type, quantity and source of waste, existing collection systems and location criteria. Prevention programs must also be drawn up, with a view to breaking the link between economic growth and the environmental impacts associated with the generation of waste.

Benefits of Recycling

Reusing of materials minimizes the need of raw material and this inherently prevents the damage to the environment and the deterioration of the natural balance by consumption which is rising up in line with population. Moreover, using recycled materials provides a large amount of energy savings. For instance, reusing aluminum materials instead of producing from raw provides 35% energy saving which is very advantageous for all parties including the producer and the end-user.

There is a limit to the amount of oil in the Earth from which we can make plastic, and a limit to the amount of aluminum ore to make cans. Resources that will run out eventually are called finite resources. Recycling reduces our consumption of finite resources. Also, when recycled materials are used to make new products, they don't go into dumps or landfills, so land is conserved. Producing products from recycled materials constantly uses much less energy than producing the same products from raw materials. Less energy consumed means less greenhouse gases, such as carbon dioxide and methane. These aids prevent global warming. Recycling one plastic bottle can save the amount of energy needed to run an average light bulb for six hours.

Glass was an expensive material until the 1800s when the mass-production of glass container started. Nowadays, the raw materials are more readily available so it is fairly cheap to make. Glass is made from three main ingredients: sand, soda ash and limestone. The ingredients are added together in a furnace and then heated until they melt. The molten glass is poured into moulds or blown to make bottles or other containers. Glass making needs a source of heat, which is usually produced by burning fossil fuels.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Interests on reusing of the limited resources and produced products is increasing with the rapid population growth, whether changes, consumption of natural resources and increasing environmental awareness (Sengül, 2009). Recycling aids to protect the environment. Recycling significantly decreases the amount of waste in waste incineration plants or amount of waste deposited in landfill areas. A lot of landfill areas in the world have been designed with considering the situation of infiltrating water system of the toxic chemicals from the decomposing solid waste. In spite of this reality, in the contemporary world, there are a lot of examples of contaminations hazardous chemicals that cause pollution of water resources.

Incineration of solid waste is efficient for electricity need but this creates an additional cost for carbon dioxide and other greenhouse gases. Therefore, recycling rate must be increased as much as possible before incineration. Recycling prevents the abandonment of wastes to the nature. Recycling of plastic, metal, glass and paper provides electricity saving. For instance, if it is assumed that 100 unit electricity is used in producing a metal box from raw material, the electricity consumed will fall to 5 units for producing new metal box from reused metal box (Ayvaz et al., 2013).

Recycling facilitates the preservation of restricted resources. Let's look at the example down for scrutinizing this benefit in an appropriate perspective;

Recycling 1 ton steel eliminates the requirement for approximately 1.2 ton iron substance, eliminates the energy requirement derived from burning 800 kg coal and approximately eliminates the requirement for 70 kg lime stone (calcareous). By means of recycling of all sort of paper excessively requirement for cutting millions of trees may be eliminated. Precious metal (gold, silver, tantalum, titanium, rhodium etc), metal (copper, aluminum, nickel etc) oil (herbal oils, industrial oils) are termed as finite resources and will be consumed in anyway sooner or later. Mobile phone and computer manufacturers progressively report their raw material requirements, many of them launched to recycle their corrupted or obsolescent products by their own efforts.

Recycling intensifies energy productivity. It considerably reduces energy consumption for the manufacture of raw material which is going to be derived processing in the form of new kernel and energy cost. Operation of mines, kernel derivation, decomposition of derived kernel and its shaping, carriage etc., will not be needed anymore.

Recycling facilitates the establishment of strong economy. Reduction of costs for energy productivity, resource protection and professional development etc., are the efficient parameters for the nations for reaching to powerful economy. Usually, during economic recession periods recyclable products even though experiencing bottom price levels, shifting to pre-crisis periods is experienced much faster compare to remaining sectors. One of the sectors experiencing minimum impact from economic crisis is the recycling sector, most impactful factor for that reason is known as raw material provision availability in much more economic ways. Specialization in recycling by means of more advanced technological implementations intensifies as the time goes on. Public institutions directly or by means of sub-contractor firms create remarkable benefits of energy save in terms of storage and waste collection.

Recycling constitutes a profession. It constitutes a wider employment field compare to storage or waste burning operation. In a period experiencing high unemployment and in case of market deregulations such a benefit is not possible to consider unimportant. Recycling also ensure qualifications for unqualified individuals. Unqualified workers gained labor training are earned for public life earning a profession; such circumstance may be useful for the elimination of guilt rates. Even illiterate individuals may be ensured with a specialized skill following professional training and business applications.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Recycling creates social structure. Fundamental fact for humans to come together and to constitute social gatherings remains on problems and related precautions. Recycling is not different than those. From diverse cities or countries individuals from diverse cultures, different educations, diverse age groups, diverse genders, political and life orientations by means of coming together behave in the same way for the well-being of environment and living creatures. Recycling is an important source for revenue. Infrastructure and investment are quite high costs while giving recycling services but the correct implementation of the waste materials (rubber, paper, plastic, glass, metal, electrical and electronics, accumulators, batteries, etc.)

Recycling makes natural resources protected. Natural resources minimize each day as a result of population increasing and the changing in the consumption habits of the world. Therefore, to reduce material consumption, with the means to recycle waste have to be considered qualified to use the world's natural resources efficiently. Whereas, recycling is an extremely significant process for the conservation and efficient use of our natural resources. For instance; with aid of recycling paper we can provide less cut trees in the forest. Similarly, oil can be saved by recycling of plastic waste.

Packaging which is used can be evaluated for use as a raw material source of waste, such as the protection of raw materials to be consumed or used instead of natural resources leads to significant savings. Our natural resources, because of the increase of the world population and consumption are decreasing every day. Hence, it is requisite to use of our natural resources in a more efficient manner. Recycling reduces the amount of waste. Reduction in the amount of waste going to recycling waste by applying a smaller amount of space for the transportation of waste and storage operations, and less energy is used. This reducing is not more weight to domestic waste. Referring constitute it is a significant proportion by volume. Recycling means less waste goes to landfill and, in addition to facilitating the transportation and storage of these wastes, because now less landfill and requires less energy.

Recycling Provide Benefits to Urban Ecology:

- Recycling leads to rise economic contribution to the municipality, especially in the quality of cleaning.
- Reducing the amount of waste to be collected every day is no need to collect recyclable waste every day, provide more progressive collection of these waste.
- Prevented the use of valuable land in the city as dump place. Fewer garbage, wrap around floating in less point, which means less obnoxious odors point.

Recycling and Environment

It is also important to reuse materials as raw materials for preventing environmental pollution. Recycling papers reduces the air pollution by around 74-94%, water pollution by 35%, water using 45%. It is possible to prevent cutting 8 trees with reusing 1 ton paper.

Simply recycling metal and glass could reduce the total cost of waste disposal by 66%, and save 147 kg of carbon emission per thousand cases. In 2009–2010, 9.7 million surgical interventions or procedures were performed; extrapolating our figures gives a sense of the annual potential for savings nationwide: approximately £1 million and 1350 tons of carbon (NHS, 2010)

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

It could be argued that the U.S. environmental movement started with recycling. For old-school environmentalists, recycling is such an integral part of the movement that it's difficult to separate the two. And in those early days, back in the 1980s, the cause was noble and pure: Why throw away products that could be new again? Why not turn trash into raw materials?

At a certain point, though, recycling developed something of a dark side from an environmental perspective. On the surface, it's still a good idea both to recycle waste and to design products and packaging with the idea of recycling them in a closed loop. Unfortunately, in its modern-day incarnation, recycling has also given the manufacturers of disposable items a way to essentially market overconsumption as environmentalism. Every year, reports come out touting rising recycling rates and neglecting to mention the soaring consumption that goes along with them.

Trade groups representing different packaging interests–plastic, paper, glass–have become the largest proponents and financial sponsors of recycling. If you go to the Environmental Protection Agency's website looking for statistics on packaging recycling, the stats on plastics recycling come from the American Plastics Council and the Society of the Plastics Industries, Inc. (SPI), both trade associations representing the plastics industry.

The plastics industry's interest in recycling is two-fold of course–on the one hand, by supporting recycling and helping to establish infrastructure for plastic recycling, the industry ensures a steady supply of new materials. On the other hand, it aids consumer to justify the consumption of more disposable plastic goods and packaged items if they can comfort themselves with the idea that whatever they throw in the bin will be recycled.

The thing is, recycling isn't the small operation it once was, it's a commodity business that fluctuates with supply and demand. It's also a global market, with recyclables collected in the United States being shipped to wherever demand is highest (often China). A few years ago, when demand for recycled paper products dropped, recyclers all over the country where warehousing stacks of cardboard, waiting for the prices to turn around. "The hope is that eventually the markets turn around and that the material is sold, but I have heard of instances where it gets landfilled, because a community doesn't have the demand or the space or the company to deal with it," says Gene Jones, executive director of Southern Waste Information Exchange - a nonprofit center for information about recycling waste.

Moreover, not everything that's "recyclable" actually gets recycled. Even when you're dealing with easily recycled items like PET or HDPE plastic (the plastics commonly used for bottles), or glass or cardboard, first you've got to get consumers to dispose of the items properly, then you've got to have a collection system in place (just over half of U.S. cities have curbside recycling, keep in mind), and then recyclers typically need to have a buyer lined up to justify recycling anything (Uzir, A. et al., 2014)

Roughly 40 million metric tons of electronic waste(e-waste) are produced globally each year, and about 13 percent of that weight is recycled mostly in developing countries. About 9 million tons of this waste - discarded televisions, computers, cellphones, and other electronics - are produced by the European Union, according to the United Nations Environment Programme (UNEP). And UNEP notes that this estimate of waste is likely too low. Informal recycling markets in China, India, Pakistan, Vietnam, and the Philippines handle anywhere from 50 percent to 80 percent of this e-waste, often shredding, burning, and dismantling the products in "backyards." Emissions from these recycling practices are damaging human health and the environment (UNEP, 2005).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

"Developing countries with rapidly growing economies handle e-waste from developed countries, and from their own internal consumers. Currently, an estimated 70 percent of e-waste handled in India is from other nations, but the UNEP estimates that between 2007 and 2020, domestic television e-waste will double, computer e-waste will increase five times, and cell phones 18 times" says Lucy McAllister. She is a Ph.D. candidate in environmental studies at the University of Colorado Boulder.

The informal sector's recycling practices magnify health risks. For example, primary and secondary exposure to toxic metals, such as lead, results mainly from open-air burning used to retrieve valuable components such as gold. Combustion from burning e-waste creates fine particulate matter, which is linked to pulmonary and cardiovascular disease.

While the health implications of e-waste are difficult to isolate due to the informal working conditions, poverty, and poor sanitation, several studies in Guiyu, a city in southeastern China, offer insight. Guiyu is known as the largest e-waste recycling site in the world, and the city's residents exhibit substantial digestive, neurological, respiratory, and bone problems. For example, 80 percent of Guiyu's children experience respiratory ailments, and are especially at risk of lead poisoning (Leung et al., 2008).

Residents of Guiyu are not the only ones at risk. Researchers such as Brett Robinson, a professor of soil and physical sciences at Lincoln University in New Zealand, warn that wind patterns in Southeast China disperse toxic particles released by open-air burning across the Pearl River Delta Region, home to 45 million people (Robinson, 2009). In this way, toxic chemicals from e-waste enter the "soil-crop-food pathway," one of the most significant routes for heavy metals' exposure to humans. These chemicals are not biodegradable, they persist in the environment for long periods of time, increasing exposure risk.

The Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and Their Disposal bans the exchange of hazardous waste, including e-waste, between developed and developing countries. The United States is the largest generator of e-waste worldwide and the only industrialized nation not yet ratifying the Basel Convention.

E-waste is an important global environmental and health issue. Promising policy responses have arisen from the European Union, which is defining the source as responsible for e-waste. With this approach, manufacturers are required to eliminate dangerous toxins from production.

Types of Recycling Products

1. **Aluminum:** There may be a symbol, such as an alu mark, on the product to indicate what metal it is made from. Drink cans are usually made from aluminium and food cans are usually made from steel. Aluminum cans are 100 percent recyclable and can also be recycled over and over again. Even better, turning recycled cans into new cans takes 95 percent less energy than making brand-new ones.
2. **Steel:** Steel is also another metal which can be recycled, and you can separate steel from aluminum with a magnet. Just like aluminum, steel products can be recycled over again without compromising the quality of the steel. More than 80 million tons of steel are recycled each year in North America, and recycling steel saves the equivalent energy to power 18 million households a year. Aluminium metal is non-magnetic whereas steel is magnetic. Food cans are mainly made from steel. You have to be sure that drink and food cans are clean before recycling. Aerosol containers can also be recycled, but only when they are completely empty.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

3. **PET Plastic Bottles:** There are about 50 different types of plastic. Pet bottles are the most used ones. Americans buy about 25 billion single-serving bottles of water each year, according to the Container Recycling Institute. Worse yet, about 80 percent of those bottles will end up in a landfill. Making plastic out of recycled resources uses about two-thirds less energy than making new plastic. And because plastic bottles, more than any other type of plastic, are the most commonly used type, they are usually the easiest to recycle. HDPE is another type of plastic which stands for high-density polyethylene, a common and more intense plastic, which is used for detergents, bleach, shampoo, milk jugs. This type of plastic is also used in household daily life and should be recycled.
4. **Glass:** Glass is separated into 3 colors: green, brown and clear. Besides recycling reusing is another method for glass. You can reuse glass whenever possible. Jars can be used as small containers and bottles can be used as vases. Recycled glass saves 50 percent energy versus virgin glass, and recycling just one glass container saves enough energy to light a 100-watt bulb for four hours. Recycled glass generates 20 percent less air pollution and 50 percent less water pollution, and one ton of glass made from 50 percent recycled materials saves 250 pounds of mining waste.
5. **Paper:** Paper is separated into the following groups: magazines, newspapers, office paper, cardboard, phone directories. Besides recycling, you can reduce paper waste by cancelling unwanted deliveries, or read news online as opposed to buying newspapers. Also you can reuse paper around the home as scrap paper or packing material. Envelopes can also be reused. According to the Environmental Protection Agency, paper makes up about one-third of the all the municipal waste stream in the U.S. That's a whole lot of paper, and since we know that recycling all that paper conserves resources, saves energy, and doesn't clog up the landfills, there's no reason not to do it. Buying recycled paper whenever possible is another way for recycling paper. On the other hand, there are so many reasons to recycle all kinds of paper that it makes no sense not to. First, recycled paper saves 60 percent of energy versus virgin paper, and also generates 95 percent less air pollution. Recycling one ton of paper saves 17 trees and 7,000 gallons of water. Sadly, though, every year Americans throw away enough paper to make a 12-foot wall from New York to California.
6. **Batteries:** All waste batteries are classified as hazardous waste and recycling is always the best option. Ordinary household batteries do contain some hazardous chemicals so ideally should not be thrown out with the day to day rubbish. Rechargeable batteries contain harmful metals, so should never be thrown away with daily rubbish, they should be returned to manufacturer for disposal or recycled elsewhere. Ordinary batteries require a lot of energy to make, so in order to save energy, use rechargeable batteries and electricity mains instead of ordinary batteries. Rechargeable batteries are the most environmentally friendly option as can last for up to several hundred charging cycles resulting in less waste being produced.
7. **Paint/Oil:** Waste such as paint, paintbrushes, car oil and oil filters have to be carefully disposed of, as they can be very damaging to the environment. Mostly, there are disposal or recycling instructions on the packaging of the product. Buying products in bulk whenever possible to reduce packaging waste and using eco-friendly alternatives whenever possible are important steps for recycling. It is crucial to recycle the engine oil correctly as even a small amount of oil can cause damage to the environment as well as making a noticeable mess.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

8. **Building Materials:** Buildings are made from many materials, many of which are recyclable such as metal, wood, glass, etc. Recycling these materials accordingly is an important environmental solution. Architectural salvage yards may take some items for reselling and many building materials can be reused, such as bricks and wood.
9. **Clinical Waste:** Clinical waste such as nappies, sanitary waste and medical supplies have the potential to be infectious so must be disposed of using special methods. Households as an environmentally conscious people should be very careful when disposing of needles and syringes and look for doctors or manufacturer instructions of how to dispose of medical waste on the packaging containers. Medicine containers can be recycled accordingly once it is empty. Many local municipalities offer free medical waste collection. Some companies are also currently implementing clinical waste treatment schemes and make money from recycling.
10. **Textiles:** Most home recycling bins, provided by your local council, accept old clothes and textiles. Recycling banks may also accept old clothes. Donating old clothes that are still usable to charity shops or take them to a jumble sale will help recycling. If they are unusable, then old clothes can be used to make other textile items, such as cushion covers or cleaning cloths.
11. **Corrugated Cardboard:** Old corrugated cardboard (OCC) represents a significant percentage of the commercial solid waste stream. In 1996, the U.S. generated 29 million tons of OCC, or 13.8% of municipal waste stream. Approximately 90% of that comes from the commercial or non-residential sector.
12. **Computers:** Electronic rubbish, and computer equipment in particular, is a rapidly expanding stream of UK waste. Low prices allow consumers to replace "gadgets" often, and rapid technological change means there are always newer, better, more powerful products on the market. The result is a burgeoning computer waste mountain. Up to 20 million "obsolete" PCs are discarded annually in the USA alone. Computers can be recycled in a couple of ways, depending on the state of the machine (Molland, 2014). Also known as e-waste, discarded computer equipment comprises monitors, printers, hard drives and circuit boards. Such items should on no account be thrown out with your household rubbish because they contain toxic substances, and are effectively hazardous waste. E-waste often ends up in the developing world, and the UN's Environment Program is alarmed by the amount of electronic goods which is improperly disposed of overseas. There is increasing concern about the pollution caused by hazardous chemicals and heavy metals in Africa, Asia and South America. A single computer can contain up to 2kg of lead, and the complex mixture of materials make PCs very difficult to recycle. Increasingly, manufacturers of electronic goods incorporate e-waste management into their environmental policies and operate consumer recycling schemes. Dell, for example, covers the cost of home pick-up, shipping to the recycling centre, and recycling of any obsolete equipment. The goods are "de-manufactured", and sorted according to type or material. Materials like steel and aluminum are then re-cycled to make new products, from car parts to plastic toys. Meanwhile non-reusable substances are disposed of in an environmentally sound manner. Another big brand, Hewlett Packard, recycled over 74 million kilograms of electronics in 2005. Since beginning the program 20 years ago, HP has expanded recycling operations to more than 40 world regions. Another option is donating old computers to non-profit organizations. A number of non-profit organisations collect electronic equipment including computers and printers, either for reuse or for de-manufacture and recycling. Recipients pay nothing for the equipment or buy it at a heavily discounted rate. Developing countries benefit most from these schemes.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

13. **Printing Cartridges:** Recycling printer cartridges really is worthwhile as cartridges can be expensive and remanufactured printer cartridges can cost as little as 10% of what original cartridges do. By lessening the amount of cartridges ending up in landfill sites, you are being kinder to the environment too. 24 million homes in the UK have a personal computer and 90% of those homes have printers. The average household uses 2-3 inkjet cartridges a year and many offices use large numbers of laser cartridges. Only 15% of the 65 million printer cartridges that are sold in the UK are recycled which means the rest end up in landfill sites and this is major bad news as the plastic used in a typical cartridge is made of engineering grade polymers and is expected to take up to 1000 years to decompose.
14. **Mobile Phones:** Most people in the developed and developing countries now own a mobile phone and they can be recycled. The first way is donating old mobile phones to friends or family. Another option may be taking back old mobile phones to manufacturers for recycling, because some companies have set up mobile phone recycling schemes.
15. **Composting:** Composting is the decomposition of materials that originated from animals and plants. These organic materials can be things such as plant trimmings, vegetable cuttings, eggshells and teabags. The composting process produces a dark, crumbly matter that can be used as fertilizer in garden soil. Composting is an excellent way to recycle kitchen and garden waste. It is very easy to build your own compost bin and use the compost to help your garden grow.
16. **Vehicles:** Up to 80% of a vehicle can be recycled, first for a more green world try and fix your vehicle instead of throwing it away, but if you want to buy a new one, then sell unwanted vehicles instead leaving them to rot.
17. **Electrical Equipment:** Most electrical equipment can be reused or broken down into parts. If the electrical equipment is still in full working order, to help the environment, sell it in a car boot sale or donate it to a charity shop. Some retailers may take back old products to recycle. Also, some councils accept electrical equipment at their waste recycling centers. Always trying to repair items rather than throwing them away will be a better option, which will allow others to find a use for the item, when you no longer want it. Choosing electrical items that have a long life span will also help environment.
18. **Furniture and Wood:** Wood can often be reused to make other items, such as a bird table for garden. Recycled wood can be used to produce unique eco-friendly furniture. Recycling old or damaged pallets prevents unnecessary landfill and reduces the need to chop down trees for new wood to make new pallets. Donating usable furniture to charity shops, schools, community centers, friends or neighbors or selling furniture at garage sales or in auctions is another option. Clean and repair broken furniture before you sell/donate it.
19. **E-Waste:** The useful life of consumer electronic devices is relatively short, and decreasing as a result of rapid changes in equipment features and capabilities. This creates a large waste stream of obsolete electronic equipment, electronic waste (e-waste). Even though there are conventional disposal methods for e-waste, these methods have disadvantages from both the economic and environmental viewpoints. As a result, new e-waste management options need to be considered, for example, recycling. But electronic recycling has a short history, so there is not yet a solid infrastructure in place. (Kang, 2005)

Aluminum

The industrial-scale production and use of aluminum is less than 150 years old. Yet in that time, the industry has grown until it is second only to the iron and steel industry among metal producers. The growth in aluminum usage was particularly rapid in the years following World War 2, and every sector of the industry can point to product that were never produce from aluminum a generation ago but are now primarily manufactured from aluminum alloy. Beverage cans, sports equipment, electrical bus work, window frames-all are now produced from aluminum, along with thousands of other product.

Books on the production of aluminum metal have previously focused on its recovery from naturally occurring raw materials. The principle natural ore for aluminum is bauxite, a mineral consisting primarily of hydrated aluminum oxides. Aluminum is recovered from bauxite by a selective leaching sequence known as Bayer process (Damgaard et al., 2009; OECD, 2010), which solves most of the aluminum while leaving impurities behind. The aluminum recovered from the leach solution by precipitating it as aluminum hydroxide. The hydroxide is the dried and calcined to generate purified alumina. The calcined alumina as in turn fed to electrolytic cells containing a molten salt electrolyte based on cryolite (Na3AIF6). The alumina this solves in the cryolite electrolyzed to generate molten aluminum metal and carbon dioxide gas. These process has been the sole approach for producing primary aluminum metal since the late 1800s and will likely continue in this role for decades to come (Schlesinger, 2013).

History of Aluminum Recycling

According to Mark A. Schlesinger from Yale, the successful recycling aluminum depends on several factors:

- A plentiful and recurring supply of the metal, concentrated sufficiently in one area to justify the cost of collecting it.
- An infrastructure for collecting the scrap metal, removing impurities, and delivering it to a recycling facility.
- A method for recycling metal that is economically competitive with the production of the metal from natural ores.
- A market for the recycled metal, should its composition or quality differ from that of primary metal.

Aluminum is recycled because it is inexpensive to turn into new aluminum products and because making new aluminum is expensive. On the other hand, it is not logical to recycle all the materials. For example, steel is much cheaper to produce from raw materials, so there is less reason to recycle it – although it can easily be recycled.

Aluminum is recycled through a variety of programs. The most generally recognized consumer programs are curbside and municipal. In these programs, items like beverage cans, aluminum foil, aluminum baking trays and pie pans are recycled. The aluminum industry actively supports the Curbside Value Partnership, which is a program dedicated to increasing participation in curbside recycling programs and to measure this growth using solid data. Within the industry, building and automotive parts are collected

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

for recycling. More than 90 percent of the aluminum in building and automotive parts is recycled at the end of use. All of these items serve as a feedstock and are sent to aluminum recyclers to be melted down in the secondary production process.

Aluminum is one of the most recycled - and most recyclable - materials on the market nowadays. Nearly 75 percent of all aluminum produced in the U.S. is still in use today. Aluminum can be recycled over and over again without any loss to quality. In fact, an aluminum beverage container can be recycled and back on the shelf in 60 days.

The economics of aluminum also contributes to its position as one of the most-recycled metals in the U.S. Unlike many other materials, aluminum pays more than for its own recycling in the consumer and industrial waste stream. The reason: demand for aluminum continues to skyrocket and recycling aluminum saves more than 90 percent of the energy required versus producing new metal.

Glass

Glass was an expensive material until the 1800s when the mass production of glass containers began. Today, the raw materials are more easily available so it is fairly cheap to make. Glass is made from three main ingredients; sand, soda ash and limestone. The ingredients are added together in a furnace and then heated until they melt. The molten glass is then poured into moulds or blown to make bottles or other containers. Glass making needs a source of heat, which is usually produced by burning fossil fuels (Morgan, 2009).

When it comes to reducing and reusing glass, there are ways of reducing the amount of glass needed. For example, modern bottles are much lighter than in the past and this saves on manufacturing and transport costs. Just 5 years ago a small beer bottle weighted 260 grams, but this has now been reduced, by almost a third, to 170 grams. Once a bottle has been used, it can either be reused or recycled. From an environmental point of view, it is much better to reuse a bottle than to recycle it. Less energy is used in the collection, cleaning and refilling of a bottle than is needed to recycle it.

During the 1950s and 1960s it was quite common to take bottles back to shops from where they would be collected and taken back to the factory. As the manufacturing plants became larger and began to supply bottles to further-away places, it became too costly to take the bottles back to the factory so this practice slowly died away. In some countries, milk is still delivered to some homes in glass bottles. The average milk bottle is used about twenty times.

In the developing world, reusing glass bottles is more common and soft drinks often come in glass bottles that are collected and returned to the factory. Clear glass containers such as jam jars are frequently reused in homes for jam making and pickling amongst other things. However, a bottle or jar that is to be collected from homes or shops and reused many times has to be made from heavier, thicker glass, in order to withstand wear and tear. Because of this, more glass is used in its manufacture and more energy in its transportation. There are also additional costs of collection, transportation and cleaning (Go Facts Environmental Issues, 2006).

The great thing about glass is that it can be recycled very easily, and this can happen over and over again without any loss of quality. It was the first material to be progressively recycled and nowadays a large percentage of all glass is recycled. For example, in Finland and Switzerland, as much as 90 per cent of glass is recycled. Glass collected from factories and bottle banks is taken to recycling plants where it is monitored for purity –that is if it is all the same color with no foil or caps- and crushed to make cullet. Then the cullet is mixed in with the other raw materials and melted (Morgan, 2009).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Another glass recycling type is CRT (cathode ray tube) glass waste. It includes the parts from TVs, PC monitors and other monitors used in special applications, and waste from the original assembly process. According to European Waste Catalogue and United States Environmental Protection Agency (EPA) CRTs are classified as hazardous household waste (Maschio et al., 2013).

Recycling Criticisms

Recycling is gaining increased acceptance worldwide, but not everyone agrees that it's the best way to deal with the environmental problems of garbage. There are several criticisms of recycling. Criticisms concerning the cost of recycling are mostly related to lack of market competition. (Tasaki, 2005)

The process of recycling an old product into something reusable uses energy and creates pollution. Critics claim that recycling is simply a zero-sum game, where the pollutants and waste from making new goods shift into the recycling industry. For some types of recycling, this may be true -- the trade-off between new products and some forms of recycled plastic, for example, are questionable. Nevertheless, there are at least as many ways to recycle that offer clear benefits in terms of energy used, natural resources consumed, pollutants released and landfill space used. There are those, though, who believe that recovering energy by incinerating waste is better, by and large, than recycling it. The Institute of Mechanical Engineers, for example, has recently urged the government to invest in heating and energy projects with local waste being used as the fuel resource, much like the schemes found in countries such as Germany and Austria. "The government should abandon its focus on recycling as the only way to rid us of landfills," it says, "as this is quite unachievable and is clearly deceiving the public about what is really happening to their waste. Recycling should only be for waste products that cannot be more sustainably converted into electricity, heat and/or transport fuels." Adam Read, a former professor of waste management at Northampton University, believes that the industry is still in the foothills when it comes to understanding the full environmental implications of each form of waste treatment. "We certainly need to understand our waste-flow better," he says. "We need a better grasp of the calorific values, water content, market values and the like of each waste source before pushing ahead. Yes, it sometimes will be more economical to burn waste, but the environmental impact is always going to be less when recycling. However, incineration will always be better environmentally than landfill because of the methane generated when organic waste rots underground."

Some claim that there's no "garbage crisis." They say there's plenty of landfill space - landfills are a safe and simple way to store as much garbage as we need to put there (EcoWorld). It's true that there's technically plenty of space in the United States and other countries in which to store our garbage, but the thought of filling valleys and fields with garbage doesn't appeal to many people, and certainly not those who live near those valleys and fields.

This criticism closely ties to the problem of recycling causing its own environmental impact. Because of this impact, recycling only represents a minor improvement over landfills or incineration of garbage. Yet, it makes people feel like they've accomplished something important in protecting the environment. Recycling can also enable an attitude of entitled consumerism - people feel that it's OK to purchase and use environmentally harmful products like bottled water or plastic diapers because they make up for it by recycling. These views point to the ultimate solution: buy less stuff. Purchasing reusable goods or simply buying fewer things we don't need is the best way to stop the garbage stream at the source (Grabianowski, 2015). Recycling is not the only way of thinking green. Reducing or reusing is also important concepts to be environmentally conscious.

CONCLUSION

This chapter briefly talks about recycling, types of recycling and examines two important recycling materials, aluminum and glass in details. Recycling is the process of making or manufacturing new products from a product that has originally served its purpose. If these used products are disposed of in an appropriate, environmentally friendly way, the process of recycling has been set in motion. A large section of the community is beginning to realize the importance of recycling. However, there are many members of the population that remain unaware or simply think it is too much of a bother.

On the other hand, it is obvious that the world has limited resources and they are finite. Recycling, reusing or reducing are all increasing the potential of the world resources. This chapter covered all materials that an informed layman and consumer should be aware of regarding most commonly known recyclable materials. We also discussed some materials that are not widely known to be recyclable. There should be special attention given to materials that bring high savings when recycled which include glass and aluminum, and they are explained in this chapter.

Recycling, just as any other business concept, is also related with supply and demand concepts. The thing is, recycling isn't the small operation it once was, it's a commodity business that fluctuates with supply and demand. It's also a global market, with recyclables collected in the United States being shipped to wherever demand is highest (often China). Nowadays, there are many companies making high profits by integrating their business model, accordingly with recycling.

Green is not only a color anymore, it is a symbol for the environmental consciousness. Furthermore, recycling is highly related with environment and has a great importance. There are many ways for recycling. It is also important to reuse materials as raw materials for preventing environmental pollution. Recycling papers reduces the air pollution by around 74-94%, water pollution by 35%, water using 45%. It is possible to prevent cutting 8 trees with reusing 1 ton paper. Simply recycling metal and glass could reduce the total cost of waste disposal by 66%, and save 147 kg of carbon emission per thousand cases.

Thinking about recycling is not enough, action is required for a better world. Moreover, not everything that's "recyclable" actually gets recycled. As we mentioned, even when you're dealing with easily recycled items like PET or HDPE plastic, or glass or cardboard, first you've got to get consumers to dispose of the items properly, then you've got to have a collection system in place, and then recyclers typically need to have a buyer lined up to justify recycling anything (Uzir, A. et al., 2014) Roughly 40 million metric tons of electronic waste(e-waste) are produced globally each year, and about 13 percent of that weight is recycled mostly in developing countries. About 9 million tons of this waste - discarded televisions, computers, cellphones, and other electronics - are produced by the European Union, according to the United Nations Environment Programme (UNEP). And UNEP notes that this estimate of waste is likely too low. Although, recycling has high efficiency rates in some products, low collection and recycling rates decreases the ultimate report results.

Aluminum and Glass are the two important recycling products examined in this chapter. Aluminum is recycled because it is inexpensive to turn into new aluminum products and because making new aluminum is expensive. Aluminum is recycled through a variety of programs. The most generally recognized consumer programs are curbside and municipal. In these programs, items like beverage cans, aluminum foil, aluminum baking trays and pie pans are recycled. Aluminum is one of the most recycled - and most recyclable - materials on the market nowadays. Nearly 75 percent of all aluminum produced in the U.S. is still in use today. Aluminum can be recycled over and over again without any loss to quality. In fact,

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

an aluminum beverage container can be recycled and back on the shelf in 60 days. These advantages make the aluminum product example of this chapter.

On the other hand, Glass was an expensive material until the 1800s when the mass production of glass containers began. Today, the raw materials are more easily available so it is fairly cheap to make. When it comes to reducing and reusing glass, there are ways of reducing the amount of glass needed. Once a bottle has been used, it can either be reused or recycled. From an environmental point of view, it is much better to reuse a bottle than to recycle it. Less energy is used in the collection, cleaning and refilling of a bottle than is needed to recycle it.

Like every concept in the world literature, recycling is also having criticisms, but these criticisms are much less than its advantages. Importance of recycling may change from one country to another, but nobody can argue that it is a useless activity. For a better environment and green future, recycling is a mandatory process.

KEY TERMS AND DEFINITIONS

Composting: The decomposition of materials that originated from animals and plants.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Quality Standards: Concise sets of prioritized statements designed to drive measurable quality improvements within a particular area of health or care.

Recyclable Products: The products that can be efficiently and effectively reused after serving its purpose.

Solid Waste: Any discarded or abandoned materials. Solid wastes can be solid, liquid, semi-solid or containerized gaseous material.

UNEP: The United Nations Environment Programme (UNEP) is the leading global environmental authority that sets the global environmental agenda, promotes the coherent implementation of the environmental dimension of sustainable development within the United Nations system and serves as an authoritative advocate for the global environment.

Waste Hierarchy: The evaluation of processes that protect the environment alongside resource and energy consumption to most favorable to least favorable actions.

Waste Reduction: The minimization of waste at its source to minimize the quantity required to be treated and disposed of, achieved usually through better product design and/or process management. Also called waste minimization.

Chapter 41
Sustainable Environmental Service – Knowledge Management:
A Case of Bangkok MSW Management

Pitchayanin Sukholthaman
Japan Advanced Institute of Science and Technology (JAIST), Japan

Kunio Shirahada
Japan Advanced Institute of Science and Technology (JAIST), Japan

ABSTRACT

Knowledge management (KM) is a key factor to increase effectiveness of management system. There have been researches of KM on many environmental services. Unfortunately, only a few researches have focused on sustainable service for Municipal Solid Waste (MSW). There are evidences of ineffective waste management causing socio-economic and environmental problems, especially in urban areas of developing countries. Humans live in service economy and knowledge society. Waste management is one of the most important public services that all residents should receive while knowledge is needed to make service run smoothly and sustainably. This paper combines concepts of sustainable service and KM to clarify the importance and how these concepts have impacts on societal well-being. Literature reviews and questionnaire surveys are main analysis methods of this paper. Sustainable service with KM roles will be described and co-created values are identified.

INTRODUCTION

Waste has become one of the most important concerns of cities all over the world. It does not only cause socio-economic impacts, but also more vitally environmental problems. Although there has been a wide attention given to make waste management system more effective, there are many obstacles causing the system faraway from accomplishment. There are evidences that socio-economic and environmental

problems are harmfully caused by ineffective waste management, especially in urban areas of developing countries, such as odor, leftover waste, or air pollution (Pires, 2011). Having an effective waste management is difficult; however, it is possible. The current ineffective municipal solid waste management (MSWM) is caused by many factors. A very important reason leading to performance of MSWM system is staff's knowledge and related stakeholders applied to each process of management system. It has been evidenced that in some processes, waste management staff do not technically know how to use machines whereas residents would like to be educated of suitable household waste management methods or how to sort waste for disposal correctly.

It is undeniable that humans live in service economy and at the same time in knowledge society. In service sector, environmental service has gained much recognition in recent years especially on a Payments for Environmental Service (PES) perspective (Kumar, 2013; Legrand et al., 2013). PES has rapidly developed all over the world. It is a mechanism of a new type of subsidy objects to protect the environment and ecosystem services based on provision of economic incentive. PES is considered as a new market-based initiative for conservation and environmental management (Fauzi & Anna, 2013). It encompasses a diversity of mechanisms ranging from voluntary compensation to non-voluntary one.

Unfortunately, there have been only a few studies related to municipal solid waste management (MSW). In those studies, PES was widely used in many applications; however, in MSWM, it was used in economical prospect such as willingness to pay for improving waste collection service, which finally contributes to a better waste management system or a public-private partnership for waste management system incentive. Despite the fact that PES schemes can improve waste collection service in some cases, it is insufficient to say that economic based incentive system can be applied to all cities, especially in developing ones. Thus, it is important to find alternative methods to increase the effectiveness of MSWM system, which this paper emphasizes on roles of KM that will eventually lead to value co-creation for a better society well-being.

Waste management is one of the most important basic public services that all residents should receive. Knowledge, in the same way, is needed to make service run smoothly, consistently, reliably, and sustainably. Every process of waste management needs different types of knowledge and different ways to exploit the knowledge. Thus a good management of knowledge is very essential for a successful waste management. The importance of effective KM has increasingly been recognized in both business viewpoint (Deng, 2010; An et al., 2013) and academic viewpoint (Nonaka & Takeuchi 1995). Knowledge is a form of capital where the main competitive advantage is an intangible asset in all types of organizations. In the past decades research on KM is fragmented across industries. Many factors are important to KM, for example, KM strategies (Shin & Chou, 2012), KM processes (Grover & Davenport, 2001), or KM enablers (Choi & Lee, 2002). On a perspective of MSWM, KM is needed in all processes. Since each process requires different knowledge to effectively manage waste, this is one of the most vital factors showing the performance of MSWM system. Moreover, to emphasize its importance, knowledge transfer and knowledge sharing are factors that should be taken into account to KM in order to avoid occurrence of knowledge gap and hidden knowledge.

As mentioned earlier, MSWM is a basic public service. It is in need that provided service should be sustainable and affordable by community. Applying a concept of sustainable environmental service is a key to increase performance of MSWM system in long-term. The concept of service sustainability is to satisfy the need of current providers and recipients to practice mutual value co-creation without decreasing the quality of future value co-creation. In other words, the provided service should meet society needs, conform to standards, and most importantly cause no harmful impacts to society, economy and the environment.

This paper combines the two very important concepts which are sustainably environmental service and KM to clarify the importance and how these concepts have impacts on society well-being in a case of an environmental service perspective. In each process of MSWM, roles of knowledge are explained. MSWM in Bangkok is an example case of the environmental service. This paper describes how sustainable service with KM has roles on MSWM system and finally identifies what co-created values contribute to better provision of waste management system for a better society as a whole. In literature review section, situation of MSWM in Bangkok and roles of KM on waste management are explained. Methodology section discusses about methodology of conducting research and comprises of primary and secondary data collection and analysis. About the results, this section explains what and how results are by focusing on roles of KM for each process of waste management and co-created values when KM plays an important role. Discussion section describes implications of MSWM by applying KM concept.

LITERATURE REVIEW

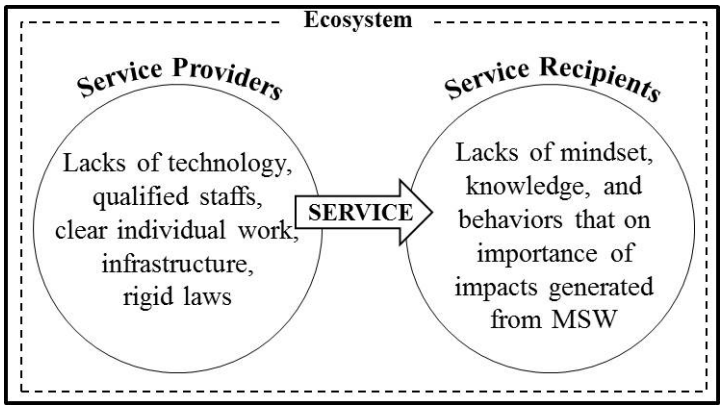
An Overview of Bangkok Municipal Solid Waste Management

MSW is one of the anthropogenic natural results. Gradually accumulated, the enormous amount of waste has caused tremendous adverse impacts to the world. In developing countries, the impacts are more severe as lacks of effective management system. Not only do poorly managed waste streams generate a vast amount of MSW, but also MSW causes a remarkable environmental pollution that exposes risks to mankind's health (Batool & Chuadhry, 2009). As mentioned earlier, Bangkok, the most condensed and fastest growing city in Thailand is chosen as a representative of an urban city in developing countries that has coped with MSW related problems. Factors that obstruct effectiveness of MSWM are vast amount of generated waste, improper waste collection and transportation, and lack of collaboration among stakeholders. The successfulness of the MSWM system highly depends on effectiveness of management processes. Unfortunately, MSWM system in many developing countries is relatively ineffective despite of a relatively high proportion of budget spent. This causes an incomplete long-term planning which eventually impacts the effectiveness of the whole system (Dyson & Chang, 2005).

Bangkok, the capital city of Thailand, has continuously witnessed accumulating MSW management problems. Both economic development and the rapid growth of population increase sharply from 48 million in 1982 to 65 million in 2012 as they really enlarge MSW generation in Thailand. As of December 2012, population in Bangkok was 5,673,560, which was about 9% of the total population in Thailand (DOPA, 2012). Due to the growth of population and economic, the amount of collected MSW has rapidly increased from 8,988 tons a day to 9,748 tons a day in 2000 and 2013 respectively (PCD, 2011; BMA, 2012). In other words, on a 3-year average MSW has increased 4.31%. As a result, this generation amount represents 21% of the country total waste generation (PCD, 2011). Bangkok Metropolitan Administration (BMA) is responsible for city management and well-being of Bangkok residents. BMA has recognized the increasing problems related to MSW and its management. Therefore, BMA has been trying to alleviate and solve the problems by having a long-term plan and policies and launching MSWM schemes. BMA has spent an amount of budget trying to make the MSWM system effective and draw public participation. Unfortunately, the attempt has not successfully been implemented due to many obstacles which can be categorized into parties as service providers, service recipients and ecosystem based on a tripartite service concept (Shirahada & Fisk, 2013). No co-created value occurs even though

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 1. Ineffective waste management with no value co-creation



the tripartite concept aims to show co-created values created by resource integration among parties, due to the ineffective management system. The following demonstration shows an unsuccessful MSWM system as there are no interactions among service providers and recipients.

Bangkok MSWM is in need for involvement of related parties to have effective MSWM collaboration. The collaboration is based on an integrated MSWM that suits the city characteristics, works well with residents, conforms to standards and laws, provides economic benefits, and is environmentally friendly to the society.

Waste is defined as any residual materials from industrial and human activities and has no residual value (Ortiz et al., 2010). According to the Thailand Public Health Act 1992, MSW includes waste from community activities generated from residential households, commercial and business establishments, fresh markets, institutional facilities, and construction and demolition activities, excluding industrial waste. In Bangkok, there are four types of waste namely organic waste, general waste, recyclable waste, and hazardous waste (DEQP, 2011; DOE, 2013).

Department of Public Cleansing (DPC) and fifty Bangkok district offices are responsible for cleansing the city. MSW is collected from receptacles in front of houses, buildings, or designated locations on the specific dates and times. After being collected, waste is transported to three waste transfer stations located in three different city borders which are, Sai Mai, On Nut, and Nong Khaem. Then collected waste is put into trailer trucks by contracted private companies to be landfilled in two landfill sites in neighboring provinces, Nakon Pathom and Chachoengsao.

Ninety percent of the collected MSW is managed by disposing in sanitary landfills and 10% of the rest is composted (PCD, 2011; DOE, 2012). Waste composition is different based on economic growth, people behavior, and activities (Ogwueleka, 2013). However, MSW in Bangkok is homogenous in every district. Figure 2 demonstrates the composition of waste at transfer stations (Jungrungrueng, 2014).

MSW is one of the five critical issues of Bangkok, BMA's targets aim at having sustainable MSWM to reduce environmental impacts and global warming in Bangkok (Jungrungrueng, 2014). To achieve the targets, BMA organizes projects, for example, solid waste management at sources and community based solid waste management, these projects have been applied to promote public participation to create mutual benefits between communities and BMA in waste reduction and increase yields of recyclable materials from being contaminated.

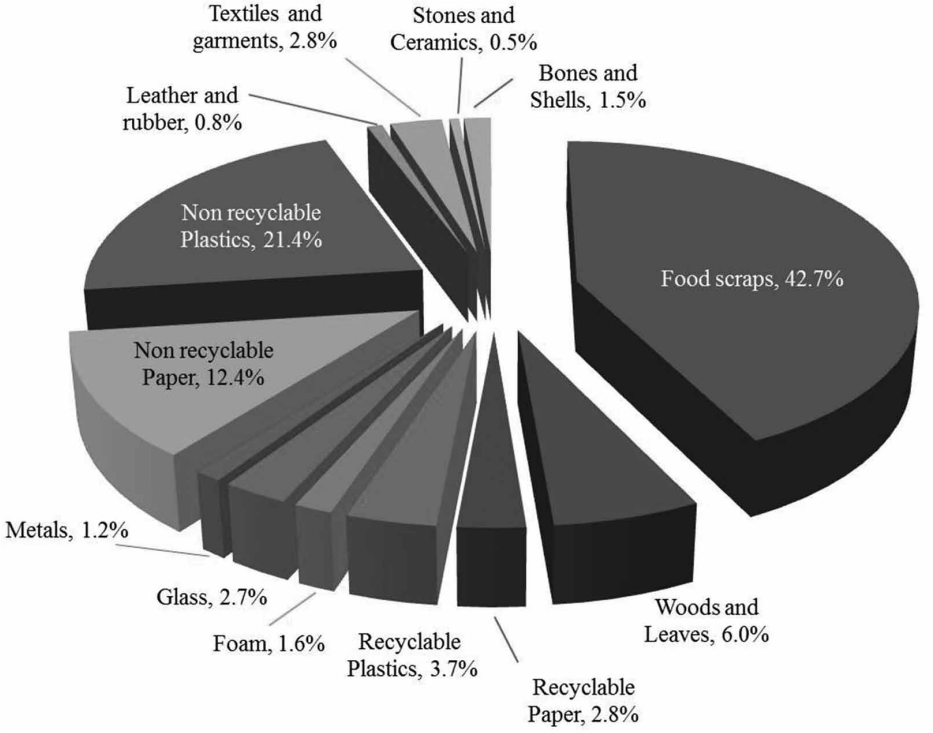
Figure 2. Waste composition at transfer stations in 2012



Municipal Solid Waste Management: An Environmental Service

According to the study of Garrod & Willis (1998), there are six functional elements of processes associated with MSWM, including waste generation, waste storage, waste collection, waste transfer, waste processing, and waste disposal. Re-categorizing those elements in terms of service recipients and providers, the first two elements are associated to waste generators which generally are the people who have demand for MSWM service. The latter four elements are more related to MSWM service providers, which is BMA in this case. However, all processes of MSWM should be received collaborative management from all related parties to create mutual benefits.

Although there have been many campaigns launched to encourage Bangkok residents to do waste reduction at source such as 3Rs programs and recycle bank programs, some of the programs were successfully implemented only for a short period. Reasons are because those programs were inconsistently promoted, lack of skills of residents, and mindset and behavior of people having less concern on the importance of the environment. Moreover, insufficient waste management infrastructure is another add-on factor that contributes to an inefficient MSWM. In other words, waste generation and waste storage are correctly done at some levels. In some cases, people do waste sorting but all sorted waste is mixed together when it is collected, this is because waste collecting trucks do not support to handle with different types of waste. In terms of waste storage, MSW is collected from the receptacles in front of houses, buildings, or designated locations on the specific dates and times. Unfortunately, in some area, people throw their waste into public places or do open air burning because of no waste management service in their areas.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

In the city environmental master plan, BMA has planned to have more waste transfer stations, but finding available lands to be transfer stations is not easy. Residents do not welcome and are not willing to live near waste dumping sites. For waste processing and disposal, there are two main concerns. First, diminishing landfill volume, the increasing generation of MSW is a major problem as there are signs of insufficient landfill capacities. The BMA has been unable to find a new land as a new landfill site. In the plan, there will be an incinerator with a pilot capacity of 300 tons per day and has expected to start operation in a few years. Second, it affects community and society, and the environment.

Waste collection policy states that all locations are to serve and make the city clean. Each district office gets support from the Department of Environment (DoE) in terms of machines, waste collection trucks, boats, and waste bins. The district offices collect waste based on the scheduled date, time, and location given by the BMA; and ensure of cleanliness that will be no leftover waste. All in all, Bangkok MSWM system seems to have all important infrastructures; however, looking into details of each process the infrastructure and resources do not suffice.

Knowledge Management on a Perspective of Waste Management

As aforementioned, KM has widely been recognized in both business and academic arrays. Having effective KM, it is important to be noted that knowledge transfer and knowledge sharing are important factors that propel created knowledge, which should be understood and accepted by all involved parties. Knowledge is a mix of framed experience, values, contextual information, and expert insights that provides a framework for evaluating and incorporating new experience and information (Davenport & Prusak, 1998).

Tacit and explicit knowledge are two types of knowledge having been suggested in Nonaka's work (Nonaka et. al., 1994). Tacit knowledge more or less related to personal knowledge. It is subjective and experienced based knowledge which cannot be expressed explicitly in words. It includes cognitive skills which are intuition, images or beliefs. On the other hand, explicit knowledge is easy to express in words. It is objective and rational knowledge. This type of knowledge includes theoretical approaches, databases, and problem solving. KM is a process of using knowledge to produce wealth for improving and developing organizations (Nonaka and Takeuchi, 1995). Moreover, it captures, develops, shares, and effectively uses organizational knowledge.

Transforming from one's tacit knowledge to be used as understandable explicit knowledge is a key for successful KM. Polanyi (1967) stated in his work that tacit knowledge is the fact that "we can know more than we can tell". He also emphasized the importance of dialogues among individuals to groups and finally to organizational levels (Polanyi, 1964). This is a way to share, transfer and transform personal tacit to explicit knowledge.

When it comes to reality, it is important that knowledge should be verified, justified, and accepted. Applying the KM concept to MSWM is a very new field of research. This paper focuses on roles of KM on each process of waste management. Before going into detail of those processes, it is inevitable to discuss about related actors in the provision of MSWM service. Starting from the very first to the last waste life cycle, MSW is generated by residents, collected by district offices, and processed and disposed of by BMA and designated companies. These four parties are main actors that directly contribute to the effectiveness of provided MSWM service. Indirect actors are also important to service performance. NGOs and private sectors act as a catalyst that makes MSWM system run correctly and transparently

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

(Heap, 1998). Above all, ecosystem is one of the most important actors acting as a service provider and a service recipient. The only difference of ecosystem among other actors is that ecosystem does not have explicit roles or activities. Instead of that, it is the source of raw materials that are produced, used, and discarded as waste. And it is the end of waste management process where all waste is disposed to.

Gap of knowledge usually happens among theories, practices, and employees in different levels. Hidden knowledge is also a form of knowledge gap when knowledge is kept individually. Other than that, it is treasure hidden in employees' minds (Greiner, 2007). As tacit knowledge is a key of personalization strategy, it is important to share this hidden tacit knowledge. Sharing hidden knowledge can be done by socialization or sharing and creating knowledge among related members. Socialization can be easily done by many communication channels, such as face-to-face interactions, video conferences, or meetings.

Knowledge sharing distributes knowledge among people in an organization. Sharing of knowledge encompasses various kinds of technologies ranges from simple ones to advanced ones. People and business practices represent organization cultures which are driving factors that determine the success or failure of KM. Knowledge sharing can be done by participation in social networks, informal meetings, or group works (Teigland & Wasko, 2003). Knowledge transfer is a mechanism of selective knowledge exchanges. Not everybody in the company needs to know everything at all times. Related stakeholders should be aware of knowledge exchange opportunities during working. Knowledge transfer needs to be worthwhile for all related parties by applying it into their activities (Krogh et al., 2001).

Applying KM concept to MSWM, in all processes of MSWM system, involved stakeholders are automated to facilitate collaboration and learning by conduction knowledge transfer and knowledge sharing. Ultimately, as an intelligent support, KM is to increase the effectiveness of MSWM system and at the same time to create a sustainable waste management service.

METHODOLOGY

Data Collection

Acquiring primary data was done by conducting questionnaire surveys, which key parts are shown in the Appendix. The surveys primarily aimed to find human aspects on KM and perspective on current provided waste management service. Conducted between December 2013 and January 2014, population frame of the surveys was 422 people in Jatujak district, selected from eight community types namely, communities, department stores, schools, universities, companies, temples, markets, hospitals and hotels (BMA, 2012; DEQP, 2011).

The survey sample size was calculated with a 95% confidence level using Yamane's simplified formula (Yamane, 1983). All 422 surveys were done by employing random sampling method which target respondents were waste generators whose age ranged from 16 to more than 60 years. All surveys were conducted by direct interviewing. Therefore, there were no missing data. Apart from the questionnaire surveys, ten experts from business, academic, and private sectors were interviewed by employing semi-structured and open-ended interview methods. Practical information on KM and implications to waste management service were given. In-depth information obtained from the interviews was transcribed and incorporated into other analyzes of this paper.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Besides, reliable data are crucial to have meaningful results which eventually are used in other researches or in Bangkok waste management system. Thus, data were collected mostly from government agencies, published journals, international databases managed by trustable organizations. Combining information from primary and secondary sources, results generated in this paper are more useful.

Data Analysis

The questionnaire consists of 105 queries from 20 questions. Out of these questions, the questionnaire is separated into four parts. The first part contains questions related to general information of respondents. The second part asks about household waste storage, disposal, and sorting behavior. The third part acquires information about human aspects on current waste management system and provided service. And for the fourth part, it relates to needed knowledge on waste management and values of applying KM concept. In this part, respondents freely expressed their opinion on waste management and what and how waste management system should be. Questions that were given to experts related to current situation of MSWM and how KM would affect the performance of waste management service. The interview aimed to obtain three topics of information which are roles of KM and how to lessen knowledge gap, impacts of KM on waste management, and their opinion on implications in combining two concepts – sustainable waste management service and KM.

All data from conducting questionnaire surveys were analyzed by a computer program which is SPSS Statistics version 17. Respondents' demographic profile and their concerns on MSWM provided service were analyzed by using descriptive statistics function, that allows precisely analyzed results by checking validity and computing univariate statistics. In terms of human aspects on needed knowledge for sustainable MSWM, a Likert five-point scale type was used for the answers, which were later grouped into the six MSWM processes. Based on these six processes, answers of aspects on value co-creation when applying KM concept are grouped and analyzed using descriptive statistics function.

Not only did questionnaire survey data obtain, but also the respondents gave insightful data while they were completing the questionnaire survey. The most useful data related to KM were data from respondents' knowledge and ideas on their aspects. Apart from quantitative data analysis, documentation, conceptualization, and examining relationships were analyzed qualitatively. Moreover, in the meantime during conducting questionnaire surveys and expert interviews, by observing surroundings and listening to what the respondents or experts spoke out, data were jotted down and recorded. After getting all required data, important factors, concepts, and relationships were identified. Examining these relationships of the concepts of KM and sustainable waste management service, personal tacit knowledge was categorized and transformed to a more understandable explicit knowledge (Adams et al., 2007).

All obtained data are analyzed and explained with mixed research methods. Increasing reliability of this paper, analyzed results are justified by theoretical support consisting of planned behavior theory, social exchange theory, and knowledge-based theory of the firm, which all details will be explained in discussion section. Moreover, practical implications of sustainable waste management service in MSWM system in Bangkok are explained which the implications were derived from the integration of quantitative SPSS data analysis and qualitative interview analysis.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

RESULTS

MSW generation shows an increasing trend parallel to the development of economic conditions, urbanization, and rapid growth of population (Beigl et al., 2008; Singh et al., 2011). MSW is a part of basic urban service and an imperative environmental service. Safe collection and disposal of MSW have been considered as one of the basic services gaining extensive attention from many countries especially developing ones (Seik, 1997). In this section, roles of KM on each process of MSWM are discussed and co-created values leading to sustainable waste management service are identified. Inefficient MSWM service has posed many serious challenges to responsible parties (BMA 2012; DOE, 2012). The significant reason causing inefficiencies is knowledge gap that should be disseminated to all related parties. Lack of proper knowledge transfer also impacts performance of MSWM. Therefore, to lessen the gap of knowledge and strengthen the quality of knowledge transfer, applying suitable KM strategies is needed. This paper provides those strategies based on analysis of human aspects.

Roles of Knowledge Management on Municipal Solid Waste Management

The results of questionnaire surveys show that there are 205 male and 217 female respondents. The majority of respondents have an average income of 10,001 to 20,000 baht or about $US300 to $US600. Average household size is 3 people per house. In terms of household waste management, 216 (51.2%) respondents do waste sorting. Putting waste in front of their houses for collection and putting waste in public waste bins are two main management methods as there are 96.7% of respondents doing these. Each household generates 1-3 kilograms of waste per day. In terms of attitudes on current waste management service, Table 1 below shows frequency results from all respondents. Table 2 shows concerns of waste management service and relationship of respondents' aspect on waste management performance and their concerns.

Table 2 shows that odor and leftover waste during collection process are the most two occurring problems that need to be urgently solved. These results go in line with information provided by Pollution Control Department (PCD). In 2013, there were 180 environmental pollution cases appealed, which 135 cases were problems related to MSW, odor, and hazardous waste (PCD, 2013). When asking about who should be major parties to be involved in MSWM for a better waste management system, majority of 368 respondents think that everyone from all sectors, including residents, NGOs, government, and private companies should be actors in the system. Almost 80% of all respondents are willing to join in waste management system for better management process.

In terms of KM, respondents think that knowledge on waste management should be consistently promoted to the public which refers to all residents, to schools which refers to lessons for students in a subject, to waste management providers which refers to direct and indirect staff. This aims mainly to

Table 1. Respondents' aspect on current performance of MSWM service

	Very good	Good	Acceptable	Bad	Very bad
Count	8	101	236	51	26
Percentage	1.9	23.9	55.9	12.1	6.2

Table 2. Residents' concerns on MSWM service

Performance level	Concerns				
	Not on time	Leftover waste	Falling waste	Odor	No service
Very good	3	2	3	1	0
Good	31	40	33	57	4
Acceptable	97	130	77	169	14
Bad	25	30	22	42	8
Unacceptable	9	14	9	20	6
Total	165	216	134	289	32

ensure that both service recipients and service providers are aware of risks and impacts that are generated by improper waste management and the importance of the ecosystem which human runs on them. Table 3 below summarizes important types of knowledge for waste management.

As shown in Table 3, there are thirteen types of knowledge that residents think the types are needed for having sustainable waste management. The checked signs show the importance of needed knowledge for each process of MSWM based on residents' knowledge. The residents state that there should be collaboration among all related stakeholders in each process along waste management chain. They

highlight that all staff should be trained to provide efficient service. An example case that happens in current MSWM in waste collection process is that people do waste sorting and put sorted waste into different bags. But once the waste is collected, staff mix all waste together and pick only materials that they consider valuable and put to big plastic bags. Those picked waste will later be sold to small recycle shops before mixed waste is dumped out at a transfer station. According to experts' insights, they suggest that waste management infrastructure be improved to be ready to support all types of waste. If all residents do waste sorting and waste collection trucks are fully equipped to support various types of waste collection, situation like the example case would not occur. Experts also comment that at each step of waste management, knowledge transfer and sharing are needed for effective KM.

Knowledge transfer can be done internally among service recipients or service providers, or externally between service recipients and providers or other indirect actors. All processes of waste management need knowledge transfer to lessen knowledge gaps. Some residents can transfer their knowledge on how to minimize waste generation by using reduce and reuse strategies. Staff in the same or different levels can train or suggest each other's knowledge to others in order to have the same knowledge leading to norm of waste management practice. Knowledge transfer can also be done when staff who are about to retire or move to another position. They should transfer their knowledge to new comers who are going to take their positions in the near future. Thus, knowledge transfer is a good and practical KM strategy that is beneficial to management of knowledge.

Knowledge sharing in waste management is practically done to give knowledge to a number of people (Piktialis & Greenes, 2007). It is a powerful way to prevent knowledge gap, as everyone receives the same information at the same time. Experts comment that knowledge sharing has been implemented in Bangkok MSWM but is not so successful. For example, demonstration of sorting waste had been done to encourage waste generators to sort their waste correctly. As time elapsed, this campaign was diminished. It can be easily seen in many places throughout Bangkok that waste is commonly discarded in all types of waste bins. Another knowledge sharing in MSWM is training, which applies to both service providers and recipients. Staff is trained to do correct waste collection and transportation procedures, whereas residents, mostly in community level, are trained to launch projects related to reduce waste generation amount and improve performance of waste management service. Community based waste management (CBM) is an example of the projects. Correct practices, procedures and important information are given by BMA. The same knowledge of creating a CBM project is shared to all residents. However, it is different when theories come into real practices. Staff still conducts same waste management practices. Only a number of CBM projects have successfully done.

Co-Created Values

A big concern for practically successful KM is ways to achieve an effective knowledge transfer and knowledge sharing. Avoiding hidden knowledge in waste management is a vital factor as it reveals out such knowledge. According to Polanyi's study, dialogues among individuals or groups lead to transferring and sharing of knowledge (Polanyi, 1964). When it comes to this question, residents respond that all processes should be transparent. They suggested that key waste management stakeholders be involved to create mutual waste management strategies which eventually provide mutual benefits.

Waste management infrastructure should be more ready to support increasing amount and types of waste. Laws should be more rigidly enforceable to ensure that everyone complies with laws. According to the interview, experts think that the most urgent problem is imperatively needed to find resolution for

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

a sustainable MSWM with suitable infrastructure. Dwivedy (2010) stated that successful implementation of waste management, other than less generation of MSW, requires the establishment of appropriate infrastructure. The other two factors contributing to the success of MSWM are practical policies and strategies to manage the system. Having a smoothly run system, effective laws should be enforced. The study of Roomratanapun shows that law enforcement is the third rank solution to solve waste management problems (Roomratanapun, 2001).

Effective knowledge sharing and knowledge transfer lead to successful KM. In service provider side, if each MSWM process along waste management chain is transparently managed based on well-planned policies complying with all stakeholders requirements, provided MSWM service performance will be improved. On service recipients perspective, if residents who are the main waste generators and any other generators are informed, educated, or known how to correctly manage with waste, waste generation rate will be decreased. Furthermore, respondents and experts have agreed that if they know what or how to reduce waste, not only waste generation will reduce, but also consumption of natural resources will decrease. An example case of value that is co-created by BMA, manufacturers, and the residents in MSWM is that there should be a campaign created by BMA and manufacturers to promote consumption of products that have less packaging materials. With this campaign, end users can purchase the same products with less cost or at the same price but more quantity. Moreover, respondents have stated that it is better to be informed of what the results of using products with less packaging are. It is an emotional strategy to learn that they are part of many people who make a better environment and save the world.

Table 4. Residents' aspects on value co-creation when applying KM concept

MSWM Process	Required knowledge/practice	Co-created values
Generation	- Campaigns to promote 3Rs or less packaging products - Information of adverse impacts caused by MSW	- Less raw material consumption - Less waste generation
Storage	- Information on suitable and practical waste sorting method - Information on waste management at home	- More recyclable waste to be used as raw materials - Better household WM - Less concerns on odor
Collection	- Information on waste collection place, date and time - Equally trained staff - Appropriate use of technologies, machines, and trucks	- Effective waste collection service - Optimal utilization of machines and trucks - Collecting cost and time reduction - Less concerns on odors, uncollected waste, and leftover waste - Less health risks and impacts to staff and residents
Transfer	- Equally trained staff - Sufficient transfer stations - Appropriate use of technologies, machines, and trucks	- Effective waste transfer service - Optimal utilization of machines and trucks - Transportation cost and time saving - Less concerns on falling waste - Less risks to staff who expose directly to MSW
Processing	- Equally trained staff - Appropriate use of technologies, machines, and trucks - Clear and practical policies and standards	- Effective waste processing - Optimal utilization of machines and trucks - Risks to frontline staff or workers are minimized - Less environmental concerns (soil, water, air)
Disposal	- Equally trained staff - Appropriate use of technologies, machines, and trucks - Clear and practical policies and standards - Mitigation and monitoring impacts in short, medium, and long-term policies	- Effective waste disposal - MSW is correctly managed and meets management standards - Less social, economic, and environmental concerns and impacts to the society

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

As shown in Table 4, values that are co-created by related stakeholders for each MSWM process are identified. Applying KM concept to MSWM service is aimed for sustainable MSWM service in Bangkok. If KM is successfully applied, respondents think that collaboration among key related actors is formed to create mutual benefits, which results in reduction of waste generation, better MSWM service, transparent and effective MSWM system as a whole, and less socioeconomic and environmental risks and impacts. In terms of value co-creation, there will be better understanding of how sustainable waste management should be among all sectors. Consequently, awareness of impacts caused by waste will be increased, so will awareness of the importance of ecosystem. Therefore, better waste management system and services eventually lead to better well-being of the society as a whole.

DISCUSSION

Based on the results of qualitative and quantitative analyses, this section provides essential factors that lead to practical implication of applying KM on sustainable waste management service in Bangkok. For waste management service providers, there are three factors that residents and experts concern on. Those three factors are readiness of waste management system, readiness of waste management strategies and legislation, and readiness of waste management human resource.

Readiness of waste management system means that the city needs to have all required infrastructures, qualified staff, and well MSWM informed residents which are important factors that support increasing amount of waste for all waste management processes including sufficient technologies of fleets and equipment, suitable number of waste transfer stations, and standardized waste disposal facilities. The city has to ensure that all infrastructures are in function and do not generate pollution to the environment. One of the BMA strategies is establishing networks to increase the efficiency of MSWM (Jungrungrueng, 2014). Knowledge sharing and transfer among MSWM staff and residents are imperative. For the staff, they have to correctly know what and how to effectively manage MSW as a whole system and especially specialize on their responsible tasks. For Bangkok residents, it is imperative to make them understand the importance of sustainable MSWM. One alternative is applying theory of planned behavior of Ajzen (1991) to MSWM plan. The theory links people's behaviors and beliefs under three concepts, including behavioral, normative, and control beliefs. If BMA informs the residents how importance of having sustainably effective MSWM system is; what roles they can have; or what roles the residents should do, the disseminated information makes residents perceive what consequences are. After a large number of residents have been informed with the same information, there happens perception of social pressures. These social pressures influence on decision of each resident whether they should be active actors who contribute to performance of MSWM system. When residents perform their roles in MSWM, they themselves perceive what changes or results that effect on performance of MSWM system. Therefore, the behaviors or roles of the residents are determined the residents themselves. Thus, it is essential for BMA to consistently and effectively share MSWM information to the residents.

All interviewed sectors agree that collaboration based on mutual agreement leads to better MSWM system. After having suitable infrastructures and appropriate technologies for waste management system, it is highly important that the city be provided with long-term strategic planning and policies on MSWM. In addition, enforceable laws should be in place. The analysis shows that public and private involvement of parties, for example, in waste management planning or policy setting creates mutual benefits. When all related parties agree with how management processes should be, problems on public appealing will

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

no longer occur. This is a big challenge of knowledge sharing and it transfers to make all parties understand the same knowledge, create the same direction of mindset of having effective waste management strategies, and have the same perception of the importance of having sustainable waste management system with rigid punishment for those who deny following. This challenging issue of knowledge sharing among related parties can be solved by adapting the concept of social exchange theory based on the analysis of social behavior (Homans, 1958). Benefits that are socially exchanged such as information, knowledge, advice, assistance, or commitment have unique significance of their own depending on each individual's preferences. In case of Bangkok's MSWM system, to get people have the same direction of mindset, it is easier to exploit interpersonal relations among residents. People tend to believe or consult with ones whose have friendly relations or are trustable. Socially exchange of MSWM knowledge among those who have good relations may result in better quality of knowledge sharing.

The most important factor that drives MSWM system is human resource. The city needs to ensure that staff at all levels has correct knowledge and practices their work activities properly. KM plays a very important role here. According to the knowledge-based theory (Grant, 1996) that focuses on the efficiency of economizing on knowledge exchange, instead of that, this paper focuses on the efficiency of MSWM activities based on knowledge transfer and sharing perspectives. Knowledge is a key productive resource that contributes to value co-creation of all staff. Therefore, knowledge should be embedded at every process of waste management starting from waste generation to waste final disposal. This is also applicable to MSWM that KM is simply applied to a simple process to a very complicated activity, for example, using equipment correctly, sorting correct types of waste, or planning waste collection routes. In addition to that well-being of front line staff should be more focused. They are directly exposed to health risks. Many frontline staff do not wear gloves or masks to protect themselves from contacting or exposing to waste directly. For sustainable waste management and better provision of service, Bangkok is highly recommended to have KM in MSWM master plan to ensure that every staff conducts all activities correctly based on the same knowledge and norm.

When waste management system and staff are ready, readiness of waste generators to be part of MSWM system is also important. It is again a huge task to build up good mindset of waste generators on effective waste management. At the very start of waste generation chain, suggested by experts, manufacturers should produce goods with less amount of packaging in more environmentally friendly way. This business practice has started implementing in the past few years, manufacturers launched campaigns of using less raw materials to reduce amount of waste. Residents also have to minimize amount of waste. Reduction of waste at source is the most powerful way to reduce generation of waste. It can be done by 3Rs activities. Education and public relation to promote correct waste management practices should be consistently available. Knowledge on importance of having effective waste management should be given. The socio-economic and environmental impacts of having and not having sustainable MSWM system should be explained. People have been more environmental concern. As the residents, main waste generators would like to live in a clean city. They have willingness to join waste management collaboration for a better and more effective waste management system. Thus, it is a task of BMA, a main actor in waste management, to mutually work with the residents, encourage and draw participation of the public to join waste management schemes on the basis of consistently promote and provide knowledge on sustainable waste management.

CONCLUSION

From the qualitative and quantitative analysis, the results show that KM is a potential factor that drives waste management to be more sustainable and better provision of service. According to the questionnaire surveys, respondents think that current waste management is acceptable but there are many concerns that the city needs improving. Odor is the most urgent problem that needs solving as it widely affects human well-being. Residents and experts suggest that knowledge is the most important factor to increase effectiveness of MSWM system in long-term. Thus, they would like proper knowledge to be consistently provided. According to the results, it is fortunately to see that people have more concerns on environmental impacts as they would like to join in waste management collaboration and have waste management system sustainable. They agree that knowledge is an important factor that makes the system effective. This leads to the importance of applying KM to waste management service.

KM cannot be effective unless successful knowledge sharing and knowledge transfer are not applied. Both residents and experts insist that all related stakeholders have the same mindset in implementing every waste management process. Thus, having an effective KM, it has to be ensured that knowledge gap is minimized, which can be done by applying knowledge sharing and knowledge transfer strategies. Moreover, it is essential to bring out personal hidden knowledge and utmost make use of this knowledge. From the results, every process from simple to complex inevitably needs KM. Thirteen needed types of knowledge are identified in this paper which the knowledge needs sharing and transferring to all related stakeholders. It is unnecessary that each person know all knowledge but at least every person needs to have the same mindset or organizational norm in business term.

We are living in service and knowledge economy, based on the analyzed results; it suffices to say that sustainable environmental service and KM concepts can perfectly blend together. This paper shows human aspects on current waste management service provided and the importance of KM. The results show that KM is an important factor for sustainable MSWM. Although thirteen needed knowledge for waste management system is identified, having an effective KM is a complicated task. This paper provides a concrete study of human aspects and requirements on having KM on an environmental service, MWSM. Further study on effective KM strategies especially on knowledge sharing and knowledge transfer is needed to identify practical implications for sustainable MSWM system which ultimately brings up the better step of well-being to the whole society in the very near future.

Part 1: General information of respondents

1. Sex
   - ☐ Male ☐ Female
2. Age
   - ☐ 16 – 20 years old ☐ 21 – 25 years old ☐ 26 – 30 years old
   - ☐ 31 – 35 years old ☐ 36 – 40 years old ☐ 41 – 45 years old
   - ☐ 46 – 50 years old ☐ 51 – 60 years old ☐ > 60 years old
3. Education
4. ☐ Primary school ☐ Secondary school ☐ High school
   - ☐ Vocational school ☐ Bachelor's degree ☐ Master's degree
   - ☐ Doctoral degree
5. Occupation
6. ☐ Student ☐ Business owner ☐ Company officer
   - ☐ Housewife ☐ Government officer/state enterprise
   - ☐ Retired ☐ Unemployed ☐ Freelance
   - ☐ Others (please specify) _____
7. Monthly income
   - ☐ < 5,000 baht ☐ 5,001 – 10,000 baht ☐ 10,001 – 20,000 baht
   - ☐ 20,001 – 30,000 baht ☐ 30,001 – 50,000 baht ☐ > 50,000 baht
8. How many people live in your house? _____ persons
   Member(s) whose age less than 16 years old: _____ persons

Part 2: MSW sorting and disposal behavior of respondents

9. Do you sort waste into different types before disposing?
   ☐ Yes ☐ No
10. How do you dispose of waste at home?
   ☐ Put garbage bags in front of the house, to be collected
   ☐ Put garbage bags at a community dumpster, to be collected
   ☐ Burn
   ☐ Leave garbage bags along roadside
   ☐ Others (please specify)_____
11. How often do you dispose of waste per week?
   ☐ Everyday ☐ Twice a week ☐ Three times a week
   ☐ Four times a week ☐ Five times a week
   ☐ Others (please specify) _____
12. How much waste is generated each time of disposal? **Approximate volume**
   ☐ < 1 kilogram ☐ 1 – 3 kilogram ☐ 3 – 5 kilogram
   ☐ 5 – 10 kilogram ☐ > 10 kilogram
   ☐ Others (please specify)_____
13. Do you have to pay for waste collection service?
   ☐ Yes, _____ baht ☐ No

Figure 5.

Part 3: MSW situation and attitudes of respondents

14. How is current performance of provided MSWM service?
   ☐ Very good ☐ Good ☐ Okay
   ☐ Bad ☐ Very bad
15. What problems do you usually experience with MSWM service?
   ☐ Waste is not collected on time ☐ Waste is left over
   ☐ Falling waste during transportation ☐ Bad smell from leachate
   ☐ No waste collection service in your area
16. For an effective sustainable MSWM, who should responsible for managing waste?
   ☐ Everyone ☐ Residents ☐ Governments
   ☐ NGOs ☐ Private companies
17. Do you think collaboration among communities, NGOs, and government for sustainable MSWM is important?
   ☐ Yes ☐ No
18. If there is a reorganization of MSWM from current system to a new sustainable collaborative system, would you like to join?
   ☐ Yes ☐ No

Figure 6.

Part 4: Needed knowledge and attitudes of respondents for sustainable management system

19. What MSWM knowledge should be provide to have a sustainable waste management system?

(1 = least important, 5 = most important)	1	2	3	4	5
- Waste sorting					
- Types of waste					
- Waste minimization					
- 3Rs (Reduce, Reuse, Recycle)					
- Education in schools					
- Laws and enforcement					
- Public involvement					
- Training or demonstration of waste management					
- Consistent support and promotion					
- Basic waste management in household					
- Risks and impacts of MSW					
- Service mindset of staff					
- Mindset of waste and the environment of residents					
- Others					

20. How should waste management system be when applying knowledge management concept? *(Please put a number according to what waste management process that will be impacted, 1=Generation, 2=Storage, 3=Collection, 4=Transfer, 5=Processing, 6=Disposal)*

- ☐ Less waste generation
- ☐ Less raw material consumption
- ☐ Less concerns on odor
- ☐ Less concerns on uncollected waste
- ☐ Less concerns on leftover waste
- ☐ Less concerns on falling waste
- ☐ Less social, economic, and environmental concerns and impacts to the society
- ☐ Less environmental concerns (soil, water, air)
- ☐ Less health risks and impacts to staff and residents
- ☐ Less risks to staff who expose directly to waste
- ☐ Save collecting cost and time
- ☐ Risks to frontline staff or workers are minimized
- ☐ Better waste management
- ☐ More recyclable waste to be used as raw materials
- ☐ Transportation cost and time reduction
- ☐ Effective waste collection service
- ☐ Effective waste transfer service
- ☐ Effective waste processing
- ☐ Effective waste disposal
- ☐ Optimal utilization of machines and trucks
- ☐ Waste is correctly managed and meets management standards
- ☐ Others _____

Chapter 42
Leachate Generation, Transport, and Control

Mohamed Shahrir Mohamed Zahari
Universiti Malaysia Terengganu, Malaysia

Shahrul Ismail
Universiti Malaysia Terengganu, Malaysia

Izan Jaafar
Universiti Malaysia Terengganu, Malaysia

ABSTRACT

This chapter will discuss in detail on the primary aspect influencing leachate generation, transport and control within the landfill area. The leachate generation will look into the various factors that contribute toward increment and reduction of water balance in the landfill cell cause by the physical, chemical and biological activities. The topic will include discuss on common methods and models for estimating water input and transformation into/inside the landfill layer. Meanwhile, leachate transport part would emphasis on the leachate movement and mobility due to the effect of waste percolation, moisture field capacity and the gravity pull. Dominant flow type and the effect upon solute transport as well as other landfill components would be emphasize within the discussion. Lastly, this chapter will elaborate on the conventional and advanced techniques that being utilized for the control of the leachate for further treatment system or as beneficial advantages in the landfill management system.

INTRODUCTION

In the past, the concern is primarily on the amount of leachate that would be generated from the landfill site as it would signify the environmental risk of the landfill area. Nowadays, leachate is being considered as multi-dimension pollutant that potentially can affect the land/soils, water and even air (either directly or indirectly). Because of that, the regulatory upon leachate was stringent for leachate treatment and the landfill gases are meant to be collected; that require the need to investigate into the waste layer

moisture and leachate mobility within the landfill cell. Protection from leachate contamination has been imposed into various countries legislations such as "Regulation 15 of the Waste Management Licensing Regulations" (UK), "Groundwater Regulations"(UK), "Pollution Prevention and Control Act" (England and Wales), "Landfills Regulations" (England and Scotland), "EU Directive on IPCC", "EC Directive on EIA", "Water Framework Directive", "Strategic Environmental Assessment (SEA) Directive" and many mores (Butt, et al., 2014). These legal requirements push toward getting better understanding onto the reactions occurs inside the landfill layer especially on the generation and mobility of leachate. Such information open a more understanding onto the reactions occurs inside the landfill layer especially toward the waste anaerobic degradation and for optimal methane production. At the same time, it is also providing the essential knowledge to maintain and controlling the flow of leachate within the landfill containment and thus preventing leakage into the surrounding environment. In the long run, managing the leachate generation and flow would account into the reduction the treatment cost and maximize the biogas production if necessary.

LEACHATE GENERATION

Leachate generation is an important and necessary aspect to estimate for potential leachate leakage prevention especially into the groundwater system. Potentially leachate leakage could occur if the leachate head in the bottom liner happen to exceed 30 cm which could easily be measure by placing pressure transducer in the leachate collection well. Looking from this aspect, greater leachate generation rates would significantly increase the leachate accumulation at the bottom liners due to the downward, vertical movement of the leachate flow and mostly probably increasing the chances of leakage into the groundwater aquifer.

Leachate is produced mostly from the incoming or water input from outside primarily through rainwater infiltration apart from the water which is already present as moisture in the deposited waste stream and small fraction that could be produced from the multiple reactions inside the landfill. Usually sanitary landfills are well designed to prevent or at least minimize the water infiltration through various approaches and practices depending on the landfill owner or contractors. Therefore, overall leachate generation modeling would require information on all these aspects for overall estimation; which include the type of wastes being disposed, landfilling practice, landfill cover practices, leachate collection system and leachate recirculation (if being employed) as summarized in Table 1.

Leachate generation prediction would have to look into the conceptual model and the numerical model of each landfill aspects. Normally, estimation can be made by looking at water balance or water budget in the landfill cell, treating the cell as a spatial lump system and calculate the leachate volume from the water balance. Figure 1 shows water balance for a landfill site.

The water balance is influenced by the outside water entering into the landfill layer (rainfall, water infiltration, and surface runoff), the water presence in the deposited waste layer (moisture, field capacity) and the water addition or loss through physical process, chemical reaction and microbiological activities within the landfill layer. In a properly covered sanitary landfill, water infiltration by the rainfall will be minimized as it is shed away as surface runoff, evaporated or transpire away by the surface vegetation. Standard hydrological tools can be used to determine the amount of water rainfall infiltration into the landfill layer. The tools require hydrological data of the landfill site including climate and site condition. There are many other complex landfill water balance models are being developed that incorporate more

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

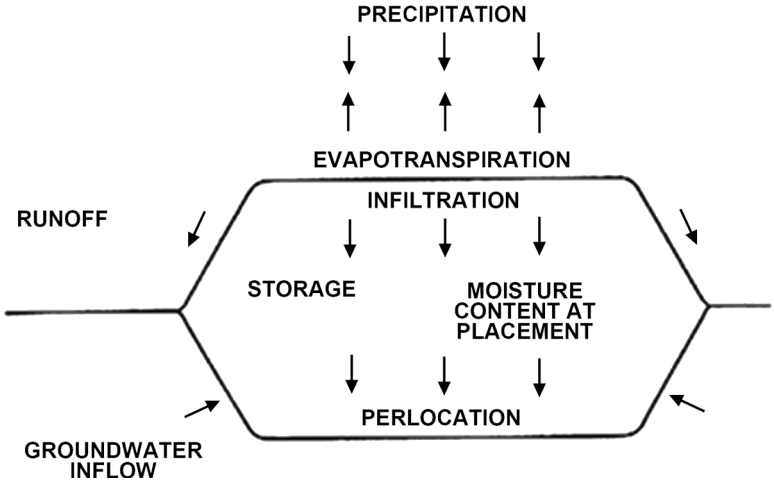
Table 1. Landfilling aspect and the significance on leachate generation

No	Landfill Aspect	Parameters	Significance
1	Waste	c) Volume of waste disposed d) Characteristic of waste	Amount of moisture being added into the landfill cell and decomposition type or rate which could either consume or generate moisture
2	Landfilling Practice	c) Landfill cell unit area d) Average high	Compaction ratio, vertical stress for the landfill layers and the influence on the moisture holding capacity
3	Landfill Cover Practice	e) Type of daily and interim cover f) Thickness of the covers g) Surface vegetation and slope h) Site precipitation data and surface runoff	Preventing water infiltration, possible erosion by surface runoff and also potential loss as water vapor or by plant uptake
4	Leachate Collection System	c) Piping layout d) Piping design parameter	Draining the excess water out of the landfill cell
5	Leachate Recirculation	c) Amount of leachate recirculation rate d) Type of recirculation system applied	The amount of water re-added into the landfill cell, the influence on waste solubilisation and possible water vapor loss from the system

advanced hydrologic techniques and climatological databases. The most commonly applied landfill water balance is the Hydrological Evaluation of Landfill Performance (HELP) which is a quasi-two-dimensional hydrological model of water mobility across, into, through and out of the landfill as well as leachate recirculation.

Any water that manages to infiltrate through the landfill cover will be either absorbed by the waste field capacity or migrate vertically due to gravity pull until it is collected at the bottom of the landfill. Many believe that the infiltrated water would be held by the waste field capacity first. Once the field capacity is reached, the amount of leachate produce would be equal to the amount of the infiltrating water. Probably about 1/8–3/8 of the water inputs would end up as leachate at the landfill bottom (Baumann & Schneider, 1998). As the rainfall infiltration is mostly retained by the surface tension (D. Bendz, Singh, & Ã…kesson, 1997), the collected leachate would came primarily from the waste material itself

Figure 1. Landfill water balance (Farquhar, 1989)



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

that accountable for about 75% of the overall portion (Abichou, Barlaz, Green, & Hater, 2013) and it is estimated that only 1500 m^3 of water leaving the landfill cell through evaporation (U. S. EPA, 2006; Xuede, Koerner, & Gray, 2002).The bulk moisture content of the waste that represent the major portion of leachate input can be calculated as shown in Equation 1:

$$\text{Moisture Content } = M_i + \frac{\Delta S}{M_W} \times 100 \quad (1)$$

where

M_i = Initial Moisture Content (%)
ΔS = Change in storage (tons of water)
M_w = Wet weight of waste (tons)

WATER TRANSFORMATION AND LOSSES

Aerobic Phase

Generally, the first phase of aerobic degradation involving organic substances only occur within limited time duration due to the high oxygen demand of waste in relation to the limited and scarce quantity of oxygen presence inside the landfill cell after disposal (illustrated in Figure 2). Therefore, upper layer would be the only layer of within a landfill that would involve in aerobic metabolism since oxygen could only be found trapped in fresh waste or could potentially being supplied by diffusion process and rainwater infiltration. During this phase, it is observed that all the readily available proteins are to be degraded into amino acids before being further decomposed into multiple compound comprise of carbon dioxide, water, sulphates, nitrate and other typical catabolites or products from aerobic processes. In that sense, the carbohydrates content within the landfill layer or more precisely on the fresh/upper layer are converted to carbon dioxide and water. In the meanwhile, the fats content would be hydrolysed into forming fatty acids and glycerol until eventually it would be furtherly degraded into simpler catabolites through intermediate formation of volatile acids and alkalis. However cellulose, which constitutes the majority of organic fraction of wastes, is not so easily processed. The natural process would require it to be degraded by the means of extracellular enzymes, producing glucose as it monomer constituent which is used subsequently eaten away by bacteria into releasing carbon dioxide and water. Elevated temperature is assumed to occur during this stage due to the exothermal reactions of biological oxidation and if the waste is not compacted. With the scarce assess for the oxygen, the aerobic phase would be relatively short-term and no substantial leachate generation will take place. In comparison to the young landfill, very old landfills would comprise higher amount of refractory organic carbon remaining within the landfilled wastes, in which a second aerobic phase may appear in the upper layer of the landfill subjected to oxygen availability. Overall, the methane production rate would be very low during this aerobic phase and the air diffusion would promote formation of aerobic zones and redox-potentials zones that is too high for methane formation (Christensen &Kjeldsen, 1989).

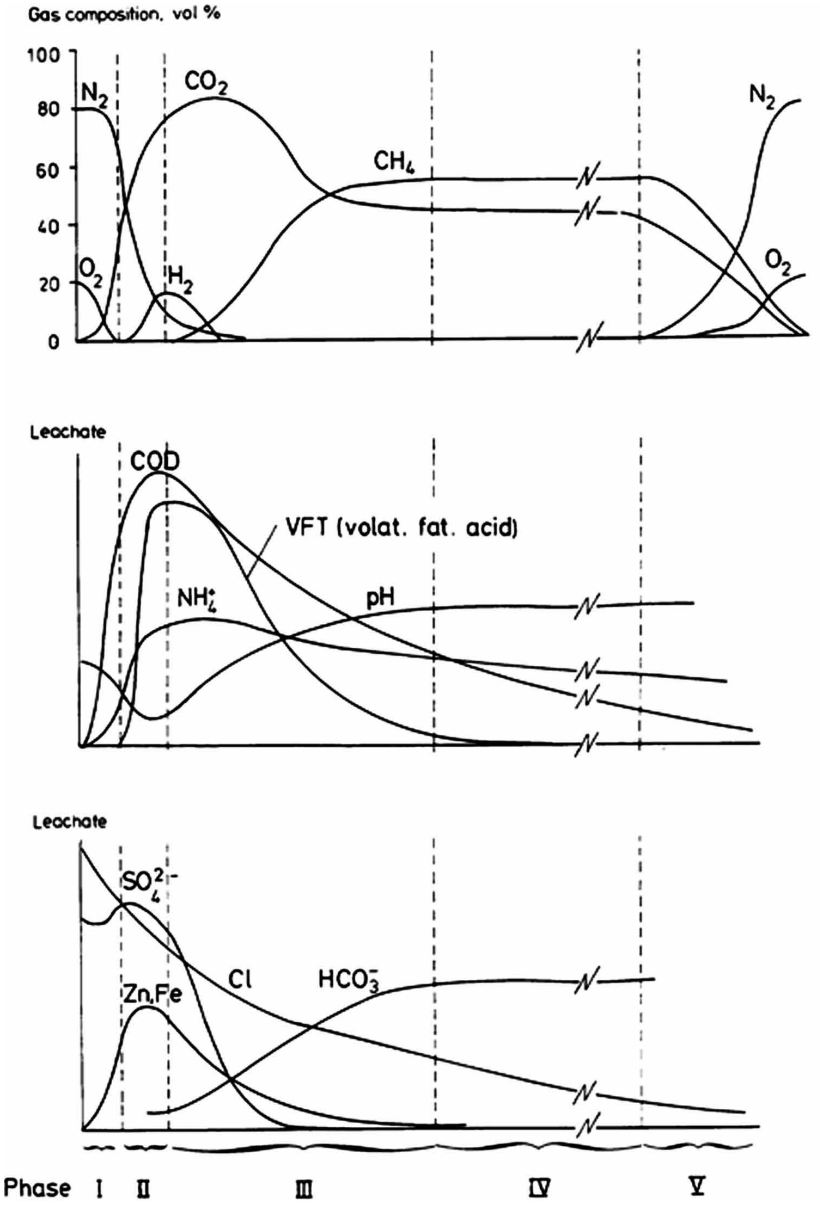
Figure 2. Illustration of developments in leachate and gas in a landfill cell (Christensen &Kjeldsen, 1989)



Anaerobic Phase

Anaerobic phase refers to the digestion processes of organic materials in the absence of oxygen, which will be degraded into biogas composed of mainly methane and carbon dioxide. The anaerobic digestion pathway of organic matter involves several biochemical reactions, performed by different microbial trophic groups, which sequentially degrade a variety of substrates and intermediate compounds (Figure 3). The microbial consortia that are involved ultimately mineralize the organic matter into methane (CH_4), carbon dioxide (CO_2), ammonium (NH_3), hydrogen sulphide (H_2S), phosphates (PO_4^{3-}) and water (H_2O).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Anaerobic digestion can be divided into four phases, related to the characteristic microorganisms and main conversion processes taking place: hydrolysis, acidogenesis, acetogenesis and methanogenesis (Figure 3). Firstly, hydrolytic enzymes are excreted by fermentative bacteria, the so called 'exo-enzymes' and fermentative bacteria actively colonized the organic matter. The non-dissolved material is converted into less complex, dissolved compounds, which can be taken up by the fermentative bacteria. Secondly, during acidogenesis, the dissolved compounds present are converted by fermentative bacteria into a number of simple compounds, which are then excreted. The compounds produced during this phase include volatile fatty acids (VFA), alcohols, lactic acid, CO_2, H_2, NH_3, and H_2S. Thirdly, the acetogenic phase, or intermediary acid-production, converts the digestion products into acetate, hydrogen (H_2) and CO_2. Lastly, methanogenesis converts acetate, hydrogen plus CO_2, formate or methanol into methane.

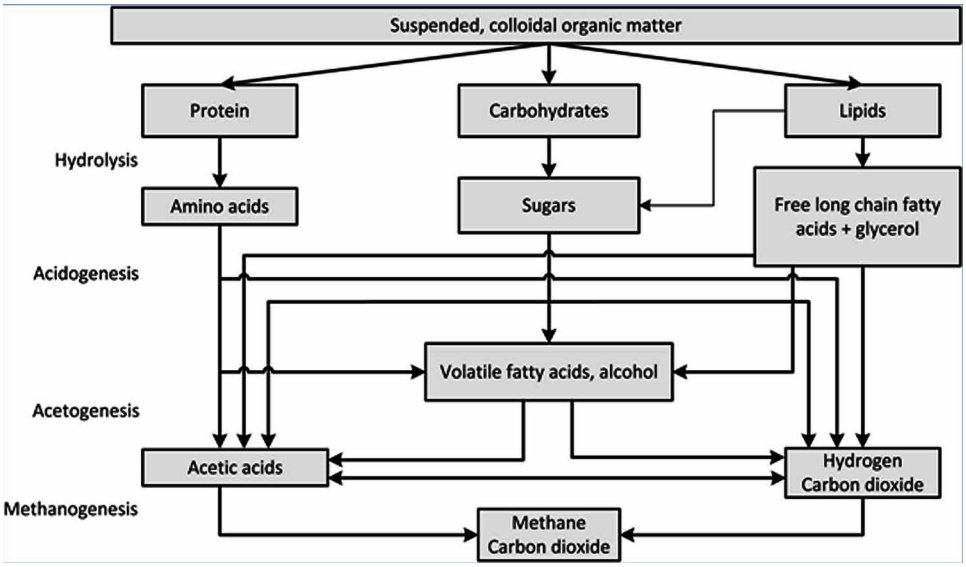
Methanogenic Phase

Methanogenic bacteria play in important role for converting organic compounds into methane and carbon dioxide during anaerobic degradation process (Figure 4). These microorganisms can be divided into two groups. First, acetate using microorganisms known as aceticlastic methanogen (producing methane from acetic acids or methanol). Second, hydrogen-using microorganisms known as hydrogenotrophic methanogen (producing methane from hydrogen and carbon dioxide).

Aceticlsastic Methanogen

This methanogenic species are prevailing in anaerobic digestion in which are capable to form methane from acetate even though at a few species number. Around 60 to 70% of all methane production being produced by this species, starting from the methyl group of the acetic acids. Two genera utilize acetate to produce methane known as Methanosarcina(prevails above 10-3 M acetate) and Methanosaeta(prevails

Figure 3. Simplified schematic representation of anaerobic degradation process



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

below this acetate levels). Methanosarcina may have higher yields and be less pH sensitive, as compared toMethanosaeta. Methanosarcina has greater growth rate thanMethanosate. However, Methanosate needs a longer solid retention time, but can operate at lower acetate concentrations. The Methanosaeta genus is known to be exclusive used of acetate and has a higher affinity with it than the methanosarcinas.

Hydrogenotrophic Methanogen

Generally methanogenic species are capable of producing methane from hydrogen and carbo dioxide, unlike aceticlasticmicrooganisms. Methanobacterium, Methanospirllium and Methanobrevibactor are among the species that frequently find in anaerobic conditions.Aceticlasstic and hydrogenotrophic are two importantmicroorganisms in anaerobic digestion since they are responsible for the essential function of consuming the hydrogen produced in the previous phase.

Leachate Generation Modeling

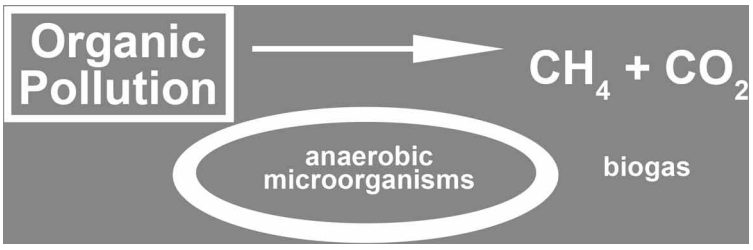
Among the modes that are commonly used to estimate the leachate generations are the water budget method and Hydrological Evaluation of Landfill Performance (HELP) method. However, water budget method tends to show too much uncertainty and a very large error since it assumes that the waste is at the field capacity and the water input produces similar amount of outflow. Simple water budget calculation is as shown in Equation 2:

$$I = P - ET - \frac{\partial S_s}{\partial t} \tag{2}$$

where

I = Net water input
P = Precipitation
ET = Evapotranspiration
dS_s/dt = Change in the water storage

Figure 4. Conversion of organic pollutants to biogas by anaerobic microorganisms



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Simple water balance could be developed by connecting data such as rainfall, infiltration, evapotranspiration and leachate drainage as being done by O'Reilly (2004) and Heimovaaraet. al. (2015). Usually, this method only considers the presence of three layers within the landfill which is the cover layer, the waste layer and drainage system. The top cover water balance would be influenced by the precipitation, surface runoff and in some case, consider the potential of evapotranspiration which are commonly only limit to the rooting depth of vegetation. From there, a small fraction of water is estimated to infiltrate into the waste layer, flowing through all the way to the drainage system. Heimovaaraet. al. (2015) assumed that the water flow is based on bimodal lognormal distribution and being model using a stochastic transfer function approach. An example of transfer-function-model is mentioned in the next sub-chapter for leachate transport. In his study, the storage volume of the top layer that would permit evapotranspiration is at about 4.1 mm/m^2 with reasonable travelling time between 8.5 (fast flow) to 64 days (slow flow). It is believed that the time taken for the water to residence in the waste layer would be an essential output for solute leaching model. As for the HELP method, the model takes into account the initial water accumulation up toward reaching the field capacity and the flow rate through the landfill (D. Bendz, et al., 1997). Moreover, the HELP can also be used to estimate infiltration, runoff and evapotranspiration (Abichou, et al., 2013; Schroeder & Ammon, 1994; Schroeder, et al., 1994). The model requires inputs such as type and thickness of cover material, slope of the surface and presence of surface vegetation. The usage of intermediate cover having high permeability material and the influence of runoff volume through relative adjacent cells could possibility increase the water infiltration volume (Abichou, et al., 2013). Table 2 below summarizes the hydrological aspects being considered by HELP method in predicting leachate generation and flow.

LEACHATE TRANSPORT

Investigation upon leachate transport is crucial because of the water content being the major constituent for landfill metabolisms. It would provide the fundamental understanding and enable prediction or simulation of landfill potential pollution and even for estimating landfill gas production. In terms of pollution prediction, leachate mobility is commonly associated with solute transport especially involving contaminants which are being solubilized from the waste media, brought along by the water content and eventually accumulates at the landfill bottom. For landfill reactions specifically involving gas collection system, those solutes would represent substrate and nutrients being redistributed by the leachate movement and thus facilitate anaerobic degradation process especially since the flow also spreads microorganism throughout the landfill layer.

Leachate generation mentioned before already emphasizes on the main factors that contribute towards the landfill water balance; present within the landfill layer either coming from the outside and inside sources. For the leachate transport, the influential factors are signified more by the space and time availability for the water storage inside the landfill layer apart from other factors which reflect on the volume of water. In that manner, one of the main aspects for leachate mobility is referred to the field capacity that define as the maximum volume of water per unit volume of landfill material held by capillary forces against gravity. Field capacity could be determined by drying a small portion of the waste (already saturated) and left to drain until the moisture cease to flow out. In actual landfill, the moisture retaining characteristic tends to be diversifying depending on the waste compositions and compaction factor imposed at each landfill site. Commonly, MSW landfill observation indicates that domestic waste

Table 2. Summary of methods and estimation used in HELP model (Schroeder, P.R., Dozier, T. S., Zappi, P. A., McEnroe, B. M., Sjostrom, J.W., & Peyton, R. L., 1994)

SURFACE PROCESSES
Weather Generator
1) WGEN Model of the U.S. Department of Agriculture (USDA) Agricultural Research Services (ARS) based on the procedure by Richardson. 2) Use to generate daily precipitation, solar radiation and the mean temperature. 3) The daily precipitation is generated by Markov chain-two parameter gamma distribution model. 4) Infiltration is equal to the sum of rainfall in the absence of snow cover (precipitation at the temperature of more than 0°C) and in the presence of snow cover, equal to the sum of outflow from the snow. Ground melt less the sum of evaporation from surface moisture or outflow of snow cover and runoff.
Runoff Modelling
1) Estimated using USDA Soil Conservation Service (SCS) curve number method. 2) Required necessary soils data such as: • Field capacity o Volumetric water content at a soil water suctions of 0.33 bars. o Must be greater than wilting point and less than the porosity. • Porosity o Volumetric water content as in the volume of water per total volume or the volume of active pore space present. o Must be greater than the field capacity but less than 1. • Initial moisture storage o Volume of water per total soil volume (soil, water and air). o Relative moisture storage is estimated using the common practice in agronomy and soil physic (on volume basis) rather than the one used by engineer (on mass basis) • Wilting point o Volumetric water content at a suction of 15 bars. o Must be greater than zero but less than the field capacity. • Hydraulic conductivity o Function of the media properties which is the void ratio, particle size, fabric, composition, degree of saturation and the kinetic viscosity of the flowing fluid. • Soil Conservation Service (SCS) runoff curve number for antecedent moisture condition II 3) All this parameters is required for all layers except for the liners and the soil liners are assumed to be saturated at all times.
Evaporation
1) **From Soil (including plant transpiration and growth):** Ritchie method as used in Simulator for Water Resources in Rural Basins (SWRRB) and the Chemicals, Runoff and Erosion from Agricultural Management System (CREAMS) 2) **Potential Evapotranspiration:** Modified Penman method 3) **Interception:** Method proposed by Horton 4) **Snowmelt Modelling:** SNOW-17 routine of the National Weather Service River Forecast System (NWSRFS) Snow Accumulation and Ablation Model 5) Evaporation coefficient is related to the unsaturated hydraulic conductivity at 0.1 bar capillary pressure at which upper and lower limits is imposed. Set to equal to 3.30 for relative field capacity less than 0.20 (for typical sand) and saturated hydraulic conductivity is less than 5×10^{-6} cm/sec (for compacted clay) while the upper limit is set at 5.50. 6) Soil water evaporation or plant transpiration is assume not occurring when the soil is frozen. 7) Potential evapotranspiration refer to the maximum quantity of evaporation rate that the atmosphere may extract in a day, when the mean daily temperature is above 32°C and the soil is not frozen. Rate of evapotranspiration is influenced by the solar radiation, humidity, temperature, vegetation type and growth, soil water content, retained surface water and other soil characteristic.
SUBSURFACE PROCESSES
Drainage
1) **Vertical:** Darcy's Law using the Campbell equations for unsaturated hydraulic conductivity based on the Brooks-Corey relationship 2) **Saturated Lateral:** Boussinesq equation model by analytical approximation to the steady-state solution, employing the Dupuit-Forchheimer assumptions 3) **Leakage:** Modelled by a compilation by Giroud utilizing a series of equations. 4) Include four types of layer which is the lateral drainage layers, vertical percolation layers, barrier soil liner and geomembrane liners. 5) Significant lateral drainage occur when the saturated hydraulic conductivity is greater than 1×10^{-3} cm/sec. 6) Leakage percolation occur by the mean of manufacturing flaws (pinholes), installation defects (cracks, tears, punctures and bad seams) and vapor diffusion

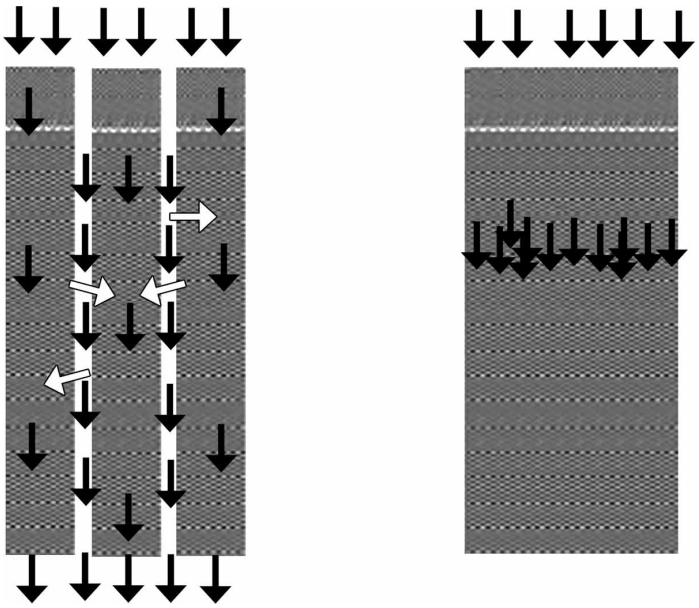
EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

has high adsorptive capacity for further moisture uptake (Holmes, 1983) even for landfill operating after 10 years deposit (Bengtsson, Bendz, Hogland, Rosqvist, & Ã…kesson, 1994). However, those capabilities would soon to reach it limit as the field capacity is found to be decreasing with age primarily due to the degradation of the adsorbing material (Blight, Ball, & Blight, 1992; El-Fadel, Findikakis, &Leckie, 1997). Therefore, significant moisture accumulation by the waste media would have to consider the aspects of waste composition and age, initial moisture content and density.

Another aspect of the leachate transport is on the flow type as it determines the amount of water reaching certain volume of waste especially on the influence of non-uniform flow. Non-uniform water flow would create unmixed and water deficient inside the landfill layer which adversely affect the biodegradation process (Bogner&Spokas, 1993). In most studies, non-uniform flows are found to be predominant because of the highly heterogeneous physical structure of the landfill layer; plus the availability of channels and voids between solid waste media. Studies have exhibited the existence of flow pathway favored through the waste media; suggesting fast flow through selective pathways and bypass parts of the media called preferential flow. As the consequence of preferential flow occurrence, the flow of the remaining water in the bypassed parts of the solid media would be very slow or could even be stagnant. Other flow routes could also be developed caused by high infiltration rate (Jasper, Atwater, &Mavinic, 1985) that would influence on the amount of moisture from the top layer of the landfill cell. Figure 2 shows the differences between preferential flow and matrix flow for downward movement of leachate. Figure 5 shows the differences between preferential flow and matrix flow for downward movement of leachate.

For fresh landfill cell, it seems that preferential flow dominantly takes place because the waste deposits have coarser structure (D. Bendz, et al., 1997) and thus makes the leachate moving with less uniformity in an actual landfill system (Fellner, Döberl, Allgaier, & Brunner, 2009). The preferential flow occurs very fast due to introduction of waste deposit and compaction activities which would draw out moisture from the new deposited waste onto the old waste layer. Similar to waste field capacity characteristic, it

Figure 5. Comparison between preferential flow (left) and matrix flow (right)



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

would also soon change depending on the waste structure, voidage volume and precipitation rate at the landfill site. As time goes by, the waste would start to settle and become more homogeneous, decreasing the voidage volume while increasing the dry density. Flow type can be determined through liquid to solid (L/S)-ratio or LRS which stands for the amount of water (in liters) passing through a given waste mass (in kg dry matter of waste) to relate on the laboratory result to actual landfill site (Fellner, et al., 2009) and use to determine the remaining pollution potential of MSW landfill (Allgaier&Stegmann, 2003).

Leachate Transport Modelling

Various methods have been utilized for stimulating the processes within MSW landfills either based on laboratory experiments (Fellner, et al., 2009; He, Liu, Zhang, &Shen, 2007; Prantl, Tesar, Huber-Humer, &Lechner, 2006), actual landfill observation (Fellner, et al., 2009) and even by using mathematical modeling (McCreanor& Reinhart, 2000; Noble & Arnold, 1991). The studies include various aspects to predict the emission such as the analysis of waste composition, batch tests, leaching tests and the operation of landfill simulation reactors either by using a made-up waste layer or the one dredged from an actual landfill site. The first three methods are mainly performed to determine the potentially mobile fraction in the overall or partial wastes deposited into the landfill whereas landfill simulation reactors test are primarily used to predict future emission from the landfills either in laboratory small scale or at the actually landfill site.

Existing approaches in predicting water flow come with their own underlying complexity and assumption ranging from relatively simplistic models to a more complex physically based model of either dual-porosity, dual-permeability or multi-region types (Šimůnek, Jarvis, Van Genuchten, &Gärdenäs, 2003). Both dual-porosity and dual-permeability models assume that the matrix or medium consist of two different regions in which water in the matrix is assume to be stagnant (does not move at all) for the dual-porosity models meanwhile dual-permeability even allow water flow in the matrix itself. These models are more fitted to determine leachate flow compared to single pore models, yet it also became the main disadvantages since more input ranging from 9 to 16 parameters depending on the existing models are required to characterize the different pore systems. The numbers of these parameters significantly increase for multi-porosity and multi-permeability models because of the need to determine the matrix hydraulic (retention and hydraulic conductivity) and mass transfers coefficient for each transport domain. For modelling leachate, hydraulic conductivity happens to be the most sensitive parameters for both preferential and matrix flow within the landfill (Fellner, J., & Brunner, P. H., 2010). Therefore, even though software had been developed and improved to ease upon the studies of these models for real time application but however, there also the need for new approaches in analyzing the complex parameter required for those models, such as through the practical use of disc or tension infiltrometers and simulation using inverse modelling techniques (Šimůnek, Jarvis, Van Genuchten, &Gärdenäs, 2003).

For practical leachate prediction, landfill investigation usually employs experimental column in the shape of cylinder, carefully driven into the waste after the top soil layer has been removed. It would alternately require excavating the waste material surrounding the column as pressure being applied to the top of the column until the bottom liner is reached. Then, a sheet could be placed flat on the bottom to cover the underneath of the column and enables the whole column assembly to be lifted out. The experimental column containing waste layer would react both as a sampling device for the tracer experiments and to reflect different condition that could occur in the landfill site such as ponding of water, water sprinkle and pulses of water inflow. Boundary effect could exist in the column that might

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

affect the flow estimation but for small water velocities, it can be assumed to be negligible. For better result, slurry of very fine quartz sand could be firmly packed around the edge of the column to avoid the boundary effect and prevent the water from flowing preferentially along the wall of the column (H. k. Rosqvist&Destouni, 2000).

Using the experimental column, tests on the leachate mobility and solute transport within the landfill layer are determined by using tracers, dyes or/and morphology methods. Tracer experiments would involve using non-reactive tracer (e.g.: lithium bromide, Brilliant Blue FCF, fluorescence dye uranine, deuterium and etc.) as its concentration could later be measured using simple analysis including photometry and the data could be used to develop the breakthrough curve. Lithium has been a conservative tracer for solid waste material (Blakey, Bradshaw, Reynolds, & Knox, 1997) but study by Woodman et. al. (2015) suggested re-evaluation on the usage of lithium as a tracer for landfill waste since only 50% of lithium was retrieved back from the column outlet. It also question the experimental validation concerning sample degradation that could occur from batch tests which employed oven-drying that possibly destroy important bio-film media and emphasize on the need for exploratory modelling regarding scale of flushing from waste in column study. Apart from those suggestions, the study reveals a good conservative result for other type of tracers which is bromide and deuterium oxide. The same could be said for other tracer such as Brilliant Blue FCF that provides simplicity in the concentration analysis while assuming minor adsorption for test conducted in high water velocities (Flury&Flühler, 1995). Sometimes, common salt such as sodium chloride could also be used as tracer if it exhibits good correlation in influencing the leachate electrical conductivity value. The breakthrough curve can be built up from the tracer experiments data and indicates the flow types experienced by the tracer transport. Early peak observed in the breakthrough curves is indicator of rapid solute transport (preferential flow) and prolonged shape indicates slow water flow.

Most of field tests involve different experimental approaches such as to predict the leachate flow for either steady state or transient flow using either constant water head or sprinkling boundary conditions. Test performed under sprinkling conditions are used to predict solute travel time probability density functions (PDF). It would enable estimation on the expected solute travel times and the solute transport volume fractions that actively involve during the leachate transport. Simple leachate transport model which also involves solute mobility can be built from those experimental data and it is usually by assuming that the deposited waste stream are evenly spread creating homogenous, porous media within the landfill layer. It would involve the use of one-dimensional water balance model. However such approach is questionable since MSW is known to be highly heterogeneous which most probably cause the water content to move in non-uniform patterns throughout the waste media. This is believed to be the main reason for inconclusive, in-different results obtained between model assumptions and actual field observations. Even more as there is evidence in the existence of fast flow or preferential flow for actual landfill site. Predictability of the flow and solute transport would be significantly affected without consideration on those two factors of waste heterogeneous nature and preferential flow. Therefore, two-domain or multi-domain concept would provide a better prediction involve the presence of preferential flow in the structured media (Gerke&Genuchten, 1993) and dual-porosity (DP) model appear to be the most suitable for waste layer compared to advection-dispersion (AD) model and hybrid AD-DP model (Woodman, N., Rees-White, T. C., Stringfellow, A., Beaven, R., & Hudson, A., 2015). Table 3 listed some models and equations use to estimate leachate flow and solute transport inside the landfill.

Effect of Leachate Flow within Landfill

The one most significant effect of leachate movement within the landfill is mainly on the landfill layer settlement (Abichou, et al., 2013) and the effect it bring to the waste degradation rate especially by accelerating physical, chemical and biochemical processes in the landfill layer (Kylefors, Andreas, & Lagerkvist, 2003). It is already revealed that water flux has a huge impact upon the waste degradation rate (Klink & Ham, 1982) since moisture is considered to be most important parameter for landfill biochemical process (Hans-JurgenEhrig, 1991).

It is believed that the movement of leachate brings about advective solute transport in which solutes or contaminants are carried along with the leachate flow. Fast advective solute transport could be accompanied by potential dominant diffusive mass transfer between different flow domains (H. k. Rosqvist&Destouni, 2000). Therefore, the contaminants movement would be dependent upon the rate and direction of the flow. However, a study conducted by Fellner et al. (2009) revealed only a small fraction about 0.2% for the actual landfill in comparison to 40% participation of pore water on the solutes transport. The differences in laboratory and actual landfill simulation were caused by faster decrease in leachate emissions and stock remaining from the landfill portions. The still on-going studies on these aspect since the hydrodynamic properties of fluid movement and solubilisation of waste portion are very much correlated and still not well define either separately and even more on the intercorrelation.

This is cause by the poor ability to fully understand and predict the fluid movement and contaminant mass removal from the waste body at different flushing. Typically there is the need for model that coupled those several processes together involving physical transport mechanisms (advection, dispersion and diffusion), biological, thermal, mechanical and multiphase flow effects. Woodman et. al (2015) had listed out the particular experimentation problems as: 1) difficulty in obtaining representative in-situ samples; 2) difficulty to reproduce the actual process in the laboratory due to the high compression stress and compaction and 3) difficulty in controlling liquid flow during gas production.

Leachate Movement Outside Landfill

The effects on leachate mobility outside the landfill are mostly concerning the contaminants movement that could pollute the groundwater aquifer and surrounding water bodies. The leachate movement could contribute toward the natural attenuation effect both upon the waste characteristic as well as the leachate quality within and outside of the landfill boundary. The process of natural attenuation is defined as any combination of physical, chemical or biological reactions that occur naturally and could effectively reduce contaminant mobility, concentrations or toxicity (A. EPA, 1999). Slow mobility of the pollutant could minimize the impact by which lowering or degradation of the contaminants; usually amplify in longer time period and differ depending on the natural attenuation properties of the landfill site.

The leachate that has penetrated and travelled outside of the landfill boundary would definitely change both in it physiochemical and biochemical compositions (Islam &Singhal, 2002). The degree of groundwater contamination is affected by physical, chemical and biological actions. The relative importance of each process may change, however if the leachate moves from the landfill to the sub-surface region (Ramachandra, 2006). Evidence of such changes has been observed by looking into the down gradient of the landfill site. Focusing and establishing the type of contaminants' presence including the reactions taken place in those layers has exhibited the differences of redox zones occurring at the down gradient of the landfill aquifer such as reduction zones for oxygen, nitrate, sulphates, ferric, manganic

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

and methane production zone depending on the presence of electron receptors (Christensen, et al., 1994). As for the geological attenuation effect, Thornton et. al. (2000) found that leachate–rock interactions are signified by acid–base and redox reactions, ion-exchange processes and sorption/precipitation of metal species whereas attenuation of leachate NH_4 is dominated by cation exchange with aquifer sediments. Even been retarded by the ion exchange, heavy metals could still impose serious problem since the soil would reach breakthrough over time causing significant increase in metal concentration over soil depth (Sizirici&Tansel, 2015). Such attenuation effect could be studied using chemical mass balance approaches, aqueous equilibrium speciation modeling and simple transport modeling. These methods are used to evaluate the key processes and aquifer geochemical properties in the landfill site which could naturally help in preventing and controlling the contaminant fate.

Apart from chemical effect, physical impact such as clogging of soil could also be expected by the leachate permeation. Studies show that the hydraulic conductivity can be reduced up to three orders of magnitude due to microbial growth and metal precipitation (R. Rowe, et al., 1997) caused by the leachate infiltration including calcium carbonate precipitation that mostly regard as the 'clog-slime' in leachate drainage (Rittmann, Fleming, & Rowe, 1996). As such it would react in further control of the leachate mobility as well as expected to contribute further for the natural attenuation especially by the biological processes of the microbial growth.

LEACHATE CONTROL

Leachate control discussed in this chapter emphasizes on the concept of containment systems to prevent water input from entering the landfill body and controlling leachate infiltration from polluting the soil, groundwater and surface water bodies. The topic involves various approaches for an effective containment strategies including on the managerial aspects; all the way down to the technical and engineering scopes. It also addresses current issues on leachate usage within the landfill boundary such as leachate recirculation that has been adopted by various landfill contractors and common problem that need to be coped for a full working containment of the landfill leachate.

Landfill Management Practice

Main contributions on leachate generation come mostly from the deposited waste and the waste that will be disposed. Management practices that allow the settlement of deposited waste and incoming waste stream could very well be employed in regulating the flow and amount of generated leachate. From legal perspective, the strict leachate control measures are primarily focused to prevent the leakage of leachate from the landfill and thus to avoid groundwater contamination (Davis &Masten, 2004). Without proper controls, infiltration by the rainwater has a very high potential to transfer pollutants from the landfill site to nearby lakes and streams. Moreover, soluble and partially soluble substances can be easily leached out from the waste site by rainwater becoming the leachate that can contaminate underground aquifers (Weiner & Matthews, 2003). Apart from preventing rainfall infiltration, the influence of soil cover could also involve upon the hydraulic resistance, smoothing between the rainfall event, evapotranspiration and the storage capacity to hold the rainfall volume. For practical purposes, neuron probe can be used to measure the soil moisture content whereas water infiltration through the soil cover can be detected using lysimeter. However, only the top shallow layers of soil that consist of the upper 0.3 m (Booth & Price,

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

1989) would have high fluctuation to seasonal change; making the soil moisture value having insignificant differences in the respect to time and rainfall events (D. Bendz, et al., 1997). Evapotranspiration can be assume to be similar as regional evaporation for a landfill with thick soil cover and good surface vegetation (H-J Ehrig, 1989); allowing taking the value of potential evaporation according to Penman's definition. Though it is generally difficult to predict the movement of escaped leachate accurately, however, the main controlling factors are the surrounding geology and hydrogeology. Escaping to the surface water may be relatively easy to control, but if it escapes to groundwater sources, it can be very difficult both to control and clean up.

Because of the possible potential risk involved in allowing leachate to percolate to the groundwater, its elimination or containment would be the best practice that needs to be employed. The best way to control leachate is through prevention that needs to be considered and systematically integrated into the site design. Under the Subtitle D rules (40 CFR 258) promulgated by EPA, new landfill must be lined in a specific manner or meet maximum contaminant levels for the groundwater at the landfill boundary (Davis &Masten, 2004). In most cases, it is necessary to control the potential liquid access, collection steps and required treatment using the following steps in implementing landfill liners as suggested by Ramachandra (2006).

1. **Natural Liners:** These refer to compacted clay or shale, bitumen or soil sealants, etc and are generally less permeable, resistant to chemical attack and have good sorption properties. They generally do not act as true containment barriers, because sometimes leachate migrates through them.
2. **Synthetic (Geo-Membrane) Liners:** These are typically made up of high or medium density polyethylene and are generally less permeable, easy to install, relatively strong and have good deformation characteristics. They sometimes expand or shrink according to temperature and age.
    - Natural and geo-membrane liners are often combined to enhance the overall efficiency of the containment system

Weiner and Matthews (2003) suggests adaptation of a contoured system for leachate collection at the landfill to secure leachate infiltration as shown in Figure 6. Such system is to promote leachate movement from the waste to the pumps for extraction with active drainage toward the surface and subsequent treatment. The arrangements are divided into three levels. In level 1, one or more pumps direct the collected leachate to the surface toward the readily available treatment technologies for the leachate, including:

1. **Sorbent Material:** Carbon and ash fly packed inside a column through which the leachate is allowed to pass through.
2. **Packaged Physical-Chemical Units:** Numerous units could very well includes chemical addition or pH adjustment before being induce for flash mixing controlled coagulation, flocculation, sedimentation, pressure filtration and reverse osmosis system.

Before a reliable leachate treatment system is established, tests must be carried out. All methods or treatment system that produces waste sludge must reach ultimate, end-point disposal.

Level 2 comprise of a secondary safeguard system made of another barrier contoured to provide a backup leachate collection system. This reacts as a fail-safe system in case of failure of the primary system. During breakdown of the level 1 system, the secondary collection system would take controls

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

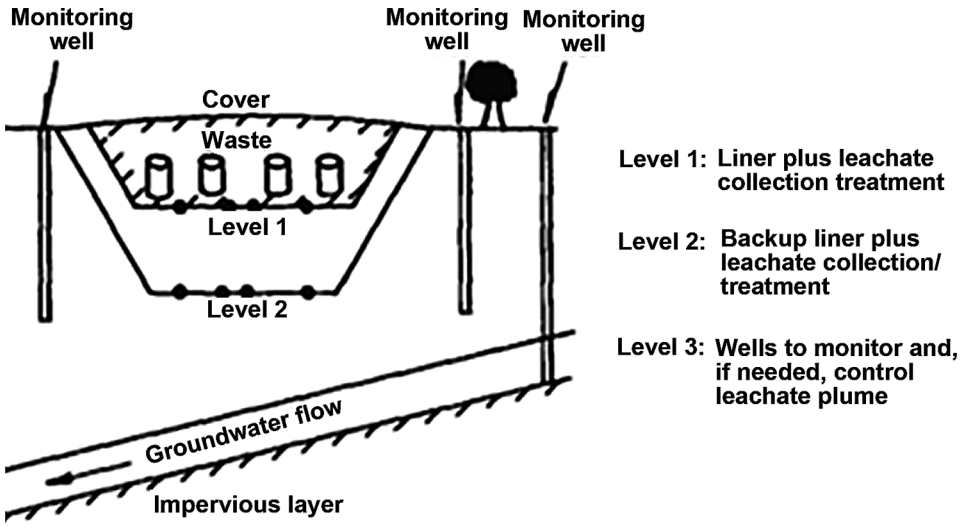
for directing and channeling the leachate to a pumping station, which in turn relates the leachate to the surface for treatment.

Finally, a secondary safeguard system (Level 3) is also advisable that would consists of a series of up gradient and down gradient discharge wells having the primary purpose for monitoring the groundwater quality in the area, and in worst case scenario, to control leachate plumes if the primary and secondary systems fail. For this purpose, the up-gradient wells will act to define the background levels of selected chemicals or recognized pollutants in the groundwater and to serve as a basis for comparing the concentrations of those chemicals/pollutants in the discharge from the down-gradient wells. Through this monitoring process, this system is able to function as an alarm mechanism if the primary and secondary systems fail.

Engineering Approaches

Commonly, landfill liners are used to limit or eliminate or restrict the movement of leachate and landfill gases from and out of the landfill site. The type of liner system selected will depend on a large extent on the local geology and environmental requirements of the landfill site. For example, in locations where there is no groundwater, a single compacted clay liner may be sufficient. In locations where both leachate and gas migration must be controlled, a combined liner comprising a clay liner and a geomembrane liner with appropriate drainage and soil protection layer will be necessary. Liners made of either impervious clay or synthetic materials such as plastics are used to try to prevent the movement of leachate into the groundwater. The seams have to be carefully sealed and a layer of soil is placed on the liner to prevent landfill vehicles and waste from puncturing it. Clay is favored for its ability to absorb and retain many of the chemical constituents found in leachate and for its resistance to the flow of the leachate (Tchobanoglous, Theisen, & Vigil, 1993). Synthetic landfill liners are useful in capturing most of the leachate but infiltration is still possible. No landfill is sufficiently tight that groundwater contamination by leachate is totally avoided. Wells have to be drilled around the landfill to check for groundwater contamination

Figure 6. Three levels of safeguard in hazardous waste landfills (Weiner & Matthews, 2003)



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

from leaking liners, and if such contamination is found, remedial action is necessary (Vesilind, Morgan, & Heine, 2004). However, the use of combine composite geomembrane and clay liners is gaining in popularity, especially because of the resistance afforded by geomembranes to the movement of both leachate and landfill gases. The characteristics, advantages and disadvantages of the geomembrane liners (also known as flexible membrane liners, FMLs) that have been used for MSW landfills are summarized in Table 4 and Table 5.

The objective of designed landfill liners is to prevent or eliminate leachate infiltration into the subsurface soils below the landfill so as to minimize the contamination risk of the groundwater. A number of liner designs have been designed and developed for that purposes and one of the proposed types of liner designs is as illustrated in Figure 7 for double layer system and Figure 8 for monofill layer system.

In the multilayer landfill liner design, each of the multiple layers has its own specific function in which the two composite liners react as a barrier to the flow motion of both the leachate and landfill gas. Meanwhile, the drainage layer is specifically design for the collecting all the leachate that were generated within the landfill. The final soil layer performs as the protective layer for the drainage and barrier layers. A geomembrane and clay layer employed into the composite liner designs will provide more protection and function more effectively in term of hydraulic compare to either type of liner alone. However, several options might be considered if leachate migration may occur at an old or existing landfill. These options include putting a cap on the surface on the landfill. The cap usually comprise of clay or a liner coated with topsoil seeded to grass to effectively provide some shade from precipitation; some sort of cutoff walls or dams keyed into an impermeable stratum to isolate the fill, pressure treatment, sealing of the bottom and sides of the fill; provide up gradient surface-water drains that goes through and around the landfill area; installed curtain drains or wells to counter and drain away the contributing groundwater flow, collection and recirculation of leachate with treatment of any excess, or in special cases, the ma-

Table 4. Landfill sealants for the control of gas and leachate movement (Tchobanoglous, et al., 1993)

Sealant		Remarks
Classification	**Representative types**	
Compacted soil	-	Should contain some clay or fine silt
Compacted clay	Bentonites, illites, kaolinites	The most commonly used sealant for landfills; these type of sealant would have a layer thickness varies from 6 to 48 in and the layer must be continuous to prevent any disfiguration of the protective layer and are not allowed to dry out or it would eventually cracked
Inorganic chemicals	Sodium carbonate, silicate or pyrophosphate	Use depends on local soil characteristics
Synthetic chemicals	Polymers, rubber latex	Experimental; use in field not well established
Synthetic membrane liners	Polyvinyl chloride, butyl rubber, hypalon, poluethylene, nylon-reinforced liners	Commonly used for leachate control; increased usage for control of landfill gas
Asphalt	Modified asphalt, rubber-impregnated asphalt, asphalt-covered polyethylene fabric, asphalt concrete	The layer must be sufficiently thick enough to maintain continuity under differential settling conditions as could be impose by the landfilling proces and leachate accumulation.
Others	Gunite concrete, soil cement, plastic soil cement	Not commonly used for control of leachate and gas movement because of shrinkage cracks after construction

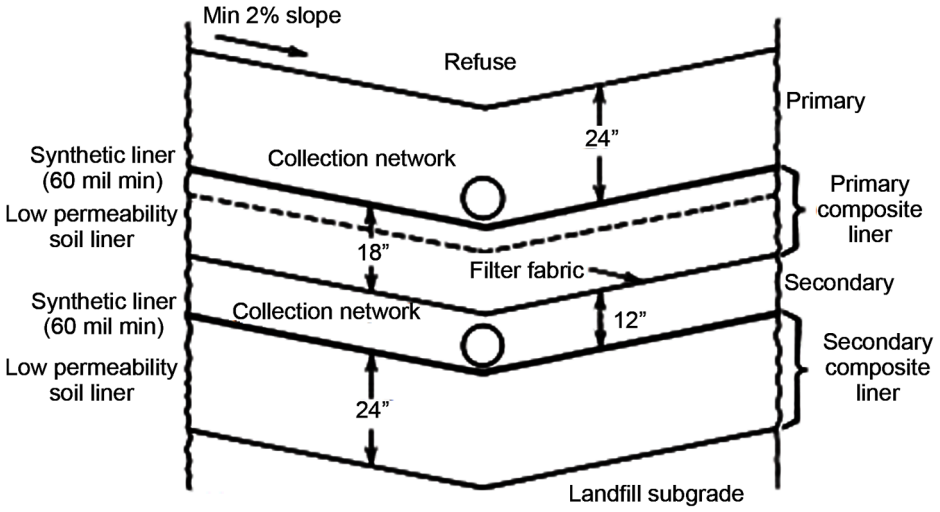
Table 5. Guidelines for leachate control facilities (Tchobanoglous, et al., 1993)

Item	Comments
Synthetic flexible membrane liners (FMLs)	Liners must be designed and constructed to contain fluids, which include wastes and leachates. For MSW waste management units, synthetic liners are not required. However, if this alternative is selected, synthetic liners must have a minimum thickness of 40 mils. These liners must be installed to cover all natural geologic materials that are likely to be in contact with waste or leachate at a waste management unit.
Bottom seals	No specific regulations exist governing the application of bottom seals at MSW waste management units. Design, construction and installation of bottom seals are subjected to the approval of the local enforcement agencies.
Artificial earthen liners	Clay liners are optional for MSW landfills. If required by site conditions, clay liners for MSW waste management units must be a minimum of 1 ft thick and must be installed at a relative compaction of at least 90 percent. A clay liner must exhibit a maximum permeability of 1 x 10^{-6} cm/s. Clay liners, if installed must cover all natural geologic materials that are likely to be in contact with waste or leachate at a waste management unit.
Subsurface barriers	A subsurface barrier is intended to be used in conjunction with the readily available, natural geologic materials of the landfill site to assure that lateral permeability standards are satisfied. Barriers may be required by regional agencies at MSW waste management units where there is high probability for lateral movement of fluid, including waste and leachate and by looking at the permeability aspect of the naturally obtained geologic materials that are used for waste containment in lieu of a liner. Barriers must be a minimum of 2 ft thick for clay material or a minimum of 40 mils for synthetic materials. These structures are required to be keyed a minimum of 5ft into the naturally obtained geologic materials that already tested and known to satisfy the permeability requirements being in the range of 1 x 10^{-6} to 1 x 10^{-7} cm/s. If a cutoff walls are to be used, excavations of the waste management units must also be keyed into the natural geologic materials that exhibiting permeability properties lower than 1 x 10^{-6} cm/s. These barriers are required to have fluid collection systems in the up gradient position to the structure. Buildup of hydraulic head against the structure need to be prevented through properly designed, constructed, operated and maintained systems. For continuous maintenance, the collection system itself must be inspected regularly and required that the accumulated fluid is constantly removed.

Figure 7. Double-bottom composite liner systems



Composite liner = Synthetic liner + Low permeability soil

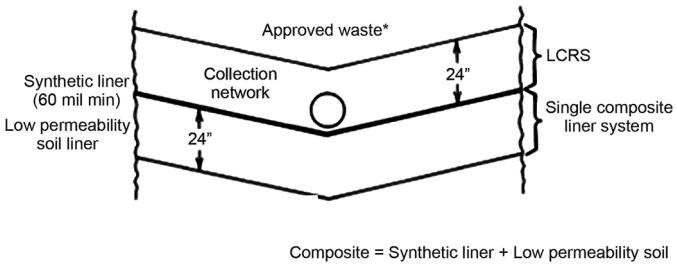
Figure 8. Monofill waste landfill liner configuration



terial in the landfill can be excavated, treated, recycled, and/or disposed of at a controlled landfill site. However, excavating of an existing landfill might pose some other problems if hazardous wastes are involved and hence must be carefully conducted from the very beginning (Nemerow&Agardy, 2009).

Apart of the designed and installed liner system, a continuous groundwater-monitoring program is essentially important for confirming the integrity of the liner system. At an early stage of site preparation, therefore a number of monitoring boreholes that needs to be provided around the site, inside and at the boundary of the landfill area. However the location, design and number of boreholes depend on the size of the landfill which need to look at the background of the area geological aspect such as the proximity to an aquifer and on the operation of the landfilling, for example on the types of waste deposited. Installation of a double liner system can make the monitoring exercise more accurate and easier to perform but it does not necessarily required excessive data analysis. Study by Sizirici and Tansel (2015) revealed that by proper adjustments in the sampling strategy could reduce the amount of collected data up to 97.7% through the mean of concentrating the monitoring point for aligned wells and suitable monitoring depth for selected contaminants in interest. However, for better maintenance and efficiency, the water should be regularly flushed through the secondary leachate collection system in order to maintain the stability of the system. In the case of the flushed water found to be polluted, the primary leachate carrier will be damaged and the collected leachate must be transported to the leachate treatment facility if the repair is unattainable (Ramachandra, 2006).

Leachate Collection System

Properly designed and managed leachate collection system should provide a good drainage of water balance in the landfill cell, both for controlling the leachate flow through the waste layer and more importantly preventing leakage into the surrounding environment. The basic elements of the leachate collection system consists of a drainage layer, leachate trench, collection pipes, leachate line clean-out ports, a leachate collection pump and lift station and a leachate storage tank (Bagchi, 2004; Ramachandra, 2006). All those components must be installed readily above the liner, prior before any waste is deposited. However leachate storage tank may not be necessary for a site in which the leachate is discharged directly to a sewer (Bagchi, 2004). In any case, particular care must be taken to prevent and maintain the drain and collection pipes from settling. During the landfill operations, waste cells are covered with soil to avoid additional contact between the waste layer and surrounding the environment but that soil layers have to be sufficiently permeable to allow downward leachate transport (Ramachandra, 2006) for the collection purposes. The leachate is discard out from the sump through piping that extending to the

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

ground surface of the active landfill area, prior for treatment and being disposed of in an environmentally acceptable manner. A leachate collection system must be designed and constructed accordingly because it could pose specific construction problem which would indefinitely result in the failure of the collection system. The sort of requirements that need to be considered including:

1. Using other specification of material than the ones in the approved design;
2. Neglecting to properly installed material specifically to the designated positioned and to follow the correct procedures specified in the design
3. Improperly clear out all the foreign objects (e.g. clumps of soil, rocks, construction debris) which would be left in drainage system piping and resulted in plugging or restrict leachate flow. It may not be able to be removed by using the designed maintenance procedures;
4. Improper usage of the construction equipment and improper placement of materials which cause damage to system components. Example: to be doing crushing or misalignment of pipes due to vertical loading of heavy equipment or dumping soil and siltation of filter or drainage layers causing unwanted up gradient drainage during construction and/or careless construction techniques; and
5. Non-conforming layout of the leachate collection system such as insufficient slope or the misalignment of piping joints or and over-elevations of piping/drainage.

The structural performance of the pipes depends on: a) the earth's pressure acting on the pipe (which is influenced by burial depth, overburden density and lateral confinement) b) the backfill configuration (i.e. whether the pipe is placed within a trench, mound or blanket) c) backfill material d) properties of the pipe and e) service conditions (e.g. temperature and chemical exposure). The functions of collection system according to Rowe et al.,(2004) are listed below:

A. For lowering the height of leachate mounding and seeps which then consequent minimized contamination of surface waters.
B. Maintaining the hydraulic gradient through the underlying barrier by reducing leachate head acting on the base of the landfill and by doing so, the Darcy velocity out of the landfill can be lowered down to an acceptable levels in many cases
C. Keeping the mass of contaminant presence within the leachate during the transport for removing contaminant from the landfill.

A leachate collection system is required above a liner in order to avoid build-up of the leachate head above the 1-ft (30.5 cm) level stipulated in the regulations. Leachate collection pipe is sized to handle the anticipated flow. A collection pipe is usually 6 inch (15 cm) in diameter, although some designers prefer an 8 inch (20 cm) diameter as a minimum (Oweis&Khera, 1990). The structural design of the leachate collection pipe depends on the vertical load on the pipe and bedding conditions. The types of pipes and their functions are as shown in Table 6.

A leachate collection and removal (LCR) system is designed for collecting leachate and to discard the leachate by flowing it out of the landfill for treatment process. The LCR system is need to be constructed by making sure that less than 30 cm of leachate accumulates above the composite liner as it is the allowable amount of leachate that the liner is designed to maintain according to Subtitle D. Therefore, the designing of a LCR system need to consider the following components:

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Table 6. Type of collection pipes (Oweis&Khera, 1990)

Pipes	Functions
Flexible pipes	Usually used in a leachate collection system. The load carrying capacity of such pipes is derived mostly from interaction with the surrounding bedding. Examples are plastic, steel and ductile iron pipes. Steel and ductile iron are susceptible to corrosion by leachate and perforations cannot be easily made
Plastic pipes	More common and may include polyvinyl chlorine (PVC), polyethylene (PE), acrylonitrile-butadiene-styrene (ABS) and others
Rigid pipes	Such as a concrete pipe (CP) derive mist of their strength from their inherent structure but are subject to chemical attack and perforations are hard to make. Corrosion-resistant rigid pipes such as vitrified clay also lack adequate bending strength. Because of all these limitation, rigid pipes are not normally used in a leachate collection system

1. **Area Collector:** The piping drain that covers the liner and collects the leachate. The area collector are also known as the blanket drain are designed to covers the entire surface of the geomembrane liner and collects the leachate accumulate over the liner. Typically, the area collector system is constructed with at least a 30 cm (12 in.) and the system is overlay with a layer of sand having hydraulic conductivity above 10^2 cm/sec. Alternatively, the blanket drain could also be constructed using geosynthetic drainage nets comprise of porous synthetic materials being applied over the geomembrane liner
2. **Lateral Collection Pipes:** The pipe network that collect and drains the landfill area. According to the U.S. EPA (1994), the regulatory limit of a 30 cm maximum liquid head above the liner cannot be achieved using an area collector alone which would require the need for collection laterals. The collection laterals are consisting of perforated pipes that direct collected leachate toward the sumps for removal purpose. During landfill operation, leachate are being directed to passes through the area collector, flow into the collection laterals before it would be finally drains to a sump and removed from the landfill. Polymeric pipes are by far the most common material for collection lateral but however, there are a number of appropriate materials that could be choose for the leachate collection systems. For that matter, HDPE and PVC are the kind of materials that were used exclusively and are available as either profiled or smooth wall construction.

Basically, the design of perforated leachate collection pipes must take into account on the stated issues:

A. The estimated leachate flow
B. Selected pipe sizes
C. The maximum allocation for pipes spacing
D. The physical and structural strength of the pipe
E. Allowable maximum range for drainage slopes

Spacing of the collection pipe being laid laterally would depend on the permeability of the collection pipes, the assumed entry rate of rainfall and the slope of the liner beneath the landfill area. The pipes need to be allocate closer if the permeability is lower. However, the slope of collection laterals should be greater than 2% as it would need to react as cleansing mechanism by achieving adequate flow velocity to clear the flow path the pipes and also prevent any kind of reverse flow within the pipelines.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

3. **Sump:** The low point where the leachate exits the landfill. In the composite liner system, sumps are usually located in the engineered low points and are constructed for the purpose of collecting leachate. Sumps are also often designed with an additional layer of geomembrane to cater for the seam-testing sumps difficulty. The leachate collection and removal standpipe must be extended through the entire landfill from lowest liner to the cover to capture leachate from the each landfill cell, and then through the cover itself. It must be maintained for the whole post closure care period whether it going to be for the next 30 years or longer.
4. Storm water and leachate separation system.

As polluted leachates appears shortly after disposal of the waste that may cause groundwater pollution and pollution of streams through sub-surface migration; liners, drainage collection, treatment of leachate and groundwater and downstream water quality monitoring are necessary to control this problem (Ramachandra, 2006). Other than the design aspect, leachate collection system would have to consider the possibility of clogging experienced within the drainage system especially for long usage duration throughout the landfill life and even after the landfill is closed. The leachate collection and removal system should be designed to be accessible for routine and constant maintenance and for the purpose of cleaning especially due to the potential for biological film clogging. It is shown that landfill producing leachate with high concentrations of organic matter (referred as COD), calcium and pH value of 7 would be highly exposed to clogging due to the anaerobic bacteria activities (Brune, Ramke, Collins, &Hanert, 1994). It was proposed that clogging is a result of mobilization processes which involve fermentative, iron and manganese-reducing bacteria followed by precipitation processes involving sulphates-reducing and methanogenic bacteria. The clogging could underlay the stone drainage blanket with significant amount of soft black slime and occupy most of the void space after 1 to 5 year exposure to the leachate (R. Rowe, et al., 1997). Field studies also had shown the increase in clogging rate caused by leachate recirculation because the system promote deposition of suspended particles, biomass growth and mineral precipitation (Feng, Cao, Zhang, &Xie, 2015a).

Leachate Recirculation

Leachate recirculation is one of the simplest forms of leachate control through the process of reintroducing collected leachate back into the landfill. It is useful in controlling the leachate volume whilst accelerating waste decomposition through addition of supplemental liquids. Recirculation of leachate also seems to facilitate in reducing the hazardous nature of leachate (Ramachandra, 2006). Leachate recirculation is known to be effective in enhancing biodegradation because the process is capable in increasing the moisture and movement of moisture (which carries nutrients). But observation by Barman et. al (2015) reveal that nutrients (sodium, calcium and potassium) leaching might be more dominant compared to nutrient trapping for higher ponding depths and higher inflow recirculation rate. Increasing the moisture content and flux in landfill waste layer would create a suitable environment for the organic waste degradation by microbes because initial moisture is not sufficient (Benbelkacem, Bayard, Abdelhay, Zhang, &Gourdon, 2010). Furthermore, the leachate percolation by the recirculation process would have a significant effect on the mobilization that accelerates solid-mass transfer, improves substrate accessibility and enhances degradation of the waste soluble organic matter (Benbelkacem, et al., 2010; Chugh, Clarke, Pullammanappallil, & Rudolph, 1998). It is assumed that the leachate addition would also react by softening the porous waste material, increase unit weight of the waste, lubricating the waste contact

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

and promote biological degradation. Bae et al. (1998) also found agreement data which reported that leachate recirculation is capable for increasing the moisture content in a controlled bioreactor system and provided overall distribution of nutrients and even valuable enzymes between methanogens and solid/liquids. In physical sense, it promotes the loss of leachate as water vapor and through consumption by the organic waste degradation process.

Various methods existed for leachate recirculation purposes that would include surface or spray irrigation, vertical injection wells, horizontal trenches and infiltration ponds (Feng, S.-J., Cao, B.-Y., Zhang, X., & Jiao, Y., 2015b). However, all those leachate recirculation procedure has to be carefully designed in preventing unnecessary consequences and to induce optimum benefit from the process since waste stabilization and biodegradation of the organic matter can be accelerated by leachate recirculation. Establishment of early gradual recirculation would promote the presence of active anaerobic biomass which are important for biological processes in each landfill cell. In legal term, RCRA Subtitle D allows leachate management by recirculation for modern landfills with a regulated composite liner and a leachate collection system (Oweis&Khera, 1990).Controlled leachate recirculation would include nutrient addition to maintain optimum moisture and pH, breakdown organics that could be exhibited through reduction of the total organic carbon (TOC) and chemical oxygen demand (COD), can enhance anaerobic microbial activity for converting solid waste organics to methane and carbon dioxide as well as encourage precipitation of heavy metals. With the aid of the process, rapid and complete biological stabilization could even be achieved within four to five years. For a landfill being design for leachate recirculation should, as a minimum requirement, would need to install a conservatively designed liner system and proper system to effectively maintained leachate collection, removal, and recirculation distribution system. Apart from that, it would at least required a venting system or in addition to a gas collection system. A double liner system with leak detection monitoring wells is suggested that would enable the landfill owners or the regulatory agencies to closely monitor the liner system performance since the leachate recirculation would accelerate fill stabilization and also increase the strength of the already concentrated leachate composition. A final site closure would definitely require the need for implementation of a relatively impermeable crowned cap and surface-water drainage system.

Improper leachate recirculation would impose problems indicating by the lab test using high recirculation rate (Sponza&Ağdağ, 2004) such as flooding, pooling or clogging especially at high precipitation area (Šan&Onay, 2001). Therefore, the optimal recirculation should be designed properly to be close but not exceeding the waste field capacity. For unsorted domestic waste, it is suggested that 50% w/w of moisture content maybe the optimal value (Gurijala&Suflita, 1993) and it might not be suitable for fresh waste or for methane production purposes since accumulation of volatile fatty acid or ammonia nitrogen could inhibit the methanogenesis process (Price, Barlaz, & Hater, 2003). As for the recirculation volume concern, a study on the leachate recirculation reveals that high volume leachate addition does not have significant effect on the leachate accumulation at the bottom liner (Abichou, et al., 2013) and high volume is required for the periodical injection to ensure uniform distribution of humidity in waste layer (Benbelkacem, et al., 2010). In term of temperature value, heating of recirculated leachate to 30°C has been found to accelerate the stabilization process (Nemerow&Agardy, 2009).

The most common methods being used for simulating the effect of recirculation upon bioreactor landfills are vertical wells and horizontal trenches (Jain, Townsend, &Tolaymat, 2010). In most cases, horizontal trenches are more common in modern landfill liners except for when vertical well are installed dues to the cost inefficiency or the difficulty in installing the horizontal trenches. Feng et. al (2015a) had simulated the effect of recirculated leachate volume and the influence upon waste layers using vertical

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

wells. The study found that leachate recirculation had significant effect by gradually decreasing the void ratio and hydraulic conductivity of the waste being measured through the pore water pressure as one of the most important factor related to landfill slope stabilities. The study concluded that the influence width of leachate recirculation is a function of waste settlement, leachate injection pressure head, initial void ratio, unit weight, and compression coefficient and biodegradation rate. Khire and Mukherjee (2007) recommended that the maximum influence width will be reach in 25 - 45 days and center-to-center spacing between wells should obtained above 90% for the degree in saturation, to eliminate dry zones between adjacent wells. Apart from that, such studies also needs to consider the difficulties in representative measurement of water content and hydraulic properties of municipal solid waste (McCreanor& Reinhart, 1999) because of the anisotropic and heterogeneous material with complex biochemical properties.

CONCLUSION

It can be conclude that the hydrological phenomena occurring from outside, into and through the landfill layers dominate the processes inside the landfill in so many ways. The leachate generation alone comprise of multiple factors coming from physical (precipitation, infiltration, transpiration and etc.) as well as being influenced by the biological and chemical interactions. Consecutively, those generated leachate would latter play an important role forthe organic portions degradability and stability of the waste layer affected through the different forms of flows movements, either horizontal or vertical channelling. The most prominent type of flow channels that need to be highly regard are the preferential flow paths apart from other flow paths and all those flow channels need to be correctly model or estimate depending on the physical characteristics of the heterogeneous waste stream, which are totally different that soil properties. The leachate movement in the multichannel flows brought not only the moisture down to the landfill base but also transporting along the contaminant constituents. In the end, effective prevention and control measure were required to completely contain the leachate for prior treatment process. Plus, those systems had to be well maintain and sufficiently controlled for a long run even after the landfill closure; especially for inducing leachate recirculation system which in part function well for minimizing the leachate quantity whilst simultaneously making good use of the leachate organic constituent to speed up the degradation of the waste layer.

Chapter 43
Bioremediation of Agricultural, Municipal, and Industrial Wastes

Shivani Garg
Kurukshetra University, India

ABSTRACT

Growth of agriculture and manufacturing industries has resulted in increased a wide range of complex and hazardous compounds to the environment. Excess growth of hazardous waste has led to reduce availability of clean water and disturbances of soil thus limiting crop production. Waste generated from different sources like Industrial, domestic and agricultural etc. having different kinds of chemical compound i.e. organic or inorganic. Traditional methods are not able to deal with some of these chemical compounds. Bioremediation process is good option in such environmental problems. Bioremediation provides a technique for cleaning up pollution by enhancing the natural biodegradation processes. It treats such waste with the help of microorganism. Number of microbes including aerobes, anaerobic and fungi are involved in bioremediation process. Specific types of microbes are used to treat specific type of chemical contaminant. The chapter include all the techniques of bioremediation used to treat different kinds of contaminant.

INTRODUCTION

Ecosystems are threatened with natural environmental changes and disturbances that remove biomass from a community, such as fire, flood, drought, or predation over time and geographic space. (Levin, 1992) These disturbances needs new techniques emerge out of the patchwork of natural experimentation and opportunity implying a good measure of ecological resilience are a cornerstone theory in an ecosystem (Folke et al., 2004). The most common types of waste can be categorized into four types: agricultural, industrial, municipal and nuclear (Alloway, 1995). Agricultural waste, have both natural and non-natural wastes, is a general term used to describe waste produced from the fields through various activities. Agricultural wastes are the by-products of various agricultural activities such as crop production, harvesting of crops, saw milling, agro-industrial processing, and others. In India sugar industry alone produces about 90 MT of bagasse per year and being used in the manufacturing of insulation boards, wall panels,

printing paper and corrugating medium (Sengupta, 2002). Generally, agricultural waste is produced in two forms- solid and liquid waste. The food harvesting and production industry generate crop residuals, as well as pre- and post- consumer food wastes. Some of the farmer burn agro- wastes after harvesting time; this causes a huge amount of air and land pollution. Municipal waste (MSW) composition can vary considerably with places and time depending on many factors, including socio-economic, climatic conditions, living standards, waste collection, and disposal methods, sampling and sorting procedures. MSW is heterogeneous in nature and have a number of different materials derived from various types of activities. Municipal waste generated from residential and domestic sources. This type of waste is commonly called trash or garbage and includes everyday items, spoiled food, broken things, or simply any item a person no longer needs or wants. The most commonly disposed of items as municipal solid waste are paper, yard trimmings, food, plastics, metals, rubbers, and textiles. In recent years, the amount of electronic waste, also known as e-waste, has increased drastically as people become more dependent on electronics, such as cell phones and computers that are replaced and disposed of frequently. Based on the definition of municipal solid waste, the waste that you dispose of everyday would fall into this category. Municipal solid waste categorized into two types: garbage and rubbish. Garbage or food waste is the animal and vegetable residue resulting from the preparation, cooking and serving of food. These wastes contain organic matter and moisture. Kitchens, restaurants, and markets are sources of garbage. Rubbish consists of old tin cans, newspaper, tires, packaging materials, bottles, plastics etc. Both combustible and non-combustible solid wastes are included in this category but do not include garbage. Trash is the combustible portion of rubbish. The rise in the number of industries producing glass, textile, leather, plastic and metal products food, and electronics, has significantly contributed to waste production. Rapid industrialization has resulted in the generation of a huge quantity of wastes, both solid and liquid, in industrial sectors such as fruit and food processing, pulp and paper, sugar, sago / starch, distilleries, dairies, tanneries, poultries, etc. These wastes are generally dumped on land or discharged into water bodies, without adequate treatment, so pollute environment and cause health hazard. In a broad sense, industrial wastes could be classified into two types i.e. Hazardous wastes and non- hazardous wastes (Table 1). Hazardous industrial wastes in India can be categorized broadly into two categories: Hazardous wastes generated from various industries in India and Hazardous industrial wastes imported into India from Western Countries for re-processing and recycling. Hazardous waste, in particular, includes products that are explosive, flammable, irritant, harmful, toxic, carcinogenic, corrosive, infectious, or toxic to reproduction. The other one is Non-hazardous or ordinary industrial waste that generated by industrial or commercial activities but is similar to household waste by its nature and composition. It is not toxic, hazardous and requires no special treatment. In particular, it includes ordinary waste produced by companies, shopkeepers and tradespeople (paper, cardboard, wood, textiles, pack, etc.). Due to its non-hazardous nature, this waste is often sorted and treated in the same facilities as household waste.

Bioremediation involves use of microbes to detoxify and degrade environmental pollutants. Recently, research is being focused in the development of genetically modified microbes or consortia for the detoxification of environmental pollutants. Microbes degrade the complex substances to simpler one that can be reuse or recycle in environmental processes. Microbes involved in the degradation naturally are aerobic or anaerobic bacteria, fungi or algae. Most of the techniques in bioremediation are aerobic in nature, but anaerobic processes are also being developed to help degrade pollutants in oxygen deficit areas (Franchi et al., 2016). In bioremediation processes, microorganisms use the contaminants as nutrient or energy sources (Hess *et al.*1997; Agarwal, 1998; Tang et al., 2007). Bioremediation is a process by which microorganisms are stimulated to rapidly degrade hazardous organic pollutants to environmentally safe

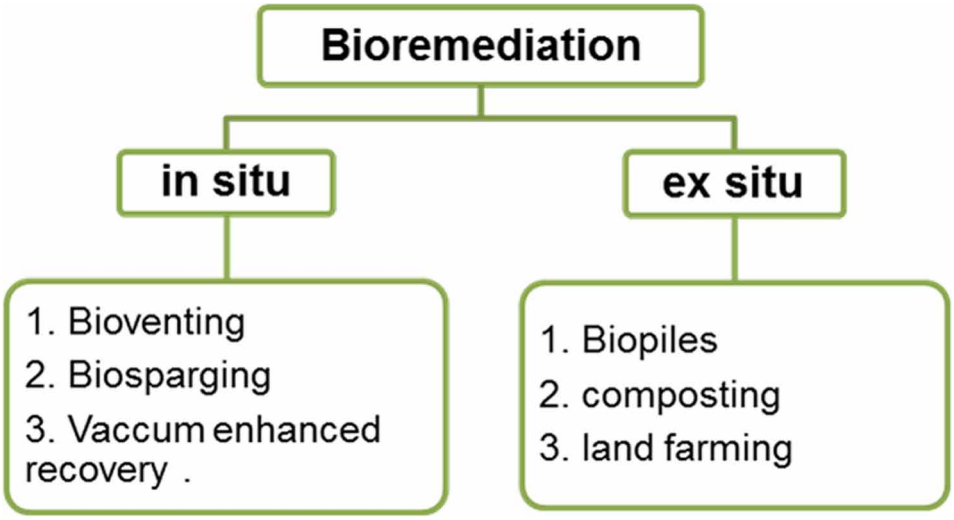
Table 1. Different types of industrial waste classified on the basis of their composition

	Hazardous Waste Component	Sources
Heavy Metals	Arsenic	Mining, non-anthropogenic geo-chemical formation
	Cadmium	Mining, fertilizer industry, battery waste
	Chromium	Mining areas, Tanneries
	Lead	Lead acid battery smelters
	Manganese	Mining areas
	Mercury	Chloro-alkali industries, healthcare institutes
	Nickel	Mining, metal refining
Hydrocarbons	Benzene	Petrochemical industries, solvents
	Vinyl chloride	Plastics
Pesticides		Insecticides
Organic chemicals	Dioxins	Waste incineration, herbicides
	PCBs	Fluorescent lights, e-waste, Hydraulic fluid

levels in soils, sediments, substances, materials and ground water. Environmental parameters should be favourable for microorganisms to grow and remediate the pollutants at a rapid rate (de la Cueva et al., 2016). Bioremediation is currently being used to reduce the organic chemical waste content of ground water, soils, effluent from food industry and chemical plants, sludge from petroleum refineries and oil spills in the ocean. Bioremediation techniques fall into two categories — in situ and ex situ bioremediation. Using bioremediation technology TERI, India, has treated 48,914 tons of waste oily sludge in batches at various oil refineries in India (Mandal et al., 2012). Bioremediation is concerned with the biological restoration and rehabilitation of historically contaminated sites and with the clean-up of areas contaminated in more recent times, either accidentally or incidentally, as a result of the production, storage, transport, and use of organic and inorganic chemicals. The uses of plants can improve bioremediation rates as plants provide habitats to microbes; improve soil porosity and help in cycling of micro nutrients with their microbial metabolism. In return, microorganisms improve plant growth by reducing soil toxicity, producing plant growth promoting metabolites, provide plant nutrients by sequestration from soil etc. (Gkorezis et al., 2016)Some examples of bioremediation technologies are phytoremediation, bioleaching, bioventing, bioreactor, land farming, composting, bio augmentation, rhizofiltration, and biostimulation. The biological approach of remediating the environment with the help of bioremediation, defined as *'the process that use biological agents to reclaim waters and soils contaminated by hazardous substances to human health and the environment'* (Atlas and Pramer, 1990). Bioremediation is an option that offers the possibility to destroy or render harmless various contaminants using natural biological activity. Industrial waste contains much kind of organic and inorganic components. Wastes produced from different sources may be in solid, liquid or gaseous form. Treatment of different types of wastes is done with the help of processes listed in Figure 1. All the techniques require specific type of conditions such as, microbial profile, energy source and electron acceptor, moisture and pH, nutrients and temperature, absence of toxicity, removal of metabolites, absence of competitive microorganisms, etc. for digestion and degradation. Some of the processes are explained below which are used for the treatment of agricultural, municipal or industrial waste. The main objective of this chapter to study and

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 1. Different strategies used for management of wastes with bioremediation



find out the different bioremediation processes which is effective in dealing with agricultural, municipal and industrial waste disposed or present in the environment and cannot be degraded by conventional processes or naturally without harming the environment.

BIOREMEDIATION OF AGRICULTURAL WASTE

There are two main methods of bio remediating agricultural waste. The first method is anaerobic digestion. The other method is composting, an aerobic process where microorganisms break down the organic material in the waste when air and water are added to the waste product. Following processes are involved in the management of agricultural waste with the help of bioremediation process which are commonly used:

- Anaerobic digestion,
- Composting,
- Vermicomposting,
- Biogas production,
- Biopile,
- Land farming, etc.

Digester systems consist of a vessel in which the waste is heated to a certain temperature, to allow the microorganisms to consume at an efficient rate. The method in which this is done varies widely, from using simple composting piles to composting vessels. Yet another option is to combine one or more composting methods to produce the desired composition of compost. All the techniques are used for bio remediating agricultural waste explained in detail below.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Anaerobic Digestion

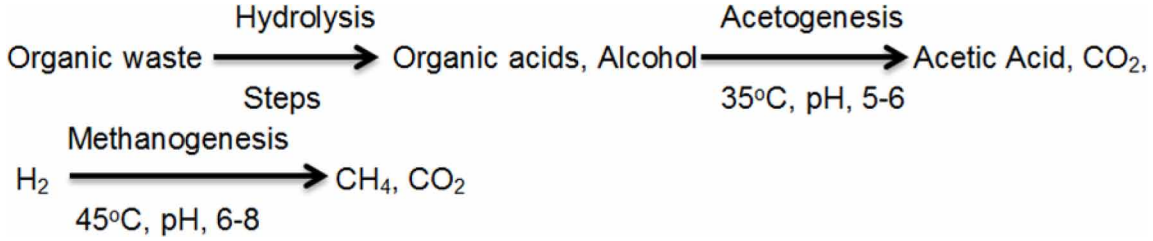
In this process about 95% of biodegradable carbon is decomposed into biogas and the rest 5% into biomass. Three main steps are involved in the breakdown of organic waste under anaerobic conditions. These steps essentially hydrolysis of biopolymers to monomers, fermentation of monomers to volatile acids and Methanogenesis. The microbial species responsible for anaerobic degradation are *Actinomyces, Arthrobacter, Citrobacter, Escherichia, Lactobacillus, Micrococcus* etc. Anaerobic treatment is a biological process carried out in the absence oxygen for the stabilization of organic materials by conversion into methane and inorganic end-products such as CO_2 and NH_3. Anaerobic process is of two types: anaerobic fermentation and anaerobic respiration. In anaerobic fermentation, the product obtained by accepting the electrons released during breakdown of organic matter and ethanol is also produced along with energy. Anaerobic respiration is used mainly by prokaryotes that live in environments devoid of oxygen. In this process, energy is used by the reaction for degradation of organic material. General process of anaerobic digestion of organic agricultural waste is as follows

There are four different types of anaerobic wastewater treatment bioreactors which are anaerobic filter reactor, anaerobic contact process reactor, fluidized bed reactor and up flow anaerobic sludge blanket (UASB). Most commonly used bioreactor is up flow anaerobic sludge blanket (UASB).

Up Flow Anaerobic Sludge Blanket Reactor (UASB)

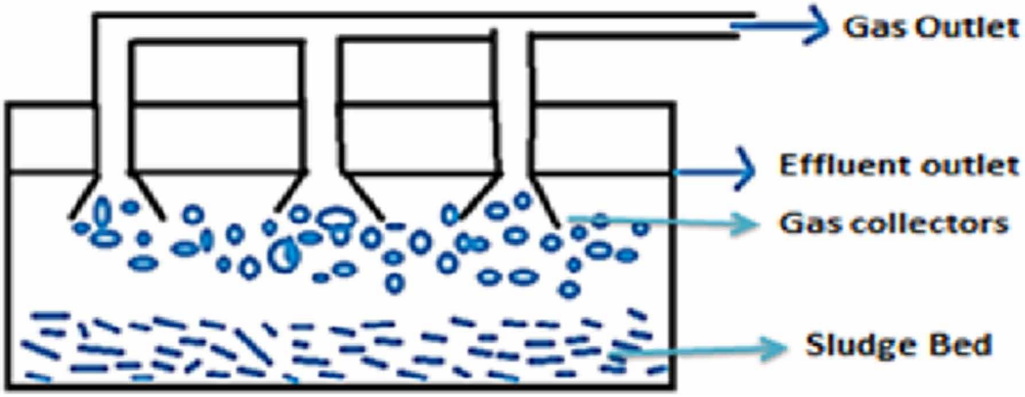
UASB reactors can treat all type of high-strength wastewater. It can be used at large-scale (e.g. agro-industrial wastes) or as decentralised treatment systems for domestic wastewaters; yet domestic treatment is still relatively new and not always successful as domestic wastewater generally lower strength. Anaerobic treatment systems such as UASB do not require an energy consuming aeration system and can be built simply than aerobic process. This process converts the organic matter into biogas, which can be recovered. The nutrient-rich effluent can be used for agricultural irrigation. Sludge, even is partly stabilised (mineralised) and can be used as an organic soil fertiliser after composting or drying. The UASB reactor is a methanogens (methane-producing) digester that evolved from the clarifier. UASB uses an anaerobic process whilst forming a blanket of granular sludge which suspends in the tank. Wastewater flows upwards through the blanket and is processed (degraded) by microorganisms. The upward flow combined with the settling action of gravity suspends the blanket with the aid of flocculants. The blanket begins to reach maturity at around 3 months. In the absence of any support matrix, the flow conditions create a selective environment in which only those microorganisms, capable of attaching to each other, survive and proliferate (Figure 2).

Figure 2. Process of anaerobic digestion of organic agricultural waste



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 3. General model of up flow anaerobic sludge bioreactor for treatment of wastewater



Eventually the aggregates form into dense compact biofilms referred to as "granules". The government of India has made a major commitment to anaerobic treatment technology in its national river basin improvement program. As of 1996, 13 new anaerobic treatment plants, with an aggregate treatment capacity of over 306 MLD are under construction in India. Anaerobic waste water treatment is the most popular method, cheaper for treatment of high strength waste water; produce energy is in the form of biogas and required very small space for installation than aerobic treatment. Biogas produced form this technique can be used for domestic or commercial purposes in household industries. This technique usually used for the treatment of liquid waste i.e. wastewater generated from agricultural land or domestic area dependent on agriculture for their occupation, sewage waste and industrial effluent. It could be recognised by some newly developed European waste treatment systems that some microbial degradation or transformation occur only in the absence of oxygen. Under anaerobic conditions, microorganisms growing on wastes can produce valuable fuels. The dry anaerobic composting process converts the organic fraction of biodegradable organic waste and refuse into energy in the form of biogas (methane and carbon dioxide) and humus- like material (Figure 3).

Figure 4. Natural method of Biogas production and uses of biogas in electricity production

Composting

Composting of manure is a valuable management tool that increases the flexibility for land application and storage, while significantly reducing the potential for contamination to soils and water that might occur if raw manure were to be improperly stored or land spread. Composting of carcasses should be restricted to poultry and small animals. Composting systems should be located at least 90 metres from a water course or a water body. Proper management of the composting system is required to ensure optimum conditions are maintained for decomposition. It is a self-heating, substrate-dense, managed microbial system and one solid phase biological treatment technology which are suitable to treatment of large amount of contaminated solid materials. It is a biological process where fresh organic wastes are allowed to be decomposed into humus like substance. The process is conducted by a complete automatic system which consists of several steps: dumping of refuse into a container, metallic particles removed by magnetic separator or mechanically, and then material is transferred to wet condition to a rotatory cylinder, analogous to a rotatory drier. The cylinder rotates slowly on large tyres and the wastes move from one end to the other. They are thoroughly mixed and pulverized by abrasion. Air is introduced at low pressure throughout the length of the cylinder. The hazardous compound reported to disappear through composting include aliphatic and aromatic hydrocarbons and certain halogenated compound. Composting can be done in- open system i.e. land treatment and closed system. The open land system is inexpensive treatment method but the temperature fluctuates from summer to winter. Therefore, rate of biodegradation of waste material declines. Secondly, land treatment system may become oxygen limited, depending on amount of substrates, depth of waste application etc. However efficiency of open treatment system can be increased by passing air. This approach is referred to as engineered soil piles and forced aeration treatment. Closed treatment system is preferred over the open land treatment system because controlled air is supplied to maintain the microbial activity. As a result of microbial growth and volatilization of hazardous compounds, increase internal temperature gradually. Therefore, use of blower for air circulation and exhaust for removal of toxic volatile are set up in closed treatment system. Ventilators supply O_2 and remove heat through evaporation of water. The main products of the biogas plants are fuel gas and organic manure (Figure 4). Biogas is a flammable gas. Composition of biogas is methane, carbon dioxide, hydrogen, nitrogen and hydrogen sulphide.

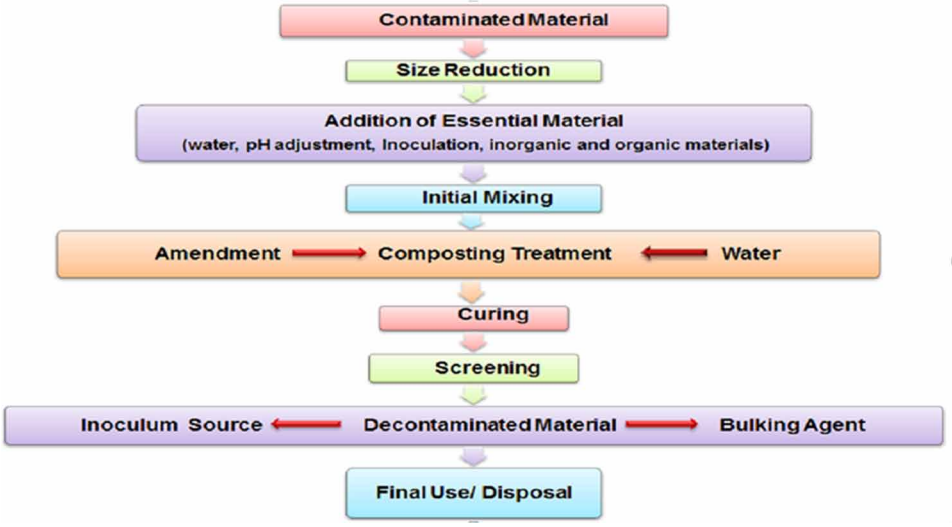
In several parts of India, compost plants are in operation for example, in Ahmedabad, Kolkata, Mumbai, Chennai, Delhi, Pune and Hyderabad. Compost has been used by Indian Agricultural Research Institute (IARI) to produce blue green algae- coated granulated compost.

Vermicomposting

Vermiculture or use of earthworm in biotechnology, where the earthworm feed on and degrade a variety of organic waste, eliminate toxic elements and convert the waste into vermicompost which is high- grade, nutrient- rich compost and a very significant bio fertilizer and soil conditioners. Vermicomposting enhances soil productivity and increases crop yield. Over 3000 species of earthworm have been identified from different parts of the world out of which 385 species have been found in India. The useful species found in India are *Lampito mauritii, Dichogaster boloui, Drawida willsi I etc.* The most important effect of earthworms in agro-ecosystems is the increase in nutrient cycling, particularly nitrogen. Lorimor et al. (2001) concluded that, in comparison with conventional composting system (as commonly used

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

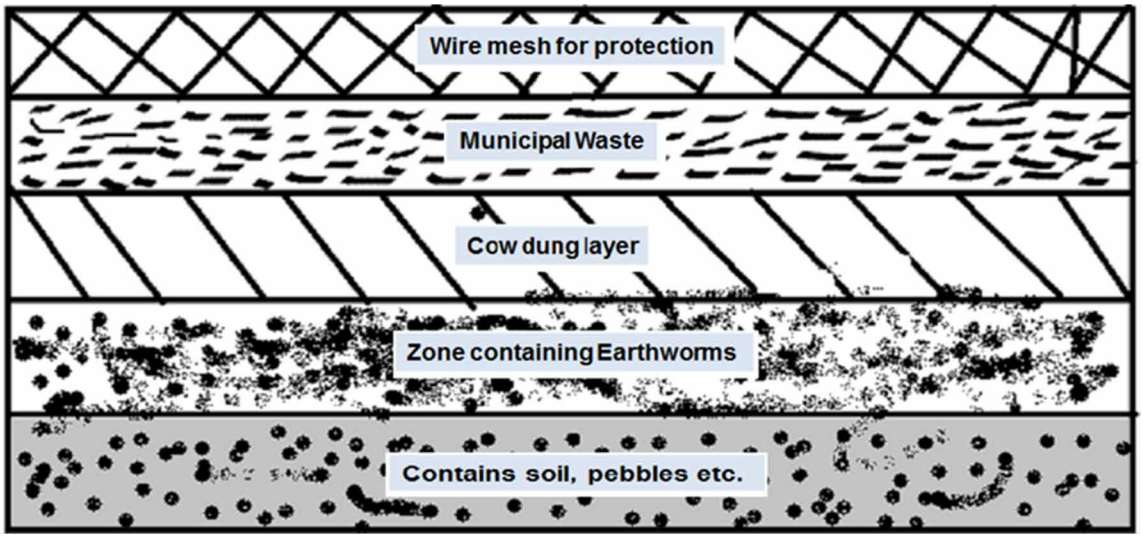
Figure 5. Flowchart of composting treatment sequence
Hogan,1998.



in India to manage crop residues and other related wastes), the vermicomposting often results in mass reduction, in shorter time for processing, and produce more humus with reduced phytotoxicity in ready material, i.e., vermicompost (Figure 5).

The crop residues amended with cattle dung in different ratios in order to produce three feed mixtures. The mixed substrate material served as bedding as well as feed for the earthworms. Earthworms alter the chemical properties of the substrates and indirectly promote microbial propagation and colonization, resulting in higher mineralization rates in vermicomposting beds than general composting (Suthar, 2008). It was concluded that the vermicomposting process accelerates the mineralization rate and subsequently

Figure 6. General model of vermicomposting pit for treatment of municipal waste



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

enriches the end product with more available forms of plant nutrients. Earthworms keep on turning the material through different layers and decompose the organic material. It takes about 45 days to make vermicompost, which is a black granular material.

Biopiling

It is a hybrid form of composting and land farming. Bio pile treatment is also known as bio cells/ bio heaps/ bio mounds/ compost piles which are used to reduce the concentration of petroleum hydrocarbon constituents in soil through the use of biodegradation. This technology involves heaping the contaminants soil into piles and stimulates the aerobic microbial activity within soil through aeration and addition of mineral nutrients and moisture. Soil bio piles are a process where piles of soil are placed over top of a bug vacuum pump. The vacuum pump pulls air through the pile of soil to allow oxygen to get though the soil to the microorganisms. Contaminants turn into gas forms is easily recovered. The basic bio pile system includes a treatment bed, an aeration system, an irrigation/nutrient system and a leach ate collection system. For proper treatment, there should be control of moisture, heat, nutrients, oxygen, and pH. The irrigation system is buried under the soil and provides air high temperature. It is mainly used for the removal of gasoline, oil, petroleum etc. The rate removal of these substances is varied from one site to another site. Bio pile treatment is a full-scale technology in which excavated soils are mixed with soil amendments, placed on a treatment area, and bio remediated using forced aeration. The contaminants are reduced to carbon dioxide and water. Soil piles can be up to 20 feet high and may be covered with plastic to control runoff, evaporation and volatilization, and to promote solar heating. If volatile organic compounds (VOCs) in the soil volatilize into the air stream, the air leaving the soil may be treated before they are discharged into the atmosphere. Treatment time is typically 3 to 6 months.

Landfarming

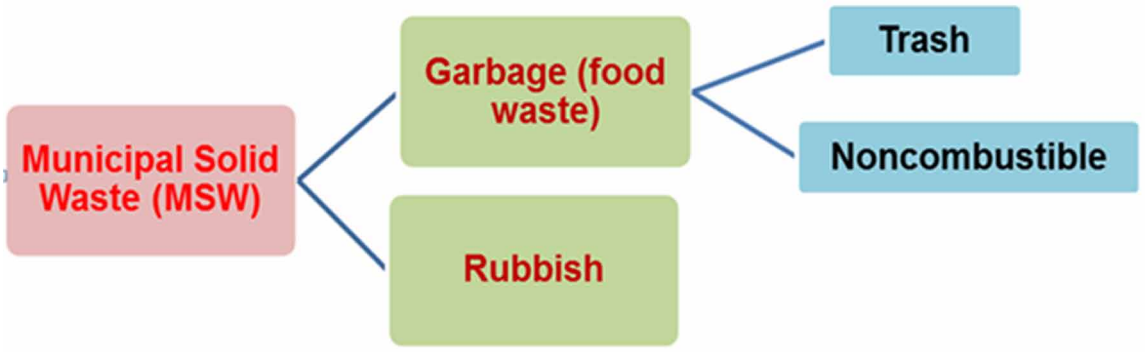
Land farming is a bioremediation treatment process that is performed in the upper soil zone or in bio treatment cells. In this technique the waste is carefully mixed with surface soil on a suitable tract of land. Microbes that can metabolize the waste may be added, along with nutrients. The soil is spread out over a pad which has a system that is used to collect any of the residual liquids from the soil which may be toxic. The soil is mixed regularly to allow aeration of excavated soil. So that the micro-organisms present in the soil are more able to break down the contaminants in the soil. Contaminated soils, sediments, or sludge are incorporated into the soil surface and periodically turned over or tilled to aerate the mixture. In land forming make a sandwich layer of excavated soil between a clean soil and a clay and concrete. Firstly, the clean soil at bottom and uppermost layers should be concrete layer. After this allow it for natural degradation. Proper maintenance of oxygen, nutrition and moisture and pH should also require with near the pH 7 by using lime. Land forming is useful mainly for pesticides. Biological treatment of certain organic wastes, such as those from the petroleum industry, is also an option (Figure 6).

BIOREMEDIATION OF MUNICIPAL WASTE

According to Ministry of Urban Development (MoUD, 2000), Government of India 1 lakh MT of Municipal Solid Waste was generated daily in the country (Figure 7, Table 2). During the year 2004-05,

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 7. On the basis of nature, different types of municipal solid waste



Central Pollution Control Board (CPCB) through National Environmental Engineering Research Institute (NEERI), Nagpur, A survey conducted in 59 cities and estimated that 39,031 Tons per day MSW generated in these cities. The survey conducted by the central institute of Plastics Engineering and technology (CIPET) at the instance of CPCB has reported generation of 50,592 tonnes of MSW per day in the year 2010-11 in same 59 cities (Keisham and Paul, 2015). Annually, Asia alone generates 4.4 billion tonnes of solid wastes and MSW comprise 790 million tonnes (MT) of which about 48 (6%) MT is generated in India (Yoshizawa, Tanaka, Shekdar, 2004). Despite the best efforts to reduce, reuse and recycle, there will always be residual waste requiring disposal. The alternative treatment and disposal technologies are:

1. Composting,
2. Anaerobic digestion,
3. Pelletisation / Refuse Derived Fuel (RDF),
4. Landfills - Sanitary Landfill / Bioreactor landfill / Secured landfill (for inert waste),
5. Incineration include gasification and pyrolysis.

Among the various treatment and disposal processes as mentioned above, MoEF (Ministry of Environment and Forest) has notified composting (windrow composting, vermicomposting), anaerobic digestion, incineration, pelletization and landfill technologies and has given relevant standards for compost quality, leachate disposal, incineration operations and emissions and landfill specifications.

Bioremediation process is a natural process so MSW management include composting, anaerobic digestion, and landfill and palletisation process. These all the techniques are explained in above part as bioremediation of agricultural wastes excluding palletisation and incineration but these both the process are chemical based process not natural and bioremediation process is a natural phenomenon.

BIOREMEDIATION OF INDUSTRIAL WASTE

The degradation and bioremediation of industrial wastes are a challenging task because there is no reliable technology till date which is effective in complete removal/reduction of these pollutants. Ultimately, diverse groups of microorganism that are already present in the nature may provide solution for the degradation and bioremediation of toxic industrial wastes. Microorganisms that are being used

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

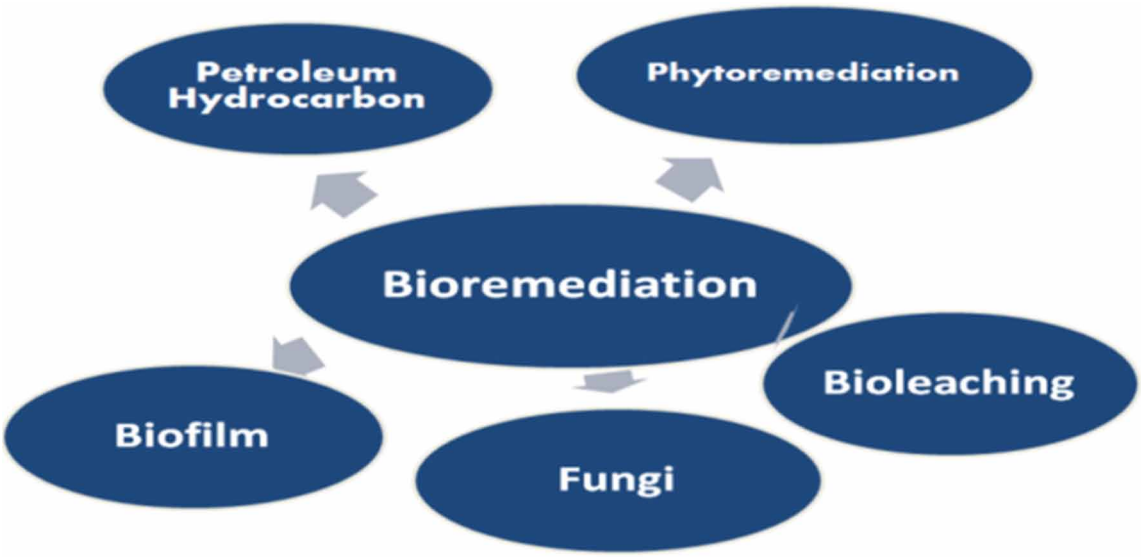
for the bioremediation and transformation of pollutants from long times (Okpokwasili, 2007). For the management of industrial waste, bioremediation processes are classified according to composition of waste to be managed.

Bioremediation of Hydrocarbons or Toxic Organic Pollutant

Petroleum and its products are hydrocarbons. Oil constitutes a variety of hydrocarbons like xylenes, naphthalene, octane's, camphor etc. The pollutants can be degraded by a consortium of microorganisms, e.g. *Corynebacterium, Pseudomoas, Mycobacterium, Arthrobacter,* and *Nocardia*. Genetically engineered bacterial strains are used to enhance bioremediation.In 1990, the USA government allowed him to use this superbug for cleaning up of an oil spill in water of State of Texas (Figure 8). It was produced on a large scale in laboratory, mixed with straw and dried.

Figure 8. Process involved in bioremediation of hydrocarbons



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Bioremediation of Pesticides

Effluent discharge from pesticide manufacturing or formulating industry and agricultural runoff are major sources of pesticides in the environment and the wastewater discharged from these industries cause a high hazard for waterbodies (Rajeswari and Kanmani, 2009). Excess fertilizer, herbicides and pesticides when washed by rain into rivers causes serious danger to life. However, improper handling and disposal may cause pollution. The immediate consequence is drop in dissolved oxygen and the Biological Oxygen Demand (BOD). Water pollution is also caused by hot water discharge from cooling engines in the industries. This increases water temperature and lowers the metabolic rate of organisms. The constituents of gases that are produced in wastewater are carbon dioxide (CO_2), carbon monoxide (CO), nitrogen dioxide (NO_2) and sulphur dioxide (SO_2). There are numerous example of bioaccumulation of different organosynthetic insecticides and pesticides due to their uncontrolled use in the past decades. Bioremediation of pesticides from wastewater can be enhanced by the use of lignolytic enzymes such as Laccases. Removal of phenolic or xenobiotic pollutants from wastewater using Laccase can be occured in several ways: 1) using purified immobilised enzyme; 2) using purified free enzyme; 3) using enzyme obtained directly from culture broths; and 4) bioremediation in reactors with immobilized or free cells (Majeau, Satinder and Tyagi, 2010). Advanced oxidation processes (AOPs) in which hydroxyl radical ($OH-$) is produced by different reactions like chemical, photochemical, photocatalytic or electrochemical reactions, are very effective for treatment of wastewaters containing highly recalcitrant organic pollutants (Gogate and Pandit, 2004). Rajeswari and Kanmani (2009) used TiO_2 for photocatalytic oxidation of pesticide wastewater. The degradation revealed 99% removal of active ingredient of pesticide and 76% mineralization. Complete mineralization could be achieved by further increasing the reaction time or by adding some additives, which would speed up reaction.

Microbial Degradation of Pesticides

It has been observed that a significant portion of pesticides residues in the environment is degraded in the soil and aquatic environment by microbes. The majority of pesticides can be degraded by fungi and bacteria. The transportation of parent pesticide molecules to less complex products is often achieved by concerted efforts of microbial communities. It is estimated that 1 g of soil contains more than 5000–7000 different species of bacteria and more than ten thousand fungal colonies (Dindal 1990; Melling 1993). The use of microbial metabolic potential for eliminating soil pollutants offers a safe and inexpensive substitute to other commonly used physico-chemical strategies (Vidali, 2001). Indigenous microorganisms (natural attenuation) can be used for detoxification of contaminants in the environment (Siddique, Okeke, Arshad and Frankenberger 2003; Kumar and Philip 2006). Soil conditions include warm temperatures, favourable pH levels, adequate soil moisture, aeration (oxygen) and fertility favours microbial growth. The amount of adsorption also influences microbial degradation. The soil fungi for e.g., *Fusarium, Penicillium* are now known to degrade pesticides with greater efficacy (Twigg and Socha, 2001). The branching, filamentous mode of fungus allows more efficient colonization and exploration of contaminated soil (Aust, Swaner and Stahl, 2004). White-rot fungi are filamentous organisms offer advantages over bacteria able to oxidise many compounds (Pointing, 2001). In addition, they are robust organisms and are generally more tolerant to high concentrations of chemical pollutants than bacteria (Evans and Hedger, 2001) and are a powerful prospective tool in soil bioremediation and some species have already been patented.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Phytoremediation of Pesticides

Phytoremediation technology comprises growing plants on contaminated sites so that polluting components percolate through the radical system of the plants and accumulate in various parts (roots, stems, leaves, etc.). There are other constraints to the use of plants alone in remediation; plant growth is dependent on a number of environmental factors like nutrients and water availability, soil texture and pH, etc. The maximum benefits of phytoremediation may therefore, be achieved in long-term applications, or when used in conjunction with other immediate remedial actions. Excluding these limitations, plants are identified to absorb a wide range of air-borne chemicals through the foliage surface. The in situ (on-site treatment) phytoremediation has widely used in Europe and the United States (Meharg and Cairney, 2000; Gaur and Adholeya 2004). This technology is beneficial when the roots of the plant are in contact with the pollutants. It could also be necessary to proceed through several cycles of culture and harvest to restore a site completely. And harvested plants must be disposed carefully (Mulligan, Yong and Gibbs, 2001).

Some Other Bioremediation Processes for Degradation of Pesticides

Bio-Stimulation

This refers to addition of specialized nutrients and suitable physiological conditions for the growth of the indigenous microbial populations. This promotes increased metabolic activity, which then degrades the contaminants (Trindade, Sobral, Rizzo, Leite and Soriano, 2005). Bio stimulation has been used to remove pesticides contamination in the environment. In this process, the activity of the indigenous microorganisms is stimulated by adding the organic and/or inorganic additives such as N or P, etc. The modifications added would be used by the indigenous microorganisms for cell growth to increase cell number as well as their activities to degrade the pesticides. In addition, the amendments could be necessary as the enzyme-inducers and/or the co-metabolic substrates in the pesticide degradation pathways (Robles-Gonzalez, Fava, Poggi- Varaldo, 2008).

Bio-Augmentations

Bio-augmentation is the introduction of exogenous microorganisms with specific catabolic abilities into the contaminated environment or into a bioreactor to initiate the bioremediation process. This can be an in situ or ex situ treatment process in which naturally occurring microbes are added to contaminated sites to eliminate toxic contaminants (Head and Oleszkiewicz, 2004; Perelo, 2010). The technique is reported to be an effective bioremediation approach for improving pesticide degradation in contaminated soils and water that lack indigenous microbial activity (Dams et al. 2007; Plangklang and Reungsang, 2010). It has been employed to degrade a wide range of chemical contaminants such as ammonia, hydrogen sulphide, insecticides, petroleum compounds, and a growing number of toxic organic chemicals present in soil and water (Hwang and Cutright, 2002; Jianlong, Xiangchun, Libo, Yi and Hegemann, 2002; Quan, Shi, Liu, Wang and Qian,2004).

Both bio-stimulation and bio-augmentation possess the ultimate goal of decontamination through biotransformation. The toxic substance is generally converted into other nontoxic forms (transformed) by a chemical reaction using microbes, aerobically or anaerobically. Anaerobic biotransformation is essentially used for degradation of organic compounds such as chlorinated hydrocarbons, polychlori-

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

nated phenols, and nitro aromatics which are recalcitrant to aerobic treatment processes (Ferguson and Pietari 2000; Marschner, Yang, Lieberei and Crowley, 2001; Somsamak, Cowan and Haggblom, 2001; Bhushan et al. 2003).

Bioremediation of Metal Contaminated Site

Accumulation of heavy metals by emissions from industrial areas, mine tailings, disposal of high metal wastes, leaded gasoline and paints, spillage of petrochemicals, sewage sludge, pesticides, wastewater irrigation, coal combustion residues, land application of fertilizers, animal manures, and atmospheric deposition contaminated soil extremely and rapidly. Soils are the major sink for heavy metals released into the environment and also their total concentration in soils persists for a long time after their introduction. To overcome the problem of soil or land pollution and restore the fertility of the soil, it is necessary to remediate it. Bacteria, algae, fungi, actinomycetes and higher plants accumulate high amount of heavy metals in their cells and bio remediate the contaminate site.

Algae

The species of *Chlorella*, *Anabaena inaequalis*, *Westiellopsisprolifica, Stigeocloniumtenue, Synechococcus sp.* tolerate heavy metals. However, several species of *Chlorella, Anabaena,* marine algae have been used for the removal of heavy metals. But the operational condition limits the practical application of these organisms. The naturally occurring cells showed higher efficiency for Cd^{++} and Ni^{++} as compared to laboratory cells.

Fungi

Fungi also are capable of accumulating heavy metals in their cells. However, several mechanisms operate in them for removal of heavy metals from the solution; a few of these have been discussed below:

Metabolism-Independent Accumulation

The positively charged ions in the solution are attracted to negatively charged ligands in cell materials. Biosorption of metal ion occurs on microbial cell surface but composition of biomass and other factors affect biosorption. For example, in Rhizopusarrhizus adsorption depends on ionic radius of Li^{3+}, Mn^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Ba^{2+}, Hg^{2+} and Pb^{2+}. However, binding of Hg^{2+}, Ag^{2+}, Cd^{2+}, Al^{3+}, Ni^{2+}, Cu^{2+} and Pb^{2+}strongly depends on concentration of yeast cells.

Metabolism-Dependent Accumulation

In fungi and yeast, heavy metal ions are transported into the cells through cell membrane. However, as a result of metabolic processes ions are precipitated around the cells, and synthesized intracellularly as metal-binding proteins. Energy-dependent uptake of Cu^{2+}, Cd^{2+}, Co^{2+}, Ni^{2+}, $Zn^{2+}$by fungi has been demonstrated. Moreover, intracellular uptake is influenced by certain external factors such as pH, anions, cations and organic materials, growth phase, etc. Microbes like algae, bacteria and fungi as well as higher plants have capabilities to uptake these pollutants. After uptake, these either accumulates or is assimilated by them. Accumulated heavy metals are recovered by recycling or disposal.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

The following bioremediation processes are used for metal contaminated sites:

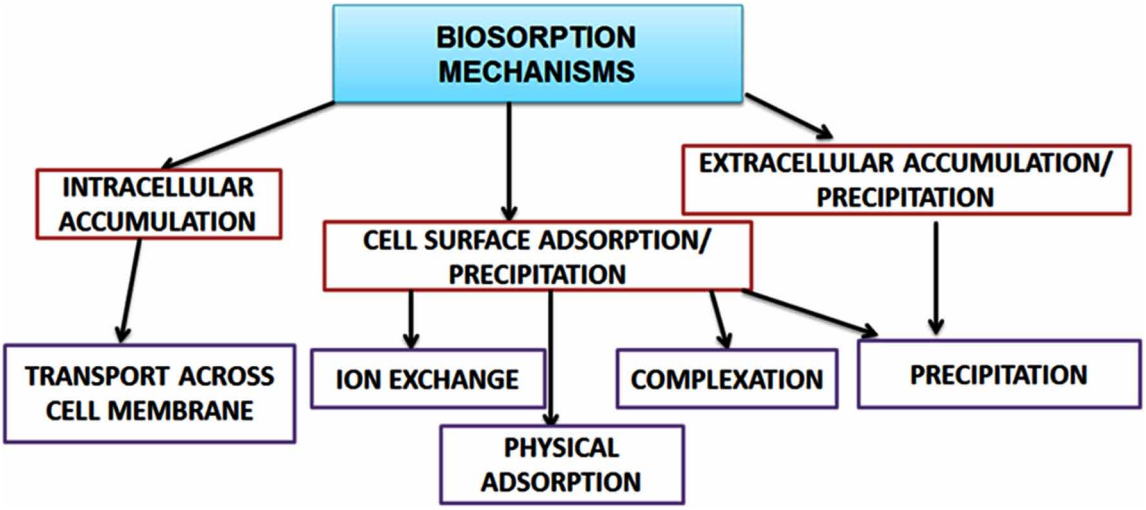
- Biosorption,
- Bioprecipitation/ Biomineralization,
- Biomining:
  - Biooxidation,
  - Bioleaching.

Biosorption

It is the physiochemical process that occurs naturally in certain biomass which allows it to passively concentrate and bind the contaminant on its cellular structure. Microorganisms responsible for this process are called biosorbents. It involves the microbial immobilization of free metal ions and their changed species and is also used for the remediation of mine waste soil. Biosorbents which are used for biosorption of metals from solutions could be classified into three broad categories i.e. exo-polysaccharides, living cultures and non- living biomass and preparations. Living and non- living microbial both cells are active in metal sorption. Non- living microbial biomass is usually preferable for biosorption technology as those precludes the necessity of adding nutrients required for microbial development, maintaining sterility of the process and adjusting parameters to values favourable for microbial growth. The biosorption process involves a solid phase and liquid phase containing a dissolved species to be sorbed. Due to the higher affinity of the absorbent for the absorbate species, the latter is attracted and bound there by different mechanisms.

The process continues till equilibrium is established between the amount of solid- bound absorbate species and its portion remaining in the solution. The degree of absorbent affinity for the absorbate determines its distribution between the solid and liquid phases. The metallic species could be deposited in the solid biosorbent through various sorption processes such as transport across membrane, physical adsorption, precipitation and chemisorption by ion exchange, coordination, chelation, and complexion.

Figure 9. Processes of bio sorption mechanism



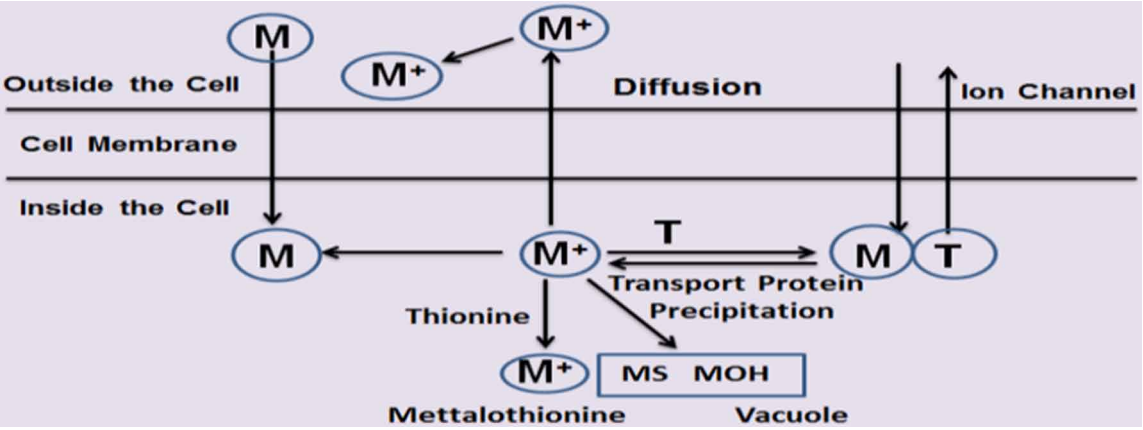
EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

1. **Transport Across Membrane:** Heavy metal transport across microbial cell membranes may be mediated by the same mechanism used to convey metabolically important ions such potassium, magnesium and sodium. The metal transport system may become difficult by the presence of heavy metals ions of the same charge and ionic radius associated with metabolic activity.
2. **Physical Adsorption:** it includes the Vander Waal's forces, Electrostatic interactions between the metal ions in the solution and cell wall of microbial cells (Figure 9 & 10).
3. **Ion Exchange:** it is reversible chemical reaction wherein an ion in the solution is exchanged for a similarly charged ion attached to an immobile solid particles. Cell walls of microorganisms contain polysaccharides and bivalent metal ions exchange with the counter ions of polysaccharides.
4. **Complexion and Precipitation:** The metal removal from solution may also take place by complex formation on the cell surface after the interaction between the metal and the active groups. Complexion found to be the only mechanism responsible for calcium, magnesium, cadmium, zinc, copper and mercury accumulation by *Pseudomonas suringae*. Fungi produce several extracellular products which can complex or precipitate heavy metals. For example, many fungi and yeast release high affinity Fe-binding compounds that chelate iron. It is called siderophores. The Fe^{3+}chelates which are formed outside the cell wall are taken up into the cell. In *Saccharomyces cerevisiae* removal of metals is done by their precipitation as sulphides e.g. Cu^{2+} is precipitated as CuS (Beveridges, 1989).

Bioprecipitation

It is the concept of rainmaking bacteria in which metal contaminants get precipitated by microorganisms in liquid medium. It is also called biomineralization. It removes metals by forming insoluble precipitates that either move into deeper layer osf soil or remain in soil without imposing any harmful effect on crops or vegetation.

Figure 10. Mechanism of bio sorption across the cell membrane of microorganisms



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Biomining

It is the extraction of desired minerals from their ores through the use of living microorganisms. It is used to aid the recovery of metal form low grade ores. It is economically sound hydrometallurgical process with lesser environmental problems than conventional commercial application. It has tremendous practical application. It consists of two processes:

Bio Oxidation

It is the process which is applied to enhance the extraction of gold and silver. An oxidation process caused by microbes where the valuable metal remains (but becomes enriched) in the solid phase. Bio-oxidation leaves the metal values in the solid phase and the solution may be discarded. This contrasts with bioleaching where the valuable metal is solubilized. (Both bioleaching and biooxidation are oxidation processes. If the valuable metal in the ore is hosted by, but not bound to, a surrounding undesired mineral matrix which is blocking the valuable metal from further chemical treatment the matrix can be degraded by selective dissolution of the undesired mineral matrix. Here the microbes causing the selective dissolution may enrich the valuable metal and facilitate metal extraction by selective dissolution of the undesired mineral matrix.

Bioleaching

Bioleaching is the process by which metals are dissolved from ore bearing rocks using microorganisms. For the last 10 centuries, microorganisms have assisted in the recovery of copper dissolved in drainage from water. Microbial technology renders helps in case of recovery of ores which cannot be economically processed with chemical methods, because they contain low grade metals. The low grade ores are discarded in waste heaps which enter in the environment. The low grade ores contain significant amount of nickel, lead, and zinc ores which could be processed by microbial leaching. Bioleaching of uranium and copper has been widely commercialized. But large scale leaching process may cause environmental problems when dump is not managed properly. These results in seepage of leach fluids containing large quantity of metals and low pH into nearby natural water supplies and ground water. Thus, bio mining is economically sound hydrometallurgical process with lesser environmental problem than conventional commercial application. However, it is an inter-disciplinary field involving metallurgy, chemical engineering, microbiology and molecular biology. It has tremendous practical application. In a country like India bio mining has great national significance where there is vast unexploited mineral potential (Mogal and Desai, 1992). The most commonly used microorganisms for bioleaching are *Thiobacillus thiooxidans* and *T.ferrooxidans*. The other microorganisms may also be used in bioleaching, *Bacillus licheniformis, B. luteus, B. megaterium, B. polymyxa, Leptospirillum ferrooxidans, Pseudomonas fluorescens, Sulfolobusacido caldarius, Thermothrix thioparus, Thiobacillus thermophilica, etc*.

Bioremediation of Dyes

Synthetic dyes are widely used in a number of industries, such as textile dyeing or printing, paper printing, cosmetics, pharmaceuticals and leather industries. These industries uses large amounts of energy and water, and they release a substantial amount of waste water with many contaminants. With the increased

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

demand for textile products, the waste waters generated from this industry have also increased proportionally and polluting the receiving water worldwide. In India, mill discharges is an average about 1.5 million litres of effluent per day, which causes chronic and acute toxicity (Sandhya et al., 2005 and Arami et al., 2006). The organic dye stuffs, chrome dyes and other chemicals during various operations and produce a large quantity of solid and liquid waste containing hexavalent chromium [chromium (VI)], salts of zinc, sulphates, copper, sodium and potassium etc., which causes severe toxicity to aquatic organisms. There is limited study on microbial degradation of azo and reactive dyes. Maximum number of dyes undergoes degradation through reduction. Kulla (1981) discussed azo- reductase of Pseudomonas strains in the chemostat culture. These enzyme catalyses azo-linkage of the dye. During degradation process of azo, NAD(P) acts as electron donor. Srivastava et al. (1995) observed degradation of black liquor pulp mill effluents by the strains of *Pseudomonas putida.* Some anaerobic bacteria, Streptomyces and fungi (e.g. *Phaenerochaete chrysosporium*) have been characterized for decoloration of chromogenic dyes. The enzymes involved in dye degradation are lignases (lignin peroxidase), Mn (II) dependent peroxidase and glyoxal oxidase. These enzymes are well associated with lignin degrading system.

Bioremediation of Xenobiotic Compounds

Man-made chemicals present in the nature at high concentrations polluting the environment are known as Xenobiotic compounds. Some microbes are capable in breaking down of xenobiotic compounds to some extent. But most of the xenobiotic compounds are non-degradable in nature and remain in the environment for many years leading to bioaccumulation or bio-magnification. Such compounds are known to be recalcitrant in nature. The recalcitrant xenobiotic compounds can be divided into different groups depending on their chemical composition like halocarbons, synthetic polymers, alkyl benzyl sulphonates, oil mixture etc. These compounds are highly toxic in nature and can affect survival of lower as well as higher eukaryotes. It also poses health hazards to humans like various skin problems, reproductively and even known as a trigger for causing cancer. They also find a way into the food chains.

For breaking down xenobiotics compounds, the enzymes act on certain groups present in the compound. For e.g. in the halocarbons, the halogen group is targeted. Enzymes like oxygenases play a major role. The bonds like ester-, amide-, or ether bonds present in the compounds are first attacked leading to breaking down of compounds. In some cases the aliphatic chains and in aromatic compounds the aromatic components may be targeted. Often it is seen that the xenobiotic do not act as a source of energy to microbes and as a result they are not degraded. The presence of a suitable substrate induces its breakdown. This substrate is known as co–metabolite and the process of degradation are known as co-metabolism. In another process, the xenobiotic serve as substrates and are acted upon to release energy. This is called gratuitous metabolism. Certain microbes on continuous exposure to xenobiotic develop the ability to degrade the same as a result of mutations. Certain mutations also resulted in developing new enzymatic pathway for xenobiotic degradation. Use of mixed population of microbes is usually recommended as it has been seen to yield faster results as the two different microbes attack different parts through different mechanisms resulting in effective break down. It also creates a condition of co metabolism. The modification of certain genes of microbes to break down xenobiotic is also recommended and is seen to produce high level of accuracy.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

CONCLUSION AND FUTURE PROSPECTS OF BIOREMEDIATION

The compounds or chemical which are produced from different sources are needed to be reused or recycle if possible so that their direct impact can be reduced on environment. It is dynamic to increase understanding of microbial communities and their activities to the environment and pollutants, expanding the knowledge of the genetics of the microbes to increase capabilities to degrade pollutants, conducting field studies of new bioremediation techniques which are cost effective, and dedicating sites which are set aside for long term research purpose. These opportunities offer potential for significant advances. *Trichoderma viridie, Beauveria bassiana, Verticillium lecanii, Metarhizium anisopliae* are tested for remediation of waste materials like temple waste, vegetable waste, fruit waste and saw dust waste. Despite its short-comings, its importance to the world is unquestionable considering present day environmental hazards. There is no doubt that bioremediation is in the process of paving a way to greener pastures and national safety in general. Bioremediation technology has also some limitations like several microorganisms cannot break toxic metals into harmless metabolites and have inhibitory effects on microbial activity. Modification in the outer membrane proteins of bacteria with potential bioremediation properties for improving metal binding abilities is to enhance their capacity for biotransformation of toxic metals. Future studies should focus on the factors involved in improved by using genetically engineered microorganisms (GEM) in situ bioremediation strategies and also the applicability and adaptability of these GEMs in all the possible adverse conditions and multiple heavy metal polluted conditions. Bioremediation and phytoremediation can be good treatment strategies for PHC pollutants but more research information and techniques is required to prepare methods for treatment.

KEY TERMS AND DEFINITIONS

Agricultural Waste: Waste in the form of the crop residues in the farm, manure from livestock operations, including dairy and piggery effluent, and poultry litter.

Anaerobic Digestion: The conversion of biodegradable waste matter into compost in the absence of oxygen.

Biogas: Biogas is the gaseous emissions from anaerobic degradation of organic matter (from plants or animals) by a consortium of bacteria. Biogas is principally a mixture of methane (CH_4) and carbon dioxide (CO_2) along with other trace gases.

Bioremediation: Bioremediation is a waste management technique that involves the microorganisms to remove or neutralize pollutants from a contaminated site.

Industrial Waste: Industrial waste is the waste produced by industrial activity which includes any material that is rendered useless during a manufacturing process such as that of factories, industries, mills, and mining operations.

Municipal Waste: Commonly known as trash or garbage—consists of everyday items we use and then throw away, such as product packaging, grass clippings, furniture, clothing, bottles, food scraps, newspapers, appliances, paint, and batteries. This comes from our homes, schools, hospitals, and businesses.

Pesticides: A pesticide is any substance or mixture of substances used to destroy, suppress or alter the life cycle of any pest. Pesticides include bactericides, baits, fungicides, herbicides, insecticides, lures, rodenticides and repellents.

Vermicomposting: The processing of organic wastes through earthworms. It is a natural, odourless, aerobic process, much different from traditional composting.

Xenobiotic Compounds: Man-made chemicals present in the nature at high concentrations polluting the environment are known as Xenobiotic compounds. These compounds are not commonly produced by nature.

Chapter 44
Polymer Consumption, Environmental Concerns, Possible Disposal Options, and Recycling for Water Treatment

Tawfik A. Saleh
King Fahd University of Petroleum and Minerals, Saudi Arabia

Gaddafi I. Danmaliki
King Fahd University of Petroleum and Minerals, Saudi Arabia

ABSTRACT

The increasing awareness of the environment has raised so much concerns in the way we live and the manner to which we dispose our waste. The rapid growth in polymer production has resulted in increasing concerns about the consumption of nonrenewable resources and the environmental impacts associated with its production and disposal. Polymer waste is one of the major components in municipal solid waste and is increasingly becoming a huge burden in industrialized nations. The rise in the use of plastic, coupled with increasing concerns about its disposal, has led to a renewed interest in its recycling and recovery. The technologies involved in the recovery and recycling of polymers are rapidly growing, however, there is no specific pattern of treating polymer waste. The technology depends on the type of material used in the production and consumption pattern. This chapter, therefore, discusses the patterns of polymer consumption, the environmental concerns, and different modes of recycling polymer waste.

1. INTRODUCTION

Plastics are lightweight durable and inexpensive materials, which can be converted into a wide array of products that can be used in a wide range of applications. The production of plastics has dramatically increased in the last 60 years due to their wide applications and ease of molding (Jefferson *e*t *a*l., 2009). The amount of polymers used in the industry far exceeds that of metals and is rapidly growing due the

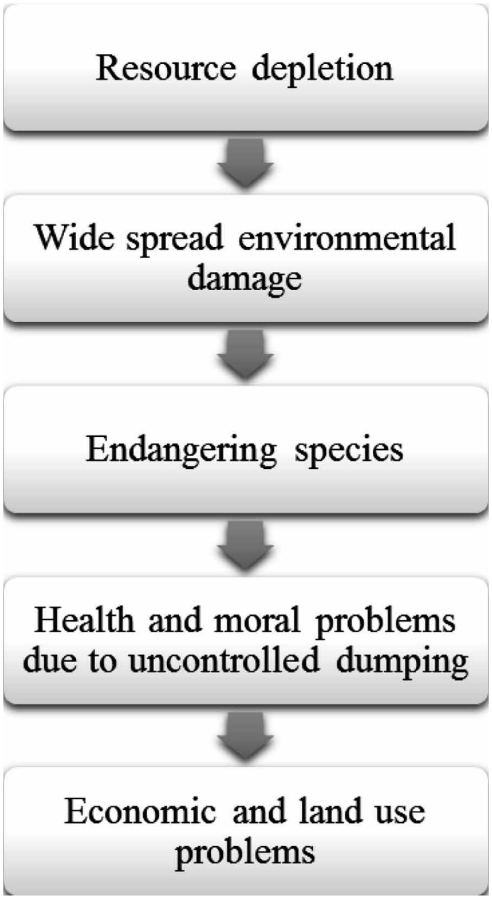
Figure 1. The impacts of polymer production



industrialization of some developing nations (2003). Polymers are inevitable products in our lives today; they are widely used in place of alternate materials because they are inexpensive and they possess better environmental disposal options due to their light weight, minimal pressure on agricultural resources, and superior insulation abilities. Despite all the advantages, the current level of their usage and disposal pose serious danger to the environment and the health of the populace. In addition, around 4 percent of annual oil and gas production (non-renewable resource) is used as the parent material (precursor for synthesis) and the sole provider of energy for plastic production (British Plastics Federation 2008). Secondly, most of the plastic produced is directed for the production of disposable items that always end up in the landfills and in delicate habitats within short period of time. The impacts of polymer production have been sum up and depicted in Figure 1.

There are so many approaches in use to reduce the impacts of polymer disposal which include: source reduction, composting, degradation, incineration, recycling and landfilling (Richard 1992). Source reduction aim at reducing the volume or toxicity of waste generated and it is the most preferred management option, composting utilized biochemical means with the aid of microorganisms to reduce the volume of plastic waste generated, degradation uses factors such as heat, chemical or light to alter the properties of the polymers and lower its molecular weight for efficient recycling. Incineration which converts combustible waste to inert residue is a viable option because energy is generated but combus-

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

tion of plastics generates significant amount of pollution. Incineration requires well-designed systems, adequate control and efficient maintenance. Disposal of plastics by landfilling is not a problem so long as space is available, however, most plastics are not biodegradable.

Recycling represents one of the most effective areas in polymer industry; it has significant advantages compared to other means of reducing polymer impacts because it reduces the consumption oil and gas, lowers emissions associated with polymer production, reduces the amount of waste generated and has ecological advantages, but its application is dependent upon the feasibility of elements of waste management i.e. handling, storage, processing, collection, sorting, and transport. Recycling of plastic materials has received rapid growth in the past few decades however, the quantities been recycled vary with locations according plastic type and application. Developments in the field of recycling are generating wide array of opportunities to people, legislators and government agencies and with proper investments, most plastic wastes been disposed to the landfills will be siphoned and directed for efficient recycling.

The recovery and recycling rate of plastics compared to other materials such as glass, paper, and metals is generally very slow. Plastic recycling even in developed nations with well-developed waste management systems in place is generally slow as compared to other materials because of the huge varieties of plastics, composites and additives used in their production. This complex nature of plastics confer added advantages when compared to other materials but it is generally problematic to recycling.

2. POLYMER CONSUMPTION

The major producers of plastics in the world are China (23.9%), Europe (20.4%), North America (20%) and the rest of Asia excluding China (15.8%) (PlasticsEurope 2013) In the Europe, (39.4%) of the whole plastic production is directed for packaging materials, followed by construction (20.3%), automotive accounts for 8.2%, electrical and electronics accounts for 5.5% the plastic demand, agricultural applications account for 4.2% while other applications such as: medical, furniture, household and consumer products and appliances accounts for 22.4% . The world plastic production from 1950-2012 is shown in Figure 2.

There are different types of plastics and they are subdivided into thermoplasts and thermosets. Thermosets are liquids or malleable products that undergo curing with the aid of heat by irradiation or irreversible chemical reaction to produce a hardened thermoset resin that cannot be reformed or tainted. Once a thermosets solidifies they stay solid which makes it difficult to be recycled. Thermosets can only be recycled through a chemical process. Types of thermosets include: epoxy resin, polyester resin, and urea and melamine formaldehydes. Thermoplasts polymer on the other hand do not undergo chemical changes when heated and can be molded again upon cooling. The classes of thermoplastic include: nylon (polyamide), Acrylic (polymethyl methacrylate), Teflon, polyurethane (PU) polyvinyl chloride (PVC), polypropylene (PP), polystyrene (PS), polyethene (PE) which is subdivided based on the distribution of polymers into: low density polyethene (LDPE), medium-density polyethylene (MDPE), high density polyethene (HDPE), ultra-high molecular weight polyethylene (UHMWPE) and cross-linked polyethylene. The types and classes of these polymers are given in Table 1 and their main applications in EU member states are depicted in Figure 2. The key plastic types used in the EU is depicted in Figure 2. The overall distribution and uses of plastics varies depending on specific conditions. This is evident as many countries have reduced the utilization of PVC in packaging however the same material when combined with PUR and PS serves as the main plastic used in building and construction. Polyolefin dominates the packaging industry.

Figure 2. World Plastic Production 1950-2012 (including thermosets, thermoplastics, elastomers, polyurethanes, coatings and sealants, adhesives, and PP-fibers)

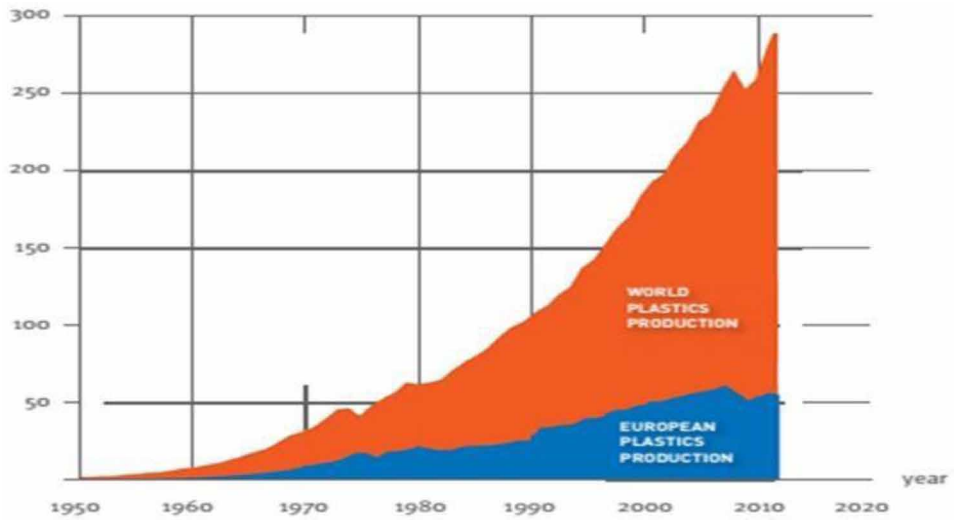

Figure 3: A) European plastic demand by segment 2012 and B) European plastic demand by resin type 2012

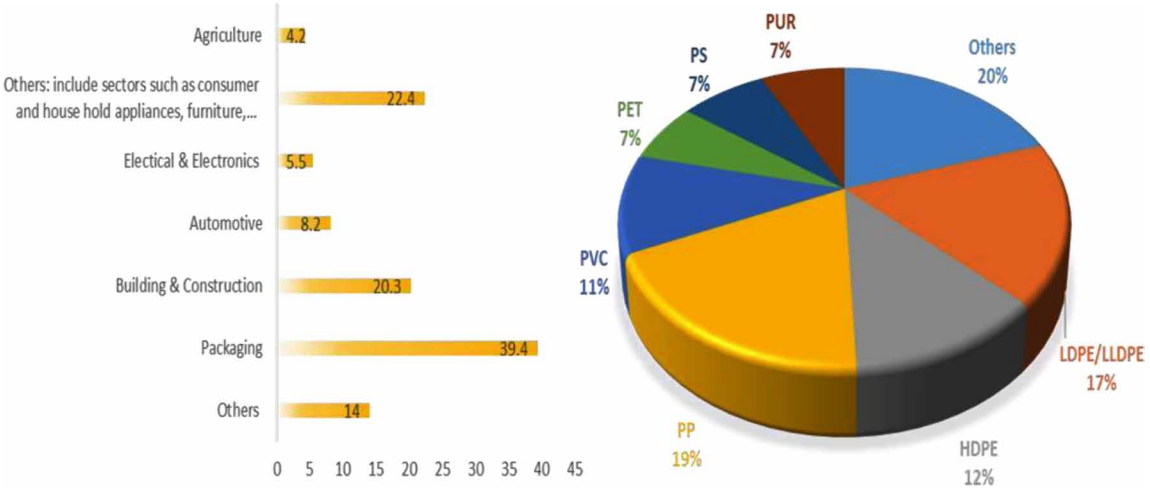

288 million metric tons of polymer was produced in the year 2012 for all types of polymers including thermoset plastics, thermoplastics, and adhesives and coatings. A 2.8% increase compared to 2011. This shows a growth rate of about 9%/annum. However in Europe, despite the growth in plastic consumption across the globe the production rate decreases by 3% from 2011 to 2012. Thermoplastic resins constitute around 2/3 of this production and their usage is growing at about 5%/annum globally (PlasticsEurope 2013).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Table 1. The most common types of plastics used, their applications and the symbol which is used in their identification

Polymer Types	Examples of applications	Symbol
Polyethylene Terephthalate	Fizzy drink and water bottles. Salad trays.	
High Density Polyethylene	Milk bottles, bleach, cleaners and most shampoo bottles.	
Polyvinyl Chloride	Pipes, fittings, window and door frames (rigid PVC). Thermal insulation (PVC foam) and automotive parts.	
Low Density Polyethylene	Carrier bags, bin liners and packaging films.	
Polypropylene	Margarine tubs, microwaveable meal trays, also produced as fibers and filaments for carpets, wall coverings and vehicle upholstery.	
Polystyrene	Yoghurt pots, foam hamburger boxes and egg cartons, plastic cutlery, protective packaging for electronic goods and toys. Insulating material in the building and construction industry.	
Unallocated References	Any other plastics that do not fall into any of the above categories - for example polycarbonate which is often used in glazing for the aircraft industry	

The UK plastic industry contributes significantly to the economic strength and development of the geographical location. It accounts for 7% all the manufacturing activity in UK, a percentage much higher than pharmaceutical and automotive industries combined. In 2011, the industry's sales turnover was £19 billion and £6.7bn value of exports a 13% increase from 2010 was recorded. Approximately 8000 firms are engaged in the plastic industry in UK, more than 3000 of this firms are termed primary processors because they are engaged in the processing of plastics raw materials for goods production. 2.5 million tons of plastics raw materials are approximately produced annually in the UK. The distribution of polymer companies in UK is depicted in Figure and the plastic consumption in the UK by application is given in Figure 4.(BPF 2012)

It is estimated that the UK produces approximately 2·5 million tonnes of plastics raw materials annually. The companies known for manufacturing different forms of polymers and polymer products in UK are: DuPont, lyondellbasell, Sabic and Ineos. UK is among the top five plastic processors in the EU consuming approximately 4.8 million tonnes of materials. A lot of capital and personnel are required in plastic processing to satisfy the individual tasks due inert and assembly work. The number of people currently employed in the UK plastic industry is approximately 180,000.

3. LIFECYCLE ASSESSMENT (LCA)

Lifecycle assessment is an analytical tool developed by government for complete evaluation of environmental aspects in a particular process or system and it allows scientist to keep record of a product from the time the raw materials are harnessed to the manufacturing till its final disposal. Public opinion and environmental directives within the last two decades have played a cardinal role in the development of methods to evaluate the environmental impacts of an industrial process. It is believed that LCA is a tool that helps in the development of public policy and design decisions (Subramanian 2000). All aspects of environment are evaluated in a process through all stages of its life cycle. LCA has the ability of creating a tentative inventory elucidating all inputs and outputs including energy sources and environmental emissions of an industrial process. LCA helps in making decisions with regard to tradeoffs in a process and the level of capital to invest in a process. LCA of plastic production measures environmental impacts associated with materials manufacturing, to their packaging and distribution, their final use and disposal.

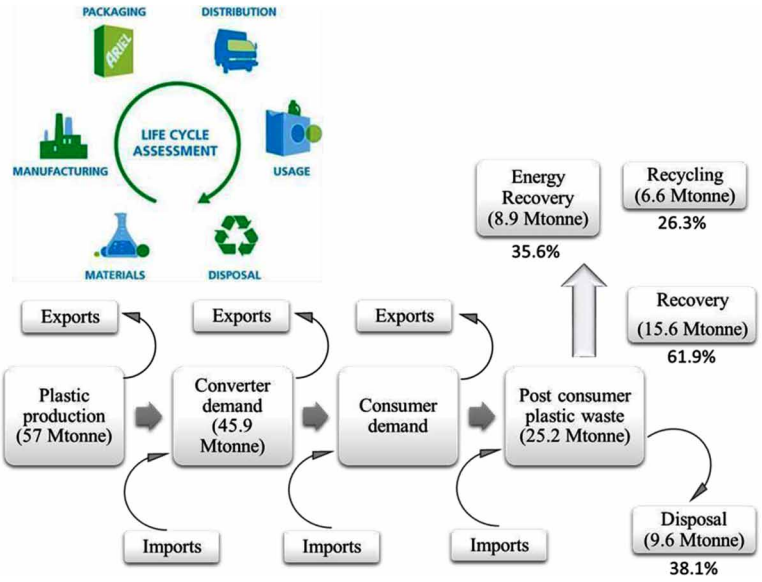
Life cycle assessment of plastics in Europe from converter demand to disposal and recovery showed that 25.2 Mtonne of plastics in 2012 ended up in the post-consumer waste streams of which 15.6 M tonne were recovered while 9.6 Mtonne were disposed of. Figure 5 gives an elucidation of the LCA of plastic in Europe.

3.1 Polymer Waste

The consumption and generation of plastic solid waste has increased remarkably over decades since industrial revolution. It was estimated that each individual in the world in 1990 produced an average of 250 kg of MSW generating in total 13 Mtons (Al-Salem *et al*., 2009). Plastic waste currently represents significant amount in MSW in 2012. 32 Mtons and 25.2 Mtons of plastics reached the post-consumer waste stream in America and Europe respectively. Environmental regulations and increasing awareness coupled with inadequate space and cost of disposal to the landfills are forcing for considerations of other environmentally and economically viable alternatives such as recycling and recovery to plastic disposal (Zia et al., 2007; Howard, 2002). Recycling has received much attention in the past few decades.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 5. Life cycle assessment of plastic in Europe in 2012



Plastics make up 32 Mtons almost 13 percent of the total municipal solid waste (MSW) generated in America. Nearly 14 Mtons of plastics were used in packaging and containers production, 11 million tons and 7 million tons as durable goods (appliances) and non-durable goods (cups) respectively. Depending on the parent material, various forms of plastics have different recycling rates. The overall plastics recycling rate in 2012 was 9 percent (28 Mtons) but the recycling rate for some categories of plastic products was higher in the same year e.g. 31 percent of PET bottles and 28 percent of white translucent bottles (HPDE) were recycled (USEPA 2012). Total MSW generated in 2012 by material is shown in Figure 2 while the total MSW recovered by material is showed in Figure 6.

In 2012, plastics recycling and energy recovery reached 15.6 Mtonne approximately 61.9% of the post-consumer waste generated in Europe. The recycling and recovery of total plastic waste in Europe from 2006 to 2012 has showed increasing trend with an annual growth rate of 4% while the disposal

Figure 6. A) Total MSW generation (by material) in 2012 251 million tons before recycling and B) Total MSW recovery (by material)

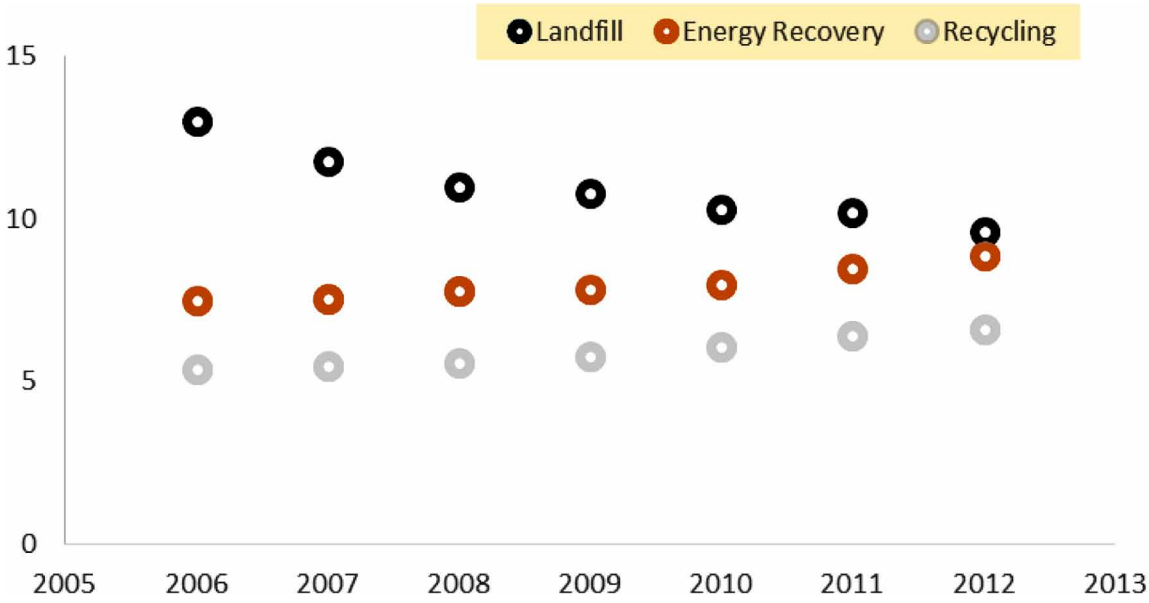
Figure 7. Total plastic waste recycling and recovery 2006-2012



through landfilling continues to diminish at an annual reduction rate of 5.5% which shows a considerable positive development. Europe is one the road towards zero plastic to landfills. Total plastic waste recycling and recovery 2006-2012 is shown in Figure 7.

4. ENVIRONMENTAL CONCERNS AND TOXICITY

The consumption and disposal of polymers have enormous effect to the environment and public health. There are evidences that the chemical building blocks of plastics contains substances that affect the environment and human health. This section will discuss the major environmental effects associated with polymer production. These effects include: excessive consumption of nonrenewable resources, emission of toxic substances such as heavy metals from uncontrolled incineration, and pollution of groundwater and surface water by landfill leachates.

There is increasing concern about the consumption of nonrenewable resources generally petroleum for the production of polymers. About 330 Mbarrels of oil (5% of total U.S. oil production) is consumed in plastic manufacturing. Petroleum products such as natural gas, liquid petroleum gas (LPG) and natural gas liquids (NGL) are used as feedstock and fuel for the production of plastics in the United States. About 190 Mbarrels of LPG and NGL equivalent to 2.7% of total U.S. petroleum consumption were used as feedstock and an equivalent of 1 Mbarrels were consumed as fuel in resin and plastic industry in 2010. About 412 billion cubic feet (Bcf) of natural gas in 2010 an equivalent of 1.7% of total U.S. natural gas consumption were utilized in plastic and resin production. In addition to petroleum product consumption, plastic manufacturing consumes a lot of electricity. It was estimated that 65 billion kW of electricity (1.7% of U.S. consumption) were consumed plastic manufacturing (EIA 2014)

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Plastic bags presents a significant danger to animal life because they are considered by the sea animals as food. Plastic bags floating in the sea when brightly colored or containing residues of food tend to attract the living species within the water bodies. Marine and land animals choke to death when strangled by plastics, causing so much distress and pain. The animals die of slow death from infection and starvation when they consume plastic bags. Plasticizers such as: Bisphenol A (BPA) and the phthalates are produced in a large quantity and they are regularly detected in aquatic environment due to their continuous release into the environment. Plasticizers used as additives in PVC and other plastics production are known to contain substances that pose adverse health effects to non-mammalian and mammalian species. They impede animal development by disrupting hormones production, interfere with normal reproduction by reducing the normal mitochondrial transport and induce cellular stress by increasing fatty acid oxidation (Justine *e*t *a*l., 2014; Jorg *e*t *a*l., 2008). Some countries still use banned plasticizers as clouding agents in food and beverages which attracts serious international attention (Tzung-Hai *e*t *a*l., 2011).

The growth of the plastic industry has a significant impact on the management of municipal solid waste by incineration and landfilling. Synthetic polymers are regarded as major SW environmental pollutants because they are resistant to physical and chemical degradation. Lack of available space and cost of disposal through the landfills have made incineration a viable alternative in plastic management, however, incineration causes the emission of toxic bottom and fly ash which contain trace levels of heavy metals such as cadmium and lead (Curlee *e*t *a*l., 1991). The presence of these substances brings about surface and groundwater pollution problems. Landfilling is the most common route for disposing of polymer waste. Brominated flame retardants (BFR) used as synthetic additives in plastic production are persistent and pose adverse effects on health. They are released in landfills leachates to the environment and they bio-accumulate (Natsuko *e*t *a*l., 2014; Ying *e*t *a*l., 2014)

5. PLASTIC WASTE MANAGEMENT

These are processes generally taken to minimize the effects of plastics on health, the environment and aesthetics. It is the systematic administration of activities that provide for the collection, source separation, storage, transportation, transfer, processing, treatment and disposal of plastic wastes. Plastic waste management is a distinct practice from resource recovery and it focuses on reducing the rate of consumption of natural resource and disposal of waste by landfilling. Figure 9 gives a graphical illustration of waste management hierarchy.

Philosophies of Waste Disposal and Management

- **Out of site out of mind**: It causes widespread environmental damage. The philosophy persists and continue to pose serious problem to the environment.
- **Dilute and Disperse**: The philosophy believes that the solution to pollution is dilution, it is no longer suitable for waste disposal and it causes widespread marine pollution issues.
- **Concentrate and Contain**: This philosophy is currently the most popular in waste management, however it is very energy intensive and expensive.
- **Resource Recovery**: The philosophy requires large volume of waste and technology to convert wastes into useful materials.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

- **Integrated Waste Management Facility (IWMF):** It is a complex set of alternatives that combines source reduction, recycling, composting, incineration and landfilling for efficient waste management.

Functional Elements in Solid Waste Management

There are six functional elements in the activities associated with the management of plastic waste from the point of generation to final disposal sites. These activities are depicted in figure and they include:

Figure 8. Plastic waste management hierarchy

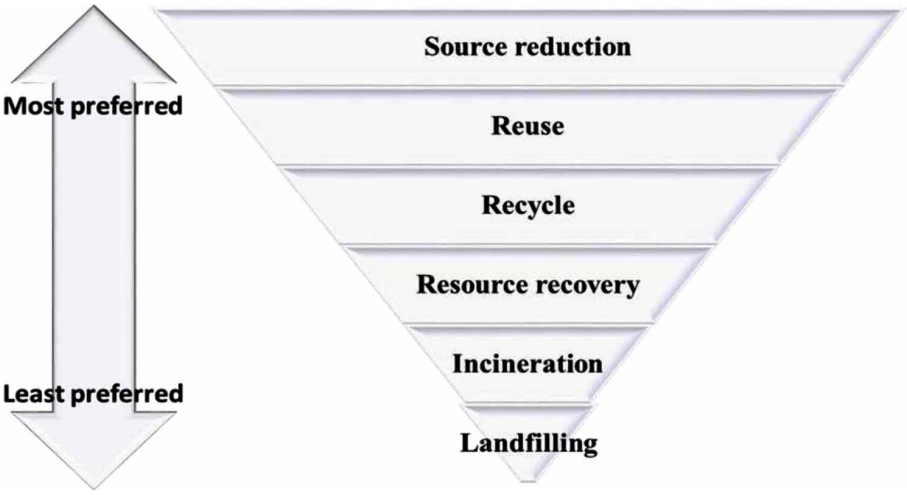


Figure 9. Functional elements of solid waste management

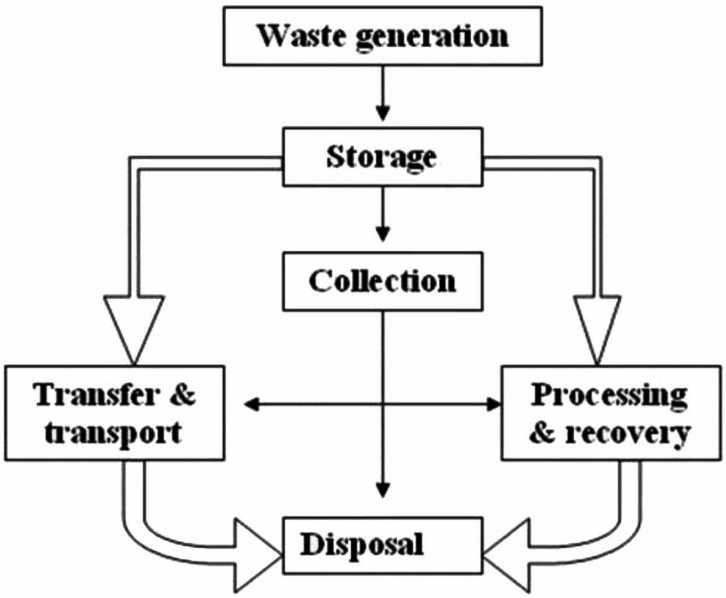
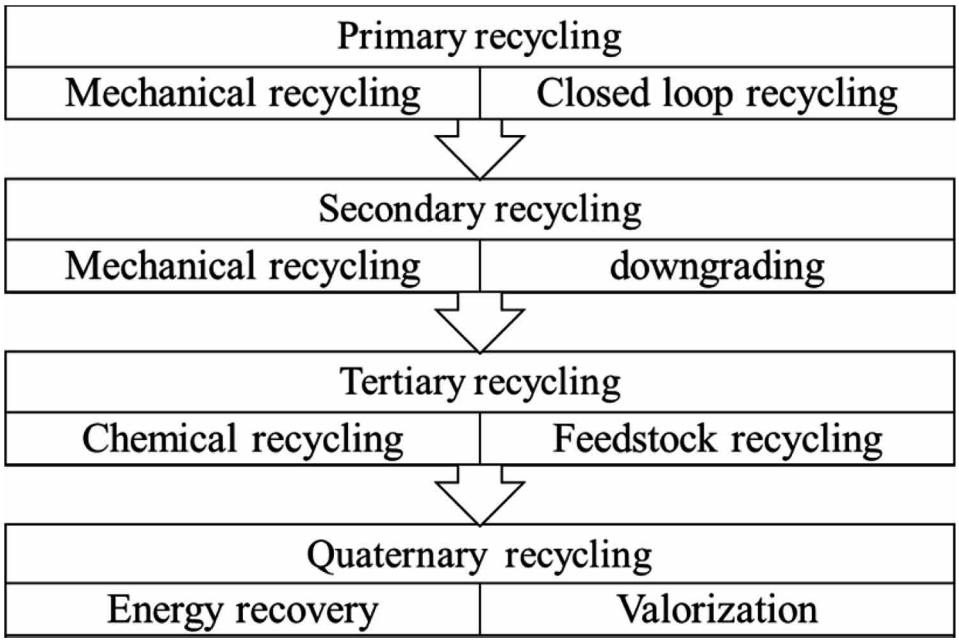


EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 10. Categories of plastic recycling



- **Plastic Generation:** They are related to those activities in which materials are identified as no longer being of value and are either thrown away or gathered together for disposal.
- **Collection:** Concerned with those activities associated with the gathering of plastic wastes and the hauling of wastes to the location where the collection vehicle is emptied. Waste collection methods vary widely among different countries and regions. Residential, commercial and industrial locations have different collection procedures. Plastic wastes are collected through bring-schemes or kerbside procedures. Bring-schemes collection methods are very slow compared to the kerbside methods because they require the willingness and commitment of the public through economic incentives. Kerbside collection methods combine most recyclables together e.g. papers, glass, plastic containers etc. but the recovery rate of plastic using this method is around 30-40% (Jefferson *et al*., 2009).
- **On-Site Handling (Sorting, Storage & Processing):** Related to those activities associated with the handling, storage, and processing of plastic wastes at or near the point of generation. Sorting is carried out through manual or automated methods to separate plastics from other recyclables. Manual methods of separation depend on the use of color and physical properties to distinguish between different forms of plastics. Material recovery and recycling facilities use automated methods such as Fourier transform near infrared spectroscopy (FT-NIR) and optical recognition camera techniques to easily separate HDPE and PET bottles out of the stream. X-ray detection methods, ballistic separators, trommels, hydrocyclones, and density based air classification systems are also used for the separation of PVC containers and flexible packaging (Arvanitoyannis 2001; Fisher 2003). Sink/float separation can be used in the separation of polyolefin i.e. PP and all classes of PE from PET, PVC and PS. Air elutriation has been used in separation of labels (low density films) from denser plastics (Chandra 2007). Raman emission spectroscopy, froth flotation, thermal kilns

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

and FT-NIR techniques have been used in reducing the PVC contaminants in PET flake (Marques *e*t *a*l., 2000). Laser-sorting is a new approach that uses emission spectroscopy in the removal of polymers by type and impurities such as nylon and silicones from other forms polymers.

- **Transfer and Transport:** Those activities associated with the transfer of wastes from the smaller collection vehicle to the larger transport equipment and the subsequent transport of the wastes, usually over long distance, to the disposal site.
- **Processing and Recovery:** These are techniques, equipment and facilities used both to improve the efficiency of the other functional elements and to recover useable materials, conversion products, or energy from plastic wastes.
- **Disposal**: They are activities associated with ultimate disposal of plastic wastes.

6. PLASTIC WASTE MANAGEMENT OPTIONS

There are several methods in use to curtail the impacts of plastic waste to our health, species, environment and aesthetics. This section will discuss some of the alternatives for plastic waste management.

Source Reduction

Source reduction means decreasing the amount and toxicity of the waste we dispose. It promotes the use of products that are environmentally benign. Plastic waste is an important target for source reduction because of their rapid growth in MSW. Plastic waste end up as litter that affects aesthetics, health, environment and the economy. Source reduction involves such measures of eliminating unnecessary packaging of products and reducing the amount of item used in packaging will reduce waste volume. The use of alternate materials that will have less ecological effects in place of polymers tend to be a viable economic and environment-friendly approach. Some notable examples are the replacements of paper for plastics in supermarkets and that of synthetic fibers (nylon) for natural degradable fibers (cotton) respectively.

Reuse

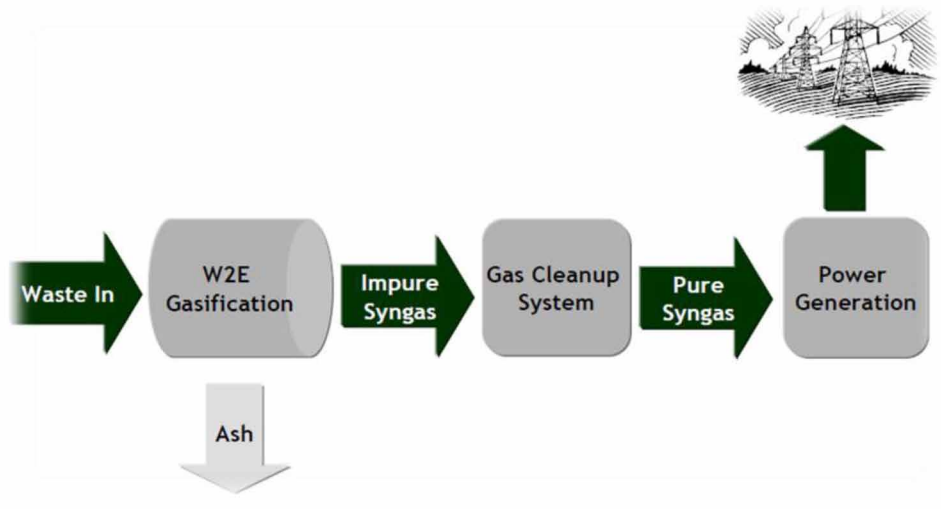
The reuse of post-consumer packaging materials is known for a long time. It has been applied for remanufacturing of vehicles and electronic equipment and in industrial scale for the reuse of pallets and containers in haulage (Thompson *e*t *a*l., 2009) Triple layer plastic bags are reused for cowpea storage in thousands of villages along West and Central African countries (Dieudonne *e*t *a*l., 2014). PET bottles are utilized as building units in some parts of Africa replacing the traditional concrete blocks. They are known for their thermal and structural stability (Ashraf *e*t *a*l., 2015). Other countries are known for reusing plastics to store medicine (Muluneh *e*t *a*l., 2014).

Recycling

This is the process of recovering and reprocessing of waste plastic into useful products that maybe entirely different from their original form. Example is evident in the production of tables and chairs by melting down plastic bottles. There are four categories in plastic recycling, these include: primary, secondary, tertiary and quaternary. Figure 11 outlines the categories in plastic recycling

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 11. The waste to energy process



Incineration

Incineration is a waste treatment process that involves the combustion of organic substances contained in waste material. It converts combustible waste into ash, flue gas and heat at a temperature of around 1000°C. Incineration reduces the amount of plastic waste sent to the landfills however, it is associated with the environmental release of halogenated additives such as dioxins, furans and other polychlorinated biphenyls released upon the combustion of PVC (Gilpin *e*t *a*l., 2003). Incineration of plastic waste as a management option is less prevalent in so many countries due to the adverse pollution problems however it is widely used in Asia due to the limited space for landfills. Incineration with energy recovery is one of the several waste to energy technologies such as: gasification, pyrolysis and anaerobic digestion. The waste to energy process is given in Figure 12.

Composting

Composting is a biochemical process of converting organic waste to humus-like material and it helps in the reduction of garbage. Composting can significantly reduce the amount of garbage on a household or municipal scale, and is less expensive. Composting is a natural process of rotting material down to make a soil like product which can be used on the garden. Composting provide fertilizers helps in reduction of waste, save water, and reduces the carbon footprint. Landfill degradation rate is a relatively slow process compared to degradation in compost piles. Biodegradable polymers are decomposed effectively using composting mixtures but it requires controlled conditions in centralized facilities.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Biodegradation

Landfilling

Plastics are difficult to recycle because both the manufacturers and consumers discard different forms of plastics. Private and public agencies are reluctant to investing in plastic recycling because it is mostly non-biodegradable plus the cost of collection, transport, sorting and degreasing. Landfills are the most common methods of waste disposal however disposal of plastic through landfills consumes a lot of space and is associated with long-term risks of contaminating groundwater and soils by persistent organic pollutants released through leachates of additives and degradation by product (Teuten et al. 2009). A major disadvantage of plastic disposal to the landfill is that none of the material used in the manufacturing process can be recovered. Some countries impose taxes on disposal of plastic to the landfill with the ultimate goal of increasing investments in energy recovery, recycling and attaining zero landfill disposal.

7. RECYCLING WASTE RUBBER POLYMERS FOR PRODUCTION OF ADSORBENTS FOR WATER TREATMENT

There are many methods to recycle waste rubber tires which are sub-divided into two categories. The first category involves physical methods of grinding the waste mechanically into smaller pieces to produce fine particles without altering chemical composition while the second category uses mechanochemical means to breakdown the three-dimensional network with the aid of different forms of energy. Thermal, mechanical, biological, chemical, ultrasonic and microwave treatments are used to convert the waste insoluble thermoset into a reprocessable elastomer (De *e*t *a*l., 2005). The best method suitable for tire recycling is pyrolysis (Kaminsky *e*t *a*l., 1995), pyrolysis is the thermal decomposition of rubbers in a closed system for the production of oil, gasses for reuse in petrochemical industries and solid remains such as carbon black for use as filler materials. There is a significant progress in the pyrolysis technology of waste rubber tire, however, despite the progress, pyrolysis is done on a limited scale due to the absence of market for the derived products (Saleh 2013; Saleh et al. 2016; Saleh and Danmaliki, 2016; Alansi et al. 2015; Saleh et al. 2014).

Researchers in recent years have focused more in the recycling and reuse of waste rubber tires among the initiative is the derivation of activated carbon after pyrolysis for various adsorption studies. Activated carbon from waste rubber tire have the ability of adsorbing different compounds however its adsorption capacity is relatively low compared with other adsorbent materials in use. There are various methods of improving the adsorption capacity of the fine powdered particles. Activated carbon from waste rubber tire was synthesized by pyrolysis at 500°C-700°C and later treated with activating agents such as zinc chloride and potassium hydroxide in a study conducted by (Nunes *e*t *a*l., 2011). The adsorbent showed a mesoporous structure containing sulfur and zinc and it showed the possibility of waste water treatment.

The work conducted by (Zabaniotou et al., 2014) derived activated carbon from waste rubber tires by pyrolysis at 800°C in a fixed bed reactor and physical method of activation using CO2 for the removal of pesticide(bromopropylate) by adsorption from aqueous solution. The surface area of the activated carbon was found to reach 432 m2 g−1 and nearly 100% of the pesticide was removed in just 60mins of the experiment. The study of (Edward et al., 2010) derived activated carbon from ELTs by carbonization for the effective removal of dyes from effluents. It was observed that temperatures above 770K resulted in lower yield adsorbent.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Waste rubber tires were pyrolyzed in carbon dioxide and nitrogen atmospheres at various temperatures for char production (Manchon-Vizuete et al., 2005). The char was activated by oxygenation at different temperatures and were used for the removal of lead and copper from aqueous solutions. The study concluded that the optimum temperature for pyrolysis in carbon dioxide and nitrogen atmospheres is 550∘C. The study of (Sani et al. 2016; Danmaliki et al. 2017; Alswat et al. 2016) used spectroscopic and computational studies to examine the chemistry of cadmium adsorption by activated from waste rubber tires in aqueous solutions. The adsorption process was found to be fast and equilibrium was achieved after 60mins of interaction. Finally, binding energy of cadmium to carbonyl groups was found to be higher than other functional groups present.

The study conducted by AlSaadi et al., 2013 synthesized activated carbon from ELT by physical activation and used it as an adsorbent for the removal of nickel and lead ions from aqueous solutions. The adsorbent was found to have more affinity to the lead ions (96% removal) and the adsorption process was believed to start from initial surface adsorption followed by intra-particle diffusion. The regeneration ability of the adsorbent was also tested and they believed it may be a substitute to the expensive commercial activated carbon currently in use for pollution clean-up. Danmaliki and Saleh 2017 synthesized different brands of activated carbon from waste rubber tires by microwave assisted chemical treatment and physical heating for the adsorption of phenolic compounds.

Granular particles of tire were carbonized and pyrolyzed by heating at 773K and 1223K respectively in nitrogen atmosphere for the production of active carbon in a study conducted by (Mui *e*t *a*l., 2010). The product produced was activated by carbon di oxide in nitrogen atmosphere and later subjected to acid treatment. The synthesized adsorbent was used in the removal of dyes from waste water and it had a higher surface area and better yield. A study conducted by (Quek et al., 2009) synthesized activated carbon possessing high surface area (414 m2/g) without pyrolysis in a one-step cost effective approach. The study used thermochemical degradation of granular tires in a carbon di oxide environment.

Chapter 45
Utilization of SVM, LSSVM and GP for Predicting the Medical Waste Generation

J. Jagan
VIT University, India

Yıldırım Dalkiliç
Erzincan University, Turkey

Pijush Samui
National Institute of Technology Patna, India

ABSTRACT

The prediction of wastes generated in the hospital will help their management for several activities like storage, transport and disposing. This chapter adopts Support Vector Machine (SVM), Least Square Support Vector Machine (LSSVM) and Genetic Programming (GP) in order to estimate the rate of medical waste generation. In the event of predicting the rate, type of hospital, capacity and bed occupancy has been used as inputs of SVM, LSSVM and GP. SVM is based on statistical learning theory, which provides an elegant tool for nonlinear system modeling. LSSVM is the re-formulation to the general SVM. GP, a best part of evolutionary algorithm and also the specification of Genetic Algorithm (GA). These SVM, LSSVM and GP have been used as the regression techniques. The results show the performance of the developed SVM, LSSVM and GP models were elegant and outstanding.

INTRODUCTION

The development of industries, urban growth together with population and population densities will automatically increase the production of wastes. World Health Organization (WHO) has advocated that the hospital wastes should be treated as the particular wastes (Rushbrook et al., 2000). These hospital wastes are more hazardous and are rapidly increasing in the society. Inadequate hospital waste manage-

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

ment will cause environmental pollution, generation of germs and insects, foul smell, etc, will lead to the contagious diseases like typhoid, cholera and AIDS through the wound from syringes and needles contaminated with the human blood (Henry & Heinke, 1996). This research has the better scope in the smart cities with more industries and population. Potentially dangerous hospital wastes can be predicted for the prevention of some hazardous diseases.

Through inventory, questionnaire survey and formal and informal interviews, data has been collected for empirical field observation in Dhaka city, Bangladesh (Hassan et al., 2008). Very deep interviews were carried out to obtain the knowledge of earlier and current management of medical wastes. Their examination provides the outcome of average waste generation 1.9 kg/bed/day. Hassan et al., (2008) delivers the reasons for improper management of medical wastes like, lack of awareness, appropriate policy and laws, and willingness. Omar et al., (2012) has considered the medical waste generation in Malaysia and determined the factors affecting management of medical wastes. They detected and detailed specifically flaw in segregation process of medical waste. Omar et al., (2012) has adopted Microsoft Excel and its pertinent statistical gadget like ANOVA for evaluating the management of medical waste. Maha et al., (2015) had thrown their limelight work distinctly on dental clinics at Lebanon. They considered 242 dental clinics arbitrarily and made survey with 32 framed questions. According to their scrutiny, the process of isolating the waste was vanished and it is mingled with the municipality wastes. Their audit provides the necessity of adopting efficient and responsible medical waste management, in order to prevent disaster in public health and pollution at Lebanon. Hence the adequate management of hospital waste is required to reduce the health and environmental risks. Unfortunately, collection, transport and disposal of waste have no proper strategy or planning behind its implementation. It urgently needs to that needs to be regulated by definitive rules (Askariana et al., 2004).

In order to determine the rate of waste generation, the data like (i) number of bed/patient available at the hospital; (ii) type of specialization (type and range of care); and (iii) number, kind, and size of departments have been utilized (Award et al., 2004). The goal of this chapter is to predict the rate of waste generation based on the mentioned criteria's. Artificial Neural Network (ANN) and Multiple Linear Regression (MLR) have been adopted for this determination (Jahandideh et al., 2009). Since ANN & MLR have some disadvantages such as the low accuracy of MLR and the black box approach, over fitting issues, lack of generalization capability and slow convergence rate of ANN (Park & Rilett, 1999; Kecman, 2001), various effective methods have been utilized.

The methodology of pursuing the medical waste generation includes the upcoming procedures. A total of 50 hospitals private, governmental, educational and non-educational, but university-related hospitals in Fars province, Sharz city, Iran have been considered for the collection of dataset (Jahandideh et al., 2009). The dataset contains information about type of hospital, Capacity(C), Bed Occupancy (B_0) and Waste generation rates (kg/day) (w_t). This chapter accommodates the machine learning techniques like Support Vector Machine (SVM), Least Square Support Vector Machine (LSSVM) and Genetic Programming (GP) for determination of rate of medical waste generation.

SUPPORT VECTOR MACHINE (SVM)

The SVM have been formulated by Vapnik (1998, 1999) based on statistical learning theory. Initially, SVM was utilized for two class classifications, later it was developed to multi-classification, regression, estimation and other similar works. Support Vector machines can be defined as systems which use hy-

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

pothesis space of a linear functions in a high dimensional feature space, trained with a learning algorithm from optimization theory that implements a learning bias derived from statistical learning theory. The formulation uses the Structural Risk Minimization (SRM) principle, which has been shown to be superior, (Burges, 1998) to traditional Empirical Risk Minimization (ERM) principle. SRM reduces an upper bound on the expected risk, whereas ERM minimizes the error on the training data. This differentiation equips SVM with a greater ability to generalize, which is the goal in statistical learning. Since SVM follows the Structural Risk Minimization (SRM) principle, it reduces the occurrence of risk during the training phase as well as enhances its generalization capability. Due to its high performance and detecting the global optimums in real applications, it is most widely used technique in many fields ranging.

Details of SVM

Let us consider the typical regression formulation for predictive learning (Cherkassky & Mulier, 1998; Hastie, Tibshirani, & Friedman, 2001; Vapnik, 1999). The intention is to assess unknown real-valued function in the relationship

$$y = r(x) + \delta \tag{1}$$

where x is a multivariate input, y is the output and δ is the noise data which is uniformly distributed zero mean random error. The estimation is based on a finite number of samples i.e. training data (x_i,y_i), $(i=1,\ldots n)$. The uniformly distributed training data samples are engendered according to the probability density function.

$$p(x,y = p(x)p(y|x) \tag{2}$$

The unknown function in equation (1) is the mean of the output regression function

$$r(x) = \int yp(y|x)dy \tag{3}$$

An estimation procedure identifies the best model $f(x,\varpi_0)$ from the set of approximating functions $f(x,\varpi)$. It is then parameterized by a set of parameters $\varpi\in\Omega$. The eminence of the approximation can be determined by the inconsistency measure $L(y,f(x,\varpi))$. The ultimate aim of learning this is to pick the best model reducing estimation risk.

$$R(\varpi) = \int L(y,f(\varpi))p(x,y)dxdyf(x,\varpi) \tag{4}$$

The regression function is equation (3) is the one minimizing estimation risk (4) with the squared loss function

$$L(y,f(x,\varpi)) = (y\text{-}f(x,\varpi))^2 \tag{5}$$

It should be noted that, carried by the learning technique may or may not have the regression function (3). Hence we have to determine the regressor function $f(x,\varpi_0)$ that reduces the prediction risk function using only the training data.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$R(\varpi) = \int (y\text{-}f(x,\varpi))^2 p(x,y)dxdy \tag{6}$$

The risk functional ascertains the accuracy of the unknown target function $r(x)$. SVM maps the input x to the n dimensional space using some non-linear mapping and then the linear mapping will be developed in the feature space (Cherkassky & Mulier, 1998; Smola & Scholkopf, 1998; Vapnik, 1998, 1999).

$$f\left(x,\varpi\right) = \sum_{i=1}^{n} \varpi_i g_i\left(x\right) + b \tag{7}$$

where $g_i(x)$, i=1,…..,n indicates the non-linear transformations and b is the bias.

Regression forecasts can be procured by the reduction of the empirical risk on the training data. Typical loss functions used for minimization of empirical risk include squared error and absolute value error. SVM regression uses a type of loss function called ε-insensitive loss proposed by Vapnik (1998, 1999).

$$L_\varepsilon\left(y, f\left(x,\varpi\right)\right) = \begin{cases} 0 & \text{if } \left|y - f\left(x,\varpi\right) \le \varepsilon\right| \\ \left|y - f\left(x,\varpi\right) \le \ \varepsilon\right| & \text{otherwise} \end{cases} \tag{8}$$

The empirical risk is defined in the following equation (9)

$$R_{emp}\left(\varpi\right) = \frac{1}{n}\sum_{i=1}^{n} L_\varepsilon\left(y_i, f\left(x_i,\varpi\right)\right) \tag{9}$$

SVM performs linear regression in a high dimensional feature space by utilizing the ε insensitive loss. Also simultaneously it engages to deduce the complexity of the model by minimizing $\|\varpi\|^2$. This can be illustrated by setting up a non-negative slack variable $\xi_i, \xi_i^* \ \ i = 1,\ldots,n$ in order to determine the divergence training samples away from ε insensitive region. Thus SVM regression is formulated as minimization of the following function:

Minimize: $\frac{1}{2}\left\|\varpi\right\|^2 + C\sum_{i=1}^{n}(\xi_i + \xi_i^*)$

Subjected to: $\begin{cases} y_i - f\left(x_i,\varpi\right) - b \le \varepsilon + \xi_i^* \\ f\left(x_i,\varpi\right) + b \le \varepsilon + \xi_i^* \\ \xi_i, \xi_i^* \ge 0 \end{cases}$ (10)

where C is the regularization parameter which is a positive constant. This optimization formulation can be transformed into the dual problem (Vapnik, 1998, 1999).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$f\left(x\right) = \sum_{i=1}^{n} (\alpha_i - \alpha_i^*) K(x_i, x) + b \tag{11}$$

The dual variables are subjected to constraint $0 \leq \alpha_i, \alpha_i^* \leq C$ and $K(x_i,x)$ is the kernel function. The points that come into view with non-zero coefficients are called support vectors. SVM generalization performance depends on the better setting of hyper parameters and the kernel parameters. The problem of determining depends upon the above mentioned hyper and kernel parameters.

The parameter C measures the tradeoff whereas the degrees of deviation are determined by ε. For example, when C is too large i.e. infinity, then the empirical risk alone can be minimized without regards to model complexity. Parameter ε controls the width of the ε -insensitive zone, used to fit the training data (Cherkassky & Mulier, 1998; Vapnik, 1998, 1999). The value of ε can affect the number of support vectors used to construct the regression function. Larger ε - value result in fewer support vectors selected, and results in more 'flat' (fewer complexes) regression estimates. Hence, both C and ε -values affect model complexity (but in a different way).

Radial basis function has been adopted for this study.

$$K\left(x_i, x\right) = \exp\left\{-\frac{\left(x_i - x\right)^T \left(x_i - x\right)}{2\sigma^2}\right\} \tag{12}$$

x_i and x are the training and test patterns, T is the transpose and σ is a the global basis function width.

The total datasets have been divided into the following two groups:

- **Training Dataset:** This is used to construct the SVM model. In this article, 35 datasets out of 50 have been adopted as training dataset.
- **Testing Dataset:** This is used to evaluate the developed SVM. This article uses the remaining 15 datasets as testing dataset.

The datasets are scaled between 0 and 1. The programming of SVM has been done by using MATLAB.

LEAST SQUARE SUPPORT VECTOR MACHINE (LSSVM)

LSSVM was proposed by Suykens et al (2002). LSSVM is the statistical learning theory which adopts the least squares linear system as the loss function to the original SVM. LSSVM retains the SRM principle which leads to the improvement of speed than the classical SVM. It was achieved due to the varying inequality constraints into equations and takes the squared loss function. Hence, it solves system of equations instead of quadratic problems. LSSVM adopts the same inputs as that of SVM.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Details of LSSVM

Consider a given training set of N data points $\left\{x_k, y_k\right\}_{k=1}^{N}$ with input data $x_k \in R^N$ and output $y_k \in r$ where R^N is the N-dimensional vector space and r is the one-dimensional vector space.

In feature space LSSVM models take the form

$$y(x) = w^T \phi(x) + b \tag{13}$$

where the nonlinear mapping $\phi(.)$ maps the input data into a higher dimensional feature space; $w \in R^n$; $b \in r$; w - adjustable weight vector; b - the scalar threshold.

In LSSVM for function estimation the following optimization problem is formulated:

$$\text{Minimize: } \frac{1}{2} w^T w + \gamma \frac{1}{2} \sum_{k=1}^{N} e_k^2$$

$$\text{Subjected to: } y(x) = w^T \phi(x_k) + b + e_k, \text{ k=1,…,N.} \tag{14}$$

where γ is the regularization parameter, determining the trade-off between the fitting error minimization and smoothness and e_k is error variable.

The Lagrangian ($L(w,b,e;\alpha)$) for the above optimization problem (14) is

$$L\left(w,b,e;\alpha\right) = \frac{1}{2} w^T w + \gamma \frac{1}{2} \sum e_i^2 - \sum \alpha_i \left\{w^T \phi\left(x_i\right) + b + e_i - y_i\right\} \tag{15}$$

with α_k Lagrange multipliers. The conditions for optimality are given by

$$\frac{\partial L}{\partial w} = 0 \Rightarrow w = \sum_{k=1}^{N} \alpha_k \phi(x_k)$$

$$\frac{\partial L}{\partial b} = 0 \Rightarrow \sum_{k=1}^{N} \alpha_k = 0$$

$$\frac{\partial L}{\partial e_k} = 0 \Rightarrow \alpha_k = \gamma e_k, \text{ k=1,…,N.}$$

$$\frac{\partial L}{\partial \alpha_k} = 0 \Rightarrow w^T \phi\left(x_k\right) + b + e_k - y_k = 0 \text{ , k=1,…,N.} \tag{16}$$

After elimination of e_k and w, the solution is given by the following set of linear equations

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

$$\begin{bmatrix} 0 & 1^T \\ 1 & \Omega + \gamma^{-1}{}_I \end{bmatrix} \begin{bmatrix} b \\ \alpha \end{bmatrix} = \begin{bmatrix} 0 \\ y \end{bmatrix} \tag{17}$$

where $y=[y_1,\ldots,y_N]$, $1=[1,\ldots,]$, $\alpha=[\alpha_1,\ldots,\alpha_N]$ and Mercer's theorem (Vapnik, 1998; Smola and Scholkopf, 1998), is applied within the Ω matrix,

$$\Omega = \phi\left(x_k\right)^T \phi\left(x_l\right) = k\left(x_k, x_l\right), \text{ k,l=1,…,N}$$

where $k(x_k,x_l)$ is the kernel function. Choosing γ>0, ensures the matrix

$$\Phi = \begin{bmatrix} 0 & 1^T \\ 1 & \Omega + \gamma^{-1}{}_I \end{bmatrix}$$

is invertible. Then the analytical of α and b is given by

$$\begin{bmatrix} b \\ \alpha \end{bmatrix} = \Phi^{-1} \begin{bmatrix} 0 \\ y \end{bmatrix} \tag{18}$$

Radial basis function has been used as a kernel in this analysis. Radial basis function is given by

$$K\left(x_k, x_l\right) = \exp\left\{-\frac{\left(x_k - x_l\right)\left(x_k - x_l\right)^T}{2\sigma^2}\right\} \text{ k,l=1,…,N} \tag{19}$$

where σ is the width of radial basis function.

The resulting LSSVM model for rate of medical waste generation prediction becomes then

$$y\left(x\right) = \sum_{k=1}^{N} \alpha_k K\left(x, x_k\right) + b \tag{20}$$

LSSVM utilizes the same dataset which was used for developing SVM.

- **Training Dataset:** This is used to build the LSSVM model. In this article, 35 datasets out of 50 have been adopted as training dataset.
- **Testing Dataset:** This is used to verify the built LSSVM. This article uses the remaining 15 datasets as testing dataset.

The datasets are scaled between 0 and 1. The programming of LSSVM has been done by using MATLAB.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

GENETIC PROGRAMMING (GP)

Genetic Programming (GP) was proposed by Koza (1992). GP is one of the best parts of the evolutionary algorithm and also the specification of genetic algorithms (GA) (Goldberg, 1989). It helps in producing the clear prediction equations which satisfies the inabilities of some soft computing techniques (Adil et al., 2008). GP adopts Darwins concept of "survival of the fittest" and also some appropriate combination of computer programs. The computer program can be exposed in terms of parse tree. The explanation of parse tree was depicted in Figure 1.

Figure 1 explains the parse tree diagram of computer program for a simple equation $[(2a - 7b) + (3x + 6y)]$.

Details of GP

This section conveys the details of the GP. In 1st step, random populations of equations were created. Then the fitness value of each equation is determined in the sequential step. 'Parents' are selected in this step. 3rd step makes 'offspring's are created through the procedure of reproduction, mutation and crossover. In 4th step, the best equation is obtained. The following Figure 2 explains the technical procedure of GP.

Crossover is one of the genetic operators used to combine the population. This operator gently selects preferable parent's chromosome and couple them to produce an offspring. The crossover point was elected randomly. The following Figure 3 explains the process of crossover.

Mutation is another genetic operator which is identical to the crossover only in selecting the chromosomes of the parent's (i.e.) in the mutation selection point only. It changes the building blocks helping to breakout from the local minimal traps. The size of the mutation is also arbitrary, which helps to get the best individual (Figure 4).

GP adopts the same dataset which was used for developing SVM & LSSVM models. The programming of GP has been done by using MATLAB.

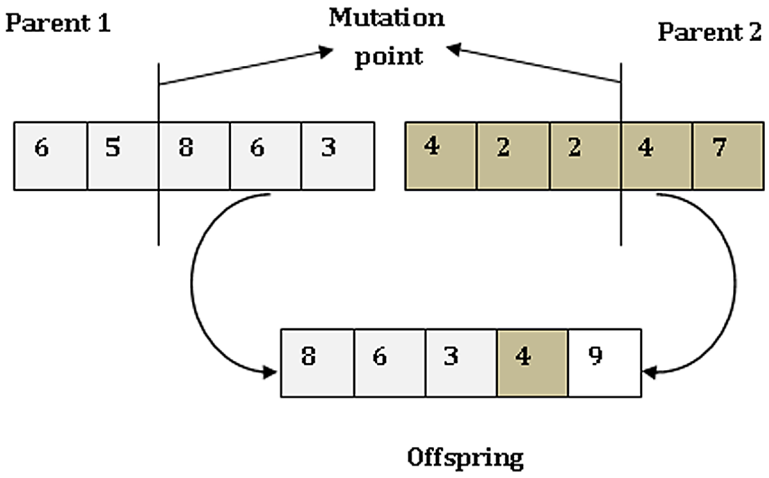
Figure 4. Methodology of mutation



RESULTS AND DISCUSSION

For developing the SVM model the design values of C, ε and σ are required. After several trials, the design values have been varied over a specific corresponding range in order to get better coefficient of correlation value. When the R value is close to one, then it is said to be a good model. At C=100, ε=0.001 and σ = 0.7, the R value is greater. Figure 5 and 6 describes the performance of training and testing datasets of the SVM model.

Therefore, the equation to determine w_t is as follows:

$$y = \sum_{i=1}^{31} w_i \exp\left\{-\frac{\left(x_i - x\right)^T \left(x_i - x\right)}{0.98}\right\} \tag{21}$$

The values of $(\alpha_i - \alpha_i^*)$ is shown in the following Figure 7.

For developing LSSVM, the design values of γ and σ have been determined by trial and error approach. The developed LSSVM gives best performance at γ=100 and σ=0.2. The performance of training and testing datasets has been determined by using the design values of γ and σ. Figures 5 and 6 illustrates the performance of LSSVM model. It can be seen from Figures 5 and 6 that the value of R is close to one.

The developed LSSVM give the following equation (by putting N=31, b=0.4258, σ=0.2, $y(x)=w_t$ and

$$K\left(x, x_k\right) = \exp\left[\frac{-\left(x - x_k\right)\left(x - x_k\right)}{2\sigma^2}\right]$$

in equation 20) for prediction of w_t.

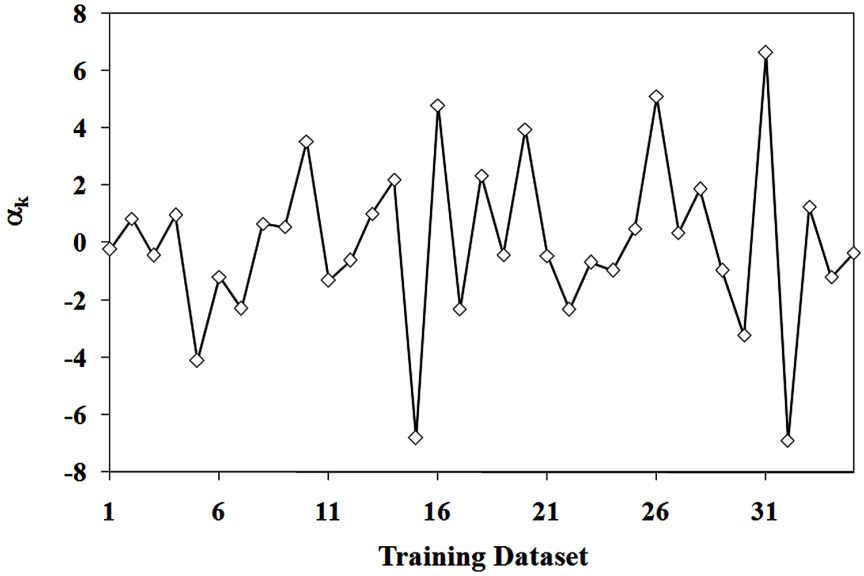
$$d = \sum_{i=1}^{31} \alpha_k \exp\left[\frac{-\left(x - x_k\right)\left(x - x_k\right)^T}{0.08}\right] \tag{22}$$

Figure 8 shows the value of α_k.

Figure 8. Values of α_k



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

The performance of the GP model was depicted in Figures 5 and 6. The merit of the GP model is that it conveys the direct equation. In order to determine the rate of medical waste generation the developed GP model generates the direct equation.

$$\begin{aligned} 0.2366\left(2x_1\right)^2 &- 0.02179\cos\left(-x_1 - 6.299x_2\right) - 0.01204x_6 \\ &+ 0.05986\sin\left(2x_2\left(x_5 - 8.176\right)\right) - 0.02338\sin\left(-8.729x_2 - 8.729x_6\right) \\ &- 0.03271\sin\left(-16.35x_2 - 16.35x_5\right) + 0.02408x_2\left(x_2 + x_5\right) + 0.04439 \end{aligned} \tag{23}$$

Different statistical criteria like Root Mean Square Error (RMSE), Mean Absolute Error (MAE), Coefficient of Efficiency (E), Root mean square error to observation's standard deviation ratio (RSR), Normalized Mean Biased Error (NMBE) and Performance Index (ρ) have been used to compare the developed model. The above mentioned statistical criteria have been determined by using the following equations.

$$RMSE = \sqrt{\frac{\sum_{i=1}^{n}\left(h_i - t_i\right)^2}{n}} \tag{24}$$

$$MAE = \frac{\sum_{i=1}^{n}\left|h_i - t_i\right|}{n} \tag{25}$$

$$E = 1 - \frac{\sum_{i=1}^{N}\left(h_i - t_i\right)^2}{\sum_{i=1}^{N}\left(hi - \overline{h}_i\right)^2} \tag{26}$$

$$RSR = \frac{RMSE}{\sqrt{\frac{1}{N}\sum_{i=1}^{N}\left(hi - \overline{h}_i\right)^2}} \tag{27}$$

$$NMBE = \frac{\sum_{i=1}^{n}\left(t_i - h_i\right)}{\overline{h}_i(n-p)} \tag{28}$$

$$\rho = \frac{RMSE}{\overline{h}_i}\frac{1}{R+1} \tag{29}$$

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

where h_i and t_i are the actual and predicted values for the i^{th} output, $\overline{h_i}$ and $\overline{t_i}$ are the average of the measured and predicted outputs, n is the total number of data and p is the number of predictor variables.

By using the above equations the values have been determined and it is tabulated in the following Table 1.

SOLUTIONS AND RECOMMENDATIONS

The regression modeling procedures utilized in this chapter convey the equations for future estimation on rate of medical waste generation. It depicts the path for easy management on the generated medical wastes. With any number of inputs, the predicted equation will provide the outcomes directly without any conditions. By predicting the rate of waste generation in smart cities, the authorities can perform flawless planning for storing, transportation and disposal of medical wastes. This will lead to the prevention of harm effects to human and environmental pollution.

FUTURE RESEARCH DIRECTIONS

The variation in the dataset ranges may lead to the inappropriate results. This can be resolved by the researchers in upcoming years. Various datasets can be collected and utilize the different procedures for foretelling the rate of medical waste generations. It is also suggested for the scientists to adopt various the adopted techniques for foretelling the generation of some other wastes like solid wastes, electronic wastes, agricultural wastes, radioactive wastes, construction and demolition wastes, etc. to escape from the ill effects for the smart cities and its citizens.

CONCLUSION

This chapter examines the capability of SVM, LSSVM and GP for prediction of rate of medical waste generation based on type of hospital, capacity and bed occupancy. The dataset plays a prominent role in the regression techniques. The dataset which goes beyond the adopted range may lead to inappropri-

Table 1. Statistical criteria's for the developed models

	SVM		LSSVM		GP	
	Training	**Testing**	**Training**	**Testing**	**Training**	**Testing**
RMSE	0.0229	0.0211	0.0043	0.0304	0.0125	0.3296
MAE	0.0079	0.0088	0.0030	0.0146	0.0106	0.2483
E	0.9804	0.9962	0.9993	0.9922	0.9941	0.0811
RSR	0.1401	0.0613	0.0263	0.0884	0.0767	0.9586
NMBE(%)	-4.5931	1.2095	0.0362	-0.5208	-0.4643	-59.5678
ρ	0.1333	0.0267	0.0249	0.0385	0.0727	0.4790

ate result which could be the practical difficulty. The researchers can try to overcome this difficulty in future. The developed SVM, LSSVM and GP give elegant and encouraging performances. GP uses four tuning parameters, whereas SVM and LSSVM use 3 and 2 parameters. SVM and LSSVM outperform the GP model. The developed equations can be used practically. This chapter issues the robust models based on SVM, LSSVM and GP for prediction of rate of medical waste generation.

KEY TERMS AND DEFINITIONS

Artificial Neural Network: Artificial Neural Network is a structure framed with densely interconnected with artificial neurons that performs the parallel computations for data processing and knowledge representations.

Estimation: The action of forecasting or predicting something is called as estimation.

Genetic Programming: Genetic programming (GP) is a systematic, domain-independent, evolutionary computation technique for computational problem solving.

Least Square Support Vector Machine: Least Square Support Vector Machine (LSSVM) least squares version of SVM. In this, the solutions can be obtained by solving the set of linear equations.

Medical Waste: Medical waste is all waste materials generated at health care facilities, such as hospitals, clinics, physician's offices, dental practices, blood banks, and veterinary hospitals/clinics, as well as medical research facilities and laboratories.

Support Vector Machine: Support Vector Machine (SVM) is supervised learning algorithm used for analyzing data and recognizes designs, also used for classification and regression analysis.

Chapter 46
Heavy Metal Pollution and its Management:
Bioremediation of Heavy Metal

Ashok K. Rathoure
Vardan Environet Guargaon, India

ABSTRACT

Environmental degradation has become a major societal issue thanks to uncontrolled anthropogenic activity, besides natural factors. Entry of toxic heavy metals and minerals in human system mainly through contaminated water, food and air, leads to overt and insidious health problems. Heavy metal pollution, a global concern today, can be managed by using bioremediation, an eco-friendly alternative. Bioremediation is one of the most promising technological approaches to the problem of hazardous waste. It is a technology for removing pollution from environment, restoring contaminated site and preventing future pollution. Bioremediation can be performed in situ or ex situ. Microorganisms directly degrade contaminants rather than merely transferring them from one medium to another, employ metabolic degradation pathways and can be used in situ to minimize disturbance of the cleanup site. Hence, microorganisms can be effective, economical and non-disruptive tools for eliminating hazardous chemicals. Its advantage generally outweigh the disadvantage, therefore may be used as management tool.

1. BACKGROUND

The rapid industrial developments have led to the generation of huge quantities of hazardous wastes, which have further aggravated the environmental problems in the country by depleting and polluting natural resources. Therefore, rational and sustainable utilization of natural resources and its protection from toxic releases is vital for sustainable socio-economic development (Chakrabarti, 2006). Hazardous waste management is a new concept for most of the Asian countries including India. The lack of technical and financial resources and the regulatory control for the management of hazardous wastes in the past had led to the unscientific disposal of hazardous wastes in India, which posed serious risks to

human, animal and plant life. A huge quantity of pollutants in the form of domestic and industrial effluents is discharged directly or indirectly into the water bodies, which has severe impacts on its biotic and abiotic environment. During rain, surface water with soil, mud and humus enter into the river, tanks and other water bodies. The soil is the target of thousands of contaminants that vary in composition and in concentration. The contaminants enter the system as a result of a wide range of actions such as intentional applications, inadequate residue disposal, accidental wastes and inappropriate use. Some human activities have resulted in the accumulation of metals in the environment. The inorganic minerals like sodium, potassium, calcium, magnesium and heavy metals like iron, manganese, lead, mercury, chromium, cadmium, nickel, cobalt, beryllium copper etc., when reach to the river with water cause water pollution. The use of various types of pesticides and insecticides in agriculture also cause water pollution. The pathogenic organisms of these wastes transmit to the water and pose serious problems (Batley, 1989; Garbarino et al., 1995; Jogdand, 1995; Agarwal, 1998; Hakeem & Bhatnagar, 2010).

2. WASTE AND ITS TYPE

Waste is an unavoidable by product of most human activity. Waste can be, in the form of solid or liquid, posed the harmful nuisance. Most solid waste is either sent to landfills or to incinerators. Ocean dumping has also been a popular way for coastal communities to dispose of their solid wastes in which large barges carry waste out to sea and dump it into the ocean. Most municipal and non municipal waste is sent to landfills. Landfills are popular because they are relatively easy to operate and can handle of lot of waste material. There are two types of landfills, sanitary landfills and secure landfills. Each day after garbage is dumped in the landfill, it is covered with clay or plastic to prevent redistribution by animals or the wind. In natural system, there is no such thing as waste. Everything flows in a natural cycle of use and reuse. Living organisms consume materials and eventually return them to the environment, usually in a different form, for reuse. Solid waste refers to a variety of discarded materials, not liquid or gas that is deemed useless or worthless. However, what is worthless to one person may be of value to someone else and solid wastes can be considered to be misplaced resources. Solid wastes are all the waste arising from human and animal activities that are normally solid waste and that are discarded as useless or unwanted. The term is all inclusive and it encompasses the heterogeneous mass of throwaways from the urban community as well as the homogeneous accumulations of agricultural, industrial and mineral wastes (USAID, 2004; Rajor & Kunal, 2011).

Electronic waste, e-waste, e-scrap or Waste Electrical and Electronic Equipment (WEEE) describe loosely discarded, surplus, outdated, broken, electrical or electronic devices. Electronic waste may be defined as all secondary computers, entertainment device electronics, mobile phones and other items such as television sets and refrigerators, whether sold, donated or discarded by their original owners. The processing of electronic waste in developing countries causes serious health and pollution problems because electronic equipment contains some very serious contaminants such as lead, cadmium, beryllium and brominates flame retardants. Electronic waste processing systems have matured in recent years, following increased regulatory, public and commercial scrutiny and a proportionate increase in entrepreneurial interest. In developed countries, electronic waste processing usually involves dismantling the equipment into various parts like metal frames, power supplies, circuit boards, plastics, by hand. The advantages of this process are the human's ability to recognize and save working and repairable parts, including chips,

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

transistors, RAM, etc. It is a major area of concern today that the wealthy countries are dumping large quantities of e waste into the developing world. According to BBC, currently the companies export 80 percent of the world's electronic trash to Asia. The problem of e-waste recycling in India involved the urgent need for educating consumers including the potential threat to public health and the environment posed by their products and for raising awareness for the proper waste management (Kesselman, 2007; Dogbevi, 2007; Beary, 2008; Mcphate, 2008; Toxic Links, 2008; Pinto, 2009).

Liquid waste can be defined as such fluids as wastewater, fats, oils, grease or used oil. The disposal of such waste, such as transmission fluid, cooking oil, spent oil, fats or grease can contaminate the groundwater or negatively impact the wastewater system. The liquid waste basically the waste water discharged from the industrial and domestic area. Wastewater is water that has been used for some purpose and is deemed unfit for further use. In fact, wastewater can be used for secondary purposes in most cases. Also, efficient use of water reduces the amount of wastewater generated. Sewage is created by residences, institutions, hospitals and commercial and industrial establishments. Raw influent or sewage includes household waste liquid from toilets, baths, showers, kitchens, sinks and so forth that is disposed of via sewers. In many areas, sewage also includes liquid waste from industry and commerce. As rainfall runs over the surface of roofs and the ground, it may pick up various contaminants including soil particles and other sediment, heavy metals, organic compounds, animal waste, oil and grease. It may be originated from various sites and by different uses (US EPA, 2000; Central New York Regional Planning and Development Board, 2004; Massoud & Ahmad, 2005).

Municipal waste water is the combination of liquid or water carried wastes originating in the sanitary conveniences of dwellings, commercial or industrial facilities and institutions, in addition to any groundwater, surface water and storm water that may be present. Wastewater is the flow of used water from a community. The characteristics of the wastewater discharges vary from location to location depending upon the population and industrial sector served, land uses, groundwater levels and degree of separation between storm water and sanitary wastes. Domestic wastewater includes typical wastes from the kitchen, bathroom and laundry, as well as any other wastes that people may accidentally or intentionally pour down the drain. Sanitary waste water consists of domestic wastewater as well as those discharged from commercial, institutional and similar facilities. Industrial wastes will be as varied as the industries that generate the wastes. Municipal waste water also contains a variety of inorganic substances from domestic and industrial sources, including a number of potentially toxic elements such as arsenic, cadmium, chromium, copper, lead, mercury, zinc etc (Xie et al., 1996, Ferrari et al., 1999).

3. INDUSTRIAL EFFLUENTS AND SOIL POLLUTION

Toxic chemicals found in wastewater pass through wastewater treatment facilities that have not been designed to remove them and can interfere with their operation. In a biological treatment process toxic materials can upset a treatment process or even kill the biological community and make the process ineffective. To remove the toxic pollutants at the treatment facility can be very costly. Therefore, it is generally advantages to remove them at the source. Source control can be achieved by the use of municipal by laws limiting pollutant discharges to the sewerage system. The removal of toxic pollutants at the source can be achieved by requiring treatment prior to discharge, recycling of waste by products, manufacturing process changes and the substitution of raw material (Thorpe, 2009).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

The effluent of the industries goes into the water system and changes the physico-chemical quality of water and also makes it unfit for drinking and other uses. Since all natural waterways contain bacteria and nutrients, almost any waste compounds introduced into such waterways will initiate biochemical reactions. These biochemical reactions are measured as BOD and COD in the laboratory. Both have been widely adopted as a measure of pollution effect. Disposal of wastewaters from an industrial plant is a difficult and costly problem. Most petroleum refineries, chemical and petrochemical plants have onsite facilities to treat their wastewaters so that the pollutant concentrations in the treated wastewater comply with the local or national regulations regarding the disposal of wastewaters into community treatment plants or into rivers, lakes or oceans. The solids can be suspended 30% as well as dissolved solids which are about 70%. The dissolved solids can be precipitated by chemical and biological processes. Organic components may consist of carbohydrates, proteins, fats and greases, surfactants, oils, pesticides, phenols etc. From a physical point of view the suspended solids can lead to the development of sludge deposits and anaerobic conditions when discharged into the receiving environment. Physically, the wastewater is usually characterized by grey colour, musty odour, 0.1% solid content and 99.9% water content (Tchobanoglous, 1987; Tchobanoglous et al., 2003; Clair, 2003; Maiti, 2004).

The soil is the target of thousands of contaminants that vary in composition and in concentration. The contaminants enter the system as a result of a wide range of actions such as intentional applications, inadequate residue disposal, accidental wastes and inappropriate use. Soil pollution is defined as the buildup in soils of persistent toxic compounds, chemicals, salts, radioactive materials or disease causing agents, which have adverse effects on plant growth and animal health. Soil is the thin layer of organic and inorganic materials that covers the earth's rocky surface. The organic portion, derived from the decayed remains of plants and animals, is concentrated in the dark uppermost topsoil. The inorganic portion, made up of rock fragments, was formed over thousands of years by physical and chemical weathering of bedrock. Soil pollution is caused by the presence of manmade chemicals or other alteration in the natural soil environment. This type of contamination typically arises from the rupture of underground storage links, application of pesticides and percolation of contaminated surface water to subsurface strata, oil and fuel dumping, leaching of wastes from landfills or direct discharge of industrial wastes to the soil. The most common chemicals involved are petroleum hydrocarbons, solvents, pesticides, lead and other heavy metals. This occurrence of this phenomenon is correlated with the degree of industrialization and intensities of chemical usage. The waste contaminates the soil. The solid waste includes garbage, domestic refuse and discarded solid materials such as those from commercial, industrial and agricultural operations. They contain increasing amounts of paper, cardboards, plastics, glass, old construction material, packaging material and toxic or otherwise hazardous substances (Knaebel et al., 1994; Franklin Associates, 1996).

Some human activities have resulted in the accumulation of metals in the environment. Both soil and aqueous effluents have been contaminated with heavy metals as the result of numerous industrial activities, including mining, smelting, jewelry, automobile battery production, vehicle emission and land filling of industrial waste and fly ash from incineration process. This contamination of the environment poses serious health threats to humans and animals, as these heavy metals tend to persist in the environment indefinitely. This kind of contamination presents a challenge, as the presence of heavy metals in soils and aqueous effluents leads to serious problems because they cannot be biodegraded. In this case, the metal ion can only be converted to the base metal, methylated, precipitated, volatilized or complexed with an organic ligand. The more common heavy metals associated with anthropogenic activities include

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

lead, cadmium, copper, chromium, nickel, iron, mercury and zinc. Methods of treating the contaminated effluents currently consist of chemical precipitation, solvent extraction, dialysis, electrolytic extraction, cementation, reverse osmosis, evaporative methods, ion exchange resins, carbon adsorption and dilution (USEPA, 2000; European Union, 2002).

4. HEAVY METALS

Metals play an integral role in the life processes of living organisms. Some metals like Ca, Co, Cr, Cu, Fe, K, Mg, Mn, Na, Ni and Zn are essential, serve as micronutrients and are used for redox processes, to stabilize molecules through electrostatic interactions; as components of various enzymes and regulation of osmotic pressure. The essential metals must be present in a certain concentration range. Too low concentrations of heavy metals lead to a decrease in metabolic activity and too high concentrations, it leads to toxicity. While other metals like Ag, Al, Cd, Au, Pb and Hg have no biological role and they are non essential. Nonessential metals are tolerated at very low concentrations and inhibit metabolic activity at higher concentrations. They are potentially toxic to living organism specially microorganisms. Toxicity of non essential metals occurs through the displacement of essential metals from their native binding sites or through ligand interactions. The many uses of heavy metals in several applications lead to wide distribution in soil, silt, waste and waste water. Such pollution of the environment by toxic metals and radionuclide arises as a result of many human activities, largely industrial, although such sources as agriculture and sewage disposal also contribute. Heavy metal contamination can be a consequence of industrial activities that eliminate residues in the soil that in long terms, promote their accumulation. Heavy metals in wastewater come from industries and municipal sewage and they are one of the main causes of water and soil pollution. The majority of the sources are originated by human actions like metal manufacture and mining industries with storage, disposal and transportation problems. Among the metals found more frequently there are Cd, Pb, Co, Cu, Hg, Ni, Si and Zn. For Cd, Pb, Cu and Zn, their toxicity increases as follows: Pb < Zn < Cu < Cd, depending on countless abiotic and biotic factors (Lloyd et al., 2001; Glick, 2003; Zenker et al., 2005).

Both soil and aqueous effluents have been contaminated with heavy metals as the result of numerous industrial activities, including mining, smelting, jewelry, automobile battery production, vehicle emission and land filling of industrial waste and fly ash from incineration process. This contamination of the environment poses serious health threats to humans and animals, as these heavy metals tend to persist in the environment indefinitely. Metals play an integral role in the life processes of living organisms. Some metals like Ca, Co, Cr, Cu, Fe, K, Mg, Mn, Na, Ni and Zn are essential, serve as micronutrients and are used for redox processes, to stabilize molecules through electrostatic interactions; as components of various enzymes and regulation of osmotic pressure. The essential metals must be present in a certain concentration range. Too low concentrations of heavy metals lead to a decrease in metabolic activity and too high concentrations, it leads to toxicity. While other metals like Ag, Al, Cd, Au, Pb and Hg have no biological role and they are non essential. In order to survive in heavy metal polluted environments, many microorganisms have developed means of resistance to toxic metal ions. These mechanisms include metal exclusion by permeability barriers, active transport of the metal away from the cell organism, intracellular sequestration of the metal by protein binding, extracellular sequestration, enzymatic detoxification of the metal to a less toxic form and reduction in metal sensitivity of cellular targets. Most microorganisms are

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

known to have specific genes for resistance to toxic ions of heavy metals. Mostly, the resistance genes are found on plasmids or on chromosomes. Plasmid encoded metal resistance determinants have been reported to be inducible (Nies & Silver, 1995; Rosen, 2002).

The intake of heavy metal ions by microbial strains normally includes a redox reaction involving the metal. Some bacteria use heavy metals for energy and their growth. Bacteria that are resistant to heavy metals also play an important role in biogeochemical cycling of metal ions. Since, the oxidation state of a metal ion may determine its solubility, many scientists have been attempting to use microbes that are capable to oxidize or reduce metals in order to remediate metal contaminated sites. Although, some heavy metals are important and essential trace elements and others are toxic at high concentrations to microbes, some microbes have adapted to tolerate the presence of metals or even to use them to grow. In addition, a number of interactions between microbial strains and metals have important environmental and health implications. Health problem due to heavy metals pollution in human being include nausea, vomiting, bone complications, nervous system impairments and even death become a major problem throughout many countries when metal ions concentration in the environment exceeded the admissible limits. Due to that, various treatment technologies had been searched to reduce the concentration of heavy metals in the environment (Nies, 1999; Lodeiro et. al., 2006).

It is needed to remove the heavy metals from the contaminated sites/waste. Several heavy metals removal technologies including chemical precipitation, ion exchange, reverse osmosis, electrodialysis, ultra filtration and pyhtoremediation are commonly used in industries. However, these technologies are becoming uneconomical and unfavorable to remove heavy metals from industrial wastewaters. The development of new treatment method such as bioremediation to remove heavy metal ions from wastewater and solid waste which could be cost effective and more efficient has spurred to overcome the conventional method. Bioremediation technology has received much attention as it offered low cost technique and non hazardous biomaterials (Lovley, 1997; Ahalya et al., 2003).

5. BIOREMEDIATION

The history of bioremediation is considerably shorter and it reflects many upturns and downturns as a result of political and economic forces. Interest in use of microorganisms to degrade specific hazardous organic chemicals probably dates back to Gayle (1952), who proposed the microbial infallibility hypothesis. Gayle postulated that for any conceivable organic compound, there exists a microorganism that can degrade it under the right conditions. If not, evolution and adaptation would produce such a strain. This hypothesis cannot wrong, because failure to degrade a contaminant can be attributed to the researcher's failure to use the right strain under the right condition. In 1970s, environmental statutes of unprecedented scope passed, such as the Occupational Safety and Health Act (OSHA) of 1970, the Clean Air Act (CAA) of 1970, the Clean Water Act (CWA) of 1972, the Safe Drinking Water Act (SWA) of 1974 and the Toxic Substance Control Act (TSCA) of 1976. This regulatory pressure stimulated interest in site remediation technologies, including bioremediation. However, bioremediation failed to meet the expectations raised by many technology salespeople, who commonly advocated the addition of specialized bacteria to contaminated site i.e. bioaugmentation. Early proponents of this approach generally did not recognize that indigenous bacteria already present at a contaminated site where probably better predisposed physiologically and genetically to mediate the degradation of the target pollutants. The first patent for a biological remediation agent was registered in 1974, being a strain of *Pseudomonas putida*

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

that was able to degrade petroleum. In 1991, about 70 microbial genera were reported to degrade petroleum compounds and almost an equal number has been added to the list in the successive two decades. Bioremediation can occur naturally or through intervention processes. Natural degradation of pollutants relies on indigenous microflora that is effective against specific contaminants and it usually occurs at a slow rate. With intervention processes, the rate of biodegradation is aided by encouraging growth of microorganisms, under optimized physico-chemical conditions. Microorganisms play a vital role in heavy metal contaminated soil and wastewater by the mechanisms of biosorption. Some microorganisms possess an astonishing catabolic versatility to degrade or transform such compounds. The need for economical, effective and safe methods for removing heavy metals from wastewater has resulted in the search for unconventional materials that may be useful in reducing the levels or accumulation of heavy metals in the environment (US Congress, 1991; Agarwal, 1998; Bouwer et al., 1998; Smith et al., 1998).

Bioremediation is the use of living microorganism to reduce the environmental pollution. It is a technology for removing pollution from the environment, restoring contaminated site and preventing future pollution. Bioremediation can be performed in situ or ex situ. With the onset of the Industrial Revolution, an ever increasing proportion of the earth's surface became contaminated with natural and xenobiotic toxic chemicals. The basic principle of bioremediation involves utilizing the activity of microorganisms naturally present in the soil and water or selected organisms inoculated into the environment, to biodegrade or detoxify contaminating compounds in situ. In the majority of cases a consortium of microorganisms will be involved in the biodegradation of the contaminant, rather than a single species. To optimize the process, promotion of the growth of indigenous microorganisms is necessary. It can be achieved by the addition of key nutrients such as nitrogen and phosphorus, which are normally present in growth limiting concentrations. This enables the natural microbial flora to develop and metabolize the contaminant (Vidali, 2001).

Alternatively, known biodegraders of the contaminant that have been identified, isolated and their activities optimized can be used as an inoculants. For example, a recent addition to the growing list of microorganisms able to sequester or reduce metals is *Geobacter metallireducens*. This bacterium can remove uranium, a radioactive waste, from drainage waters in mining operations and from contaminated ground waters. However, the most radiation resistant bacterium known is *Deinococcus radiodurans*; this organism is also being developed to help clean up soil and water contaminated by solvents, heavy metals and radioactive waste. A genetically engineered strain of *D. radiodurans* has been produced which can detoxify mercury (genes derived from *Escherichia coli*) and degrade toluene (genes derived from *Pseudomonas putida)* in radioactive environments (Bouwer & Zehnder, 1993; Bernard et al., 2007).

6. REQUIREMENTS OF BIOREMEDIATION

Bioremediation is a fairly new technology and holds the promise of becoming the solution to our polluted environment. This new technology gives us alternative routes to cleaning up contaminated sites was thought to be not possible previously. Nonetheless, the technology of bioremediation still has a long way more to go). Bioremediation faces several challenges and some of the most common ones are deficit of knowledge, lack of integrated research, lack of revenue and inadequate tool and infrastructure (Aksu, 1998; Vidali, 2001; Ahluwalia & Goyal, 2007). A deficit of knowledge on the different fundamental branches of sciences that are involved in the process of bioremediation hinders the progress of bioremediation. Examples of the different disciplines of sciences are such as structural and molecular biology,

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

microbiology, genomics, geochemistry, along with hydrology and transport processes. To date, little is known on how introduced microorganisms interact with different hydrological environment. Research in each of the variety of fields is needed to further researchers' comprehension on the actual activity or rather, the chemistry that is involved and interactions between contaminants, native organisms on site and remedial organisms. There is still much to learn and gain from research as contaminated sites are complex systems, each composed of different types of contaminants, diverse organisms and dissimilar environment (Doyle, 1989; Prescott, 2002). Bioremediation is a multidisciplinary field and researchers from various fields need to integrate their knowledge. The success and efficiency of bioremediation requires the involvement of microbiologists, biochemists, engineers, geologists and soil scientists among others. Knowledge on the combined factors is not enough and mostly these are the rate limiting factors of the process of bioremediation. Interdisciplinary research of at the least two fields is unavoidable to advance this technology. Assimilation of scientific ideas across disciplines is most needed to optimize the potential of bioremediation (Blackburn & Hafker, 1993; Boopathy, 2000; Bernard & Jack, 2007). There is no doubt that governmental and private sectors are investing on biotechnology companies but not much of the revenue goes to the improvement of bioremediation. Lack of revenue is an obstruction to advancement in bioremediation as it prevents further research and discoveries from taking place. Thereupon, progress of bioremediation is delayed as a result of material deficiency (Gadd, 1988; Bouwer & Zehnder, 1993). Infrastructure and materials are needed to carry out research. Accuracy in experimental procedures is crucial to ensure successful treatment when introduced to contaminated site. However, there is inadequacy of infrastructure to analyze the conditions of contaminated sites as well as monitor the process of degradation that has been introduced to the site. Insufficiency of advanced tools specifically designed to aid research on bioremediation would also hold back development of research methodology and prevent discoveries from happening. Despite its shortcomings, its pertinence in this world is unquestionable in the light of present day environmental hazards. Bioremediation provides a technique for cleaning up pollution by enhancing the same biodegradation processes that occur in nature and potential for significant advances (Bouwer et al., 1998; Boopathy, 2000; Chatterjee et al., 2008; Shazia et al., 2009; Hakeem & Bhatnagar, 2010).

7. METAL TOXICITY AND MANAGEMENT

The pollution of the environment with toxic heavy metals is spreading throughout the world along with industrial progress. Effluents from textile, leather, tannery, electroplating, galvanizing, dyes and pigment, metallurgical industries and other metal processing and refining operations at small and large scale sector contains considerable amounts of toxic metal ions (White et al., 1995). Cadmium, chromium, cobalt, copper, iron, manganese, mercury, molybdenum, nickel, silver and zinc are known to be the most commonly heavy metals used and the more widespread contaminants of the environment (FWPCA, 1998). Traces of these heavy metals are necessary as co-factors of enzymatic reactions, but high levels of them may cause extreme toxicity to living organisms due to inhibition of metabolic reactions. Many compounds that are legally considered to be hazardous can be transformed to harmless products. This eliminates the chance of future liability associated with treatment and disposal of contaminated material. Instead of transferring contaminants from one environmental medium to another from land to water or air, the complete destruction of target pollutants is possible (Agarwal, 1998).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Arbitrary and hysterical discharge of industrial and urban wastes into the environmental sink has become an issue of major global concern. Intensification of agriculture and manufacturing industries has resulted in increased release of a wide range of xenobiotic compounds to the environment. Excess loading of hazardous waste has led to scarcity of clean water and disturbances of soil, thus limiting crop production. Although enactment of stringent regulation has led to less indiscriminate disposal of organic and inorganic wastes, challenges remain that require other intervention (Hess et al., 1997). Waste comprises liquid waste discharged by domestic residences, institutions, hospitals, commercial properties, industry or agriculture and can encompass a wide range of potential contaminants and concentrations. In the most common usage, it refers to the municipal wastewater that contains a broad spectrum of contaminants resulting from the mixing of wastewater from different sources. Raw influent includes household waste liquid from toilets, baths, showers, kitchens, sinks and so forth that is disposed to the river via sewers. This affects the BOD, COD, turbidity and also causes the physico-chemical changes in the river. In many areas, sewage also includes liquid waste from industry and commerce. As rainfall runs over the surface of roofs and the ground, it may pick up various contaminants including soil particles and other sediment, heavy metals, organic compounds, animal waste and oil and grease (APHA, 1995; 1998; FWPCA, 1998). The metal ions from metal mining pose problems to the water environment by discharging mine water from underground and open pit mines (Knaebel, 1994). Leachate water and runoff water from overburden/waste rock dumps also contaminate nearby water streams (Ferrari et al., 1999). The principle pathways by which leached contaminants can enter into groundwater are leakage or spills from storage ponds, leach pad liners, storm water run on/off, uncontrolled leaching from heaps and dumps. These toxic metals ions not only cause potential human health hazards but also affect other life forms (Malik, 2004). Heavy metal pollution usually results from electroplating, plastic manufacturing, fertilizer, pigment industries, mining and metallurgical processes (Nirmal Kumar et al., 2009).

Heavy metals can be emitted into the environment by both natural and anthropogenic causes. The major causes of emission are the anthropogenic sources specifically mining operations (Hutton & Symon, 1986; Nriagu, 1989). Much of the metal salts within the oceans, lakes, streams and estuaries are in the form of magnesium, calcium, potassium and sodium salts. While many other constituents are clearly available in solution, no element having a concentration less than 2 nmol in the ocean is generally considered essential for life. The metals cannot degraded to harmless products and hence persist in environmental indefinitely (Silver, 1996). The metals leached out and in sloppy areas, are carried by acid water downstream or run-off to the sea. Through mining activities, water bodies are most emphatically polluted (INECAR, 2000; European Union, 2002). The heavy metals refer to any metallic element that has a relatively high density than $5g/cm^3$, is toxic or poisonous even at low concentration and its pollution is the major concern faced by the society today (Aksu, 1998; Nies, 1999). Heavy metals are on the forefront of academic and regulatory concern, since millions of gallon of water containing toxic heavy metals are generated annually from several metal processing industries and discharged into the environment (Gardea et al., 2005).

Metals discharged into water bodies are not biodegraded but undergoes chemical or microbial transformations, creating large impact on the environment and public health. Heavy metals influence the microbial population by affecting their growth, morphology, biochemical activities and ultimately resulting in decreased biomass and diversity (Roane and Pepper, 2000). The microorganisms respond to the heavy metals by several processes; including transport across the cell membrane, biosorption to the cell walls and entrapment in extracellular capsules, precipitation, complexation and oxidation-reduction reactions (Veglio et al., 1997). The discharge of wastewater containing high concentrations of heavy metals

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

to receiving water bodies has serious adverse environmental effects. Their occurrence and accumulation in the environment is a result of direct or indirect human activities, such as rapid industrialization, urbanization and anthropogenic sources (EPA, 2000; Hussein et al., 2005; Gardea et al., 2005). Metals, when present in our body, are capable of causing serious health problems by interfering with our normal body functions. Some metals are useful to the body in low concentrations like arsenic, copper, iron and nickel but are toxic at high concentrations. Other metals like aluminum, beryllium, cadmium, lead and mercury have no biological functions and are highly toxic disrupting bodily functions to a large extent (European Union, 2002).

The most metal ions have to enter the microbial cell for its physiological or toxic effect. Usually, microorganisms have solved the problem by using two types of uptake systems for metal ions. One is fast, unspecific and driven by the chemiosmotic gradient across the cytoplasmic membrane of bacteria. The second type of uptake system has high substrate specificity, is slower, generally uses ATP hydrolysis as the energy source and is only produced by the cell in times of need, starvation or a special metabolic situation (Nies & Silver, 1995; Nies, 1999). Heavy metals contamination is becoming a great concern to the environmental awareness and government policies. Several heavy metals removal technologies including chemical precipitation, ion exchange, reverse osmosis, electrodialysis, ultrafiltration and phytoremediation are commonly used in industries (Ahalya et al., 2003). However, these technologies are becoming uneconomical and unfavorable to remove heavy metals from industrial wastewaters. With increasing environmental attention and legal constraint on discharge effluents, a need of cost effective technologies are essential (Agarwal, 1998). Therefore, the search for efficient, eco-friendly and cost effective remedies for wastewater treatment has been initiated. In recent years, research attention has been focused on biological methods for the treatment of effluents, some of which are in the process of commercialization (Prasad and Freitas, 2003). Removal of heavy metals remains a major challenge in environmental biotechnology. The pollutants generally include organic wastes and heavy metals. Heavy metal removal is important for survival of the environment (Lenntech, 2004; Gardea et al., 2005).

There are three principle advantages of biological technologies for the removal of pollutants; first, biological processes can be carried out in situ at the contaminated site; second, bioprocess technologies are usually environmentally benign, no secondary pollution and third, they are cost effective. Of the different biological methods, bioaccumulation and biosorption have been demonstrated to possess good potential to replace conventional methods for the removal of metals (Volesky, 1995, King et al., 1997). Microorganisms are critical to nutrient recycling in ecosystems as they act as decomposers. Researchers develop a feasible method to accelerate the process of decay and removal by encouraging the microbial and associated flora and fauna within the ecosystem to accumulate, degrade and remove the pollutants from the identified sites (Vidali, 2001; Ahalya et al., 2003; Dubey, 2004). Bioremediation is the use of biological systems, almost invariably microorganisms to clean up a contaminated site. In bioremediation processes, microorganisms use the contaminants as nutrient or energy sources. Bioremediation uses naturally occurring or genetically engineered microorganisms such as bacteria and fungi to transform harmful substance into less toxic or non-toxic compounds. Compared to other methods, bioremediation is a more promising and less expensive way for cleaning up contaminated soil and water (Hess et al., 1997; Agarwal, 1998; USEPA, 1999; Kamaludeen et al., 2003; Tang et al., 2007).

In bioremediation, solubilization of heavy metal contaminants provides a means of removal from the solid substance. Some microbial species subject heavy metal ions to enzymatic reduction, the reduced form of heavy metal ions are quite insoluble and they precipitate out of solution (Nies, 1999). Most microorganisms can reproduce rapidly and microbes such as bacteria can also freely exchange genes

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

by conjugation, transformation and transduction between widely divergent species. The organisms that are utilized vary, depending on the chemical nature of the polluting agents and are to be selected carefully as they only survive within a limited range of chemical contaminants (Shazia et al., 2009). Contaminant compounds are transformed by living organisms through reactions that take place as a part of their metabolic processes. Biodegradation of a compound is a result of the actions of multiple organisms. When microorganisms are imported to a contaminated site to enhance degradation, the process is known as bioaugmentation (Agarwal, 1998). Bioremediation is the process whereby organic wastes are biologically degraded under controlled conditions to an innocuous state or to levels below concentration limits established by regulatory authorities. Bioremediation is the elimination or reduction of toxic pollutant from the contaminated sites with the help of biological organisms such as bacteria, fungi and plants by degradation, assimilation or transpiration in the atmosphere. Moreover, the toxicity of heavy metals in wastewater was shown to be dependent on factors like metal species and concentration, pH, wastewater pollution load and solubility of the metal ions (Vidali, 2001; Strong and Burgess, 2008). Organic contaminants may be degraded biologically and CO_2 and H_2O are the final products, which are not hazardous and may be recycled. In contrast to toxic organic and inorganic substances, the metallic species released into the environment cannot be degraded biologically, chemically or physically (Singh and Ward, 2004). Bioaccumulation is the accumulation of materials which are not critical components of an organism by that organism. Usually, it refers to the accumulation of metals. Heavy metal ions accumulate in microbial cells through membrane transport proteins by active transport. Various microbial species including bacteria, fungi, algae and actinomycetes have been shown to be efficient in bioaccumulation of heavy metal ions from polluted effluents (Wong et al., 1993). The bioremediation of heavy metals using microorganisms has received a great deal of attention in recent years, not only as a scientific novelty but also for its potential application in industry. Metal accumulative bioprocess generally falls into one of two categories; biosorptive uptake by nonliving, non-growing biomass or biomass products and bioaccumulation by living cells (Aksu, 1998). Microbes can remove heavy metals from contaminated solutions either by bioaccumulation, precipitation or biosorption. In comparison with biosorption, bioaccumulation is a growth dependent process. Since, bioremediation is based on natural attenuation, therefore, it is considered more acceptable than other technologies. Most bioremediation systems are run under aerobic conditions, but running a system under anaerobic conditions may permit microbial organisms to degrade otherwise recalcitrant molecules (Bernard & Jack, 2007, Ke et al., 2009).

The foundation of bioremediation has been the natural ability of microorganisms to degrade organic compounds (Mostafa et al., 1992). This technology is based on the use of naturally occurring or genetically engineered microorganisms to restore contaminated sites and protect the environment. As bioremediation can be effective only where environmental conditions permit microbial growth and activity, its application involves the manipulation of environmental parameters to allow microbial growth and degradation to proceed at a faster rate. Like other technologies, bioremediation has its limitations (Teresa & Lee, 1994). Some contaminants, such as chlorinated organic or high aromatic hydrocarbons, are resistant to microbial attack. Most frequently, in situ bioremediation is applied to the degradation of contaminants in saturated soils and groundwater. It is a superior method to cleaning contaminated environments. Since, it is cheaper and uses harmless microbial organisms to degrade the chemicals. Chemotaxis is important to the study of in situ bioremediation because microbial organisms with chemotactic abilities can move into an area containing contaminants. So by enhancing the cells' chemotactic abilities, in situ bioremediation will become a safer method in degrading harmful compounds (Takehiko, 2004).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Microbes able to degrade the contaminant increase in numbers when the contaminant is present and when the contaminant is degraded, the biodegradative population declines (Bernard and Jack, 2007). Theoretically, bioremediation is useful for the complete destruction of a wide variety of contaminants.

8. BIOLOGICAL TREATMENT

Recent studies in molecular biology and ecology offers numerous opportunities for more efficient biological processes. Notable accomplishments of the studies include the cleanup of polluted water and land areas. Bioremediation leads to changes in the solubility, sorption characteristics, transport properties and toxicity metals. It promotes the growth of microorganisms to degrade contaminants by utilizing those contaminants as carbon and energy sources (Teresa & Lee, 1994). The bioremediation systems in operation today rely on microorganisms native to contaminated sites, encouraging them to work by supplying them with the optimum levels of nutrients and other chemicals essentials for their metabolism (Shazia et al., 2009). Microorganisms can be isolated from almost any environmental conditions (Holt et al., 1994). The search for alternative and innovative treatment techniques has focused attention on the use of biological materials such as algae, fungi, yeast and bacteria for the removal and recovery technologies and has gained importance during recent years because of the better performance and low cost of the biological materials. Since, numerous types of pollutants are to be encountered in a contaminated site, diverse types of microorganisms are likely to be required for effective mediation (Gogoi et al., 2003). Microbes can adapt and grow at subzero temperatures, as well as extreme heat, desert conditions, in water, with an excess of oxygen and in anaerobic conditions, with the presence of hazardous compounds or on any waste stream. The main requirements are an energy source and a carbon source (Teresa & Lee, 1994). In situ biodegradation involves supplying oxygen and nutrients by circulating aqueous solutions through contaminated soils to stimulate naturally occurring bacteria to degrade organic contaminants. It can be used for soil and groundwater. *In situ* bioremediation means there is no need to excavate or remove soils or water in order to accomplish remediation. Generally, this technique includes conditions such as the infiltration of water containing nutrients and oxygen or other electron acceptors for groundwater treatment. Bioremediation can be carried out on site without causing a major disruption of normal activities (Thassitou & Arvanitoyannis, 2001). This also eliminates the need to transport quantities of waste off site and the potential threats to human health and the environment that can arise during transportation. Bioremediation can prove less expensive than other technologies that are used for clean-up of hazardous waste (Singh & Ward, 2004; Ramirez et al., 2009). The complex structure of microorganisms implies that there are many ways for the metal to be taken up by the microbial cell (Volesky & Holan, 1995). The presence and activity of microorganisms in biological wastewater treatment are vital to the process. With regard to microbial removal of heavy metals, biosorption phenomenon is crucial (Knauer et al., 1997). The mechanism by which microorganisms remove heavy metals can be divided into three categories; the first mechanism is the biosorption of metals ions on the cell surface, second intracellular uptake of metals ion and third chemical transformation of metal ions by microorganism (Pardo et al., 2003). Among the different technique employed for metals removal from multi elemental system, biosorption has been found to be highly selective. Furthermore, the metal accumulating bacteria can be used to remove, concentrate and recover metals from industrial effluents (Loick et al., 2009).

9. BIOSORPTION

Biosorption is a metabolism independent binding of heavy metals to living cells, non living biomass or microbial extracellular pathways resulting in bioprecipitation of heavy metals or their mechanisms of removal (Cotoras et al., 1993). The mechanism of metal biosorption is a complicated process, mainly ion exchange, chelations, adsorption by physical forces, entrapment in inter and intrafibrilliar capillaries and spaces of the structural polysaccharide network as a result of the concentration gradient and diffusion through cell walls and membranes. In metal biosorption process by living cells, the metal ions are adsorbed to the surface of cells by interactions between metals and functional groups displayed on the surface of cells. All the metal ions before gaining access to the cell membrane and cell cytoplasm come across the cell wall. The cell wall consists of a variety of polysaccharides and proteins and which acts as active sites of binding metal ions. The mechanism of metal biosorption can be influenced by the status of biomass, living or non-living, types of biomaterials, properties of metal solution chemistry, ambient/ environmental conditions such as pH (Gee & Dudeney, 1998). There are several chemical groups that would attract and sequester the metals in biomass such as acetamido groups of chitin, structural polysaccharides of fungi, amino and phosphate groups in nucleic acids, amido, amino, sulphhydryl and carboxyl groups in proteins, hydroxyls in polysaccharide and mainly carboxyls and sulphates in polysaccharides of marine algae that belong to the divisions Phaeophyta, Rhodophyta and Chlorophyta (Diels et al., 2002). It does not necessarily mean that the presence of some functional group guarantees biosorption, perhaps due to steric, conformational or other barriers (Gunasekaran et al., 2003).

Difference in the cell wall composition among the different groups of microorganisms, viz. algae, bacteria, cyanobacteria and fungi, cause significant differences in the type and amount of metal ion binding to them. The potential metal binding groups in this class of microbes are carboxylates, amines, imidazoles, phosphates, sulfhydryls, sulfates and hydroxyls (Giller et al., 1998). The amines and imidazoles groups are positively charged when protonated and may build negatively charged metal complexes. Cell walls of bacteria are principally composed of peptidoglycans which consist of linear chains of the disaccharide N-acetylglucosamine (Gunasekaran et al., 2003). Heavy metal binding by biopolymers happens by chance and the relative removal efficiency depends upon the metal species and concentration, the reactivity of the available biopolymers or biomass and the composition of other wastewater components. Moreover, surface exposure of metal binding biopolymers improves the metal binding properties of microorganisms based not only on biosorption but also on microbial metabolic activities. Biosorption of heavy metals by microbial cells has been studied extensively as an alternative technology for the treatment of wastewaters. It is a promising process that can reduce capital costs by 20%, operational costs by 36% and total treatment costs by 28%, compared with conventional systems (Loukidou et al., 2004).

Microbes are exploited by people in biotechnology, both in traditional food and beverage preparation and in modern technologies based on genetic engineering (Giller et al., 1999). Bacteria, like the more complex eukaryotic organisms, have all the inner workings for cell function, cellular division and growth, genetic transcription, translation and energy production (Silver et al., 1990). All of this activity within a single bacterium typically takes place within a volume of 1.5-2.0 μm^3. How the bacteria alter their environment is equally important as how they are impacted by their surroundings. Much of this interaction takes place throughout and external to the outer structures. The enveloping layers that make up the outer structures of the bacterial cell consist of a cytoplasmic membrane, a capsule, sheaths, an S-layer and flagella (Beveridge, 1985). The cell wall consists primarily of a cytoplasmic membrane and a thick layer of peptidoglycan. All cells have a highly selective permeable barrier known as the cyto-

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

plasmic membrane, separating the life sustaining metabolic activity of the cell from its environment and allowing all food materials, nutrients and waste products to pass (Silver, 1996). The metals can be captured in the outer portions of the cell such that the organism can be considered to be continuously enveloped in a brine of various ions. This phenomenon of capturing metals can act as the first step in the bacteria's active accumulation and assimilation of metals at various concentrations. This concentration of metal ions may have developed as a method for accumulating essential cations, if the bacteria find itself in a more dilute environment. The outer membrane may also immobilize heavy metals, thus preventing their penetration into the cell. Microorganisms' ability to oxidize metals plays an important role in the biological cycling of metals on a global scale. Microorganisms are also considered for their ability to accumulate metal ions within and on the membrane surface of the cell. Such interactions are so predominant that they can be utilized for economic or ecological gain (Sattelmacher, 2001).

Bacterial and fungal survival in the presence of toxic metals mainly depends on intrinsic biochemical and structural properties, physiological and genetically adaptation, including morphological changes and environmental modification of metal speciation, availability and toxicity, the relative importance of each being difficult to determine. It is probably more appropriate to define resistance by means of a mechanism produced in direct response to the metal species concerned, e.g. synthesis of metallothioneins (Eccles & Hunt, 1986; Gadd, 1992). Arbitrary terms such as resistance and tolerance which are used rather loosely and interchangeably in the literature are generally based on the ability to grow on a certain metal concentration in laboratory media (Ehrlich, 1997). Metal tolerance may be defined as the ability of an organism to survive metal toxicity by means of intrinsic properties and/or environmental modification of toxicity. Intrinsic properties that can determine survival include possession of impermeable pigmented cell walls, extracellular polysaccharide and metabolite excretion, especially where this leads to detoxification of the metal species by binding or perception (Aksu, 1998; Giller et al., 1999). However, in many cases distinctions are difficult because of the involvement of several direct and indirect physico-chemical and biological mechanisms implicated in fungal survival as distinct from environmental modification of toxicity include extracellular precipitation, complextion and crystallization, transformation of metal species by oxidation, reduction, methylation and dealkylation, biosorption to cell walls, pigments and extracellular polysaccharide, decreased transport or impermeability, efflux, intracellular compartmentation and precipitation and/or sequestration. A particular organism may directly and/or indirectly rely on several survival strategies (Peng et al., 2010).

The heavy metal removal from water and wastewater is crucial to protect the water environment from the heavy metal pollution. The heavy metal resistant microorganisms have significant role in bioremediation (Zouboulis et al., 2004; Peng et al., 2010). The metal and organic pollutants can be removed by the microbial flora. *Bacillus sp.* was very much efficient to remove the Au, Cd, Cr, Fe, Mn, Ni, Pb, U and Zn. It was recorded that *Bacillus sp.* can efficiently removed the metal pollutants from the waste or industrial effluents (Gunasekaran et al., 2003) and some aromatics, long chain alkanes, phenol, cresol (Cybulski et al., 2003). *Pseudomonas sp.* were reported to Cd, Cr, Cu, Ni, Pb, U and Zn (Sar and D'Souza, 2001; Tarangini, 2009). Ilhan et al., (2004) observed that *Staphylococcus saprophyticus* reduced Cr, Cu and Pb ions. The isolate was adsorbed 100% Pb ions at different pH range of 3-5 and at 27^0C temperature. *Corynebacterium sp.* and *Flavobacterium sp.* were reported for removal of organic contaminants and halogenated hydrocarbons, phenoxyacetaes and aromatic hydrocarbons (Jogdand, 1995). *Corynebacterium glutamicum* was able to reduce the thorium and uranium (Tarangini, 2009). The biosorption of heavy metal Cd and Cu by *Flavobacterium sp.* was reported by Rajbanshi, (2008) whereas, biosorption of Cu, Fe and Zn by *Corynebacterium sp.* was reported by Odokuma, (2009). Many investigators

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

(Mattuschka et al., 1993; Jogdand, 1995; Tarangini 2009) reported that *Streptomyces sp.* can be used to remove the metal ions of Ag, Cd, Cu, Cr, Ni, Pb, U and Zn from the waste. *Streptomyces noursei* was able to reduce the metal ions in order Pb>Ag> Cu>Cr (Mattuschka et al., 1993). *Aspergillus niger* was reported to remove Ag, Au, Cd, Cu, Th, U and Zn (Townsley et al., 1986; Kuyucak & Volesky, 1988; Gunasekaran et al., 2003). *S. meliloti* has huge potential to reduce the toxicity from the environment reported by Chauhan (2015). Biosorption is being established as a useful alternative to conventional systems for the removal of toxic metals from industrial effluents/waste. Bioremediation provides a technique for cleaning up pollution by enhancing the natural biodegradation processes. So, by developing an understanding of microbial communities and their response to the natural environment and pollutants, expanding the knowledge of the genetics of the microbes to increase capabilities to degrade pollutants, conducting field trials of new bioremediation techniques which are cost effective and dedicating sites which are set aside for long term research purpose, these opportunities offer potential for significant advances (Sutar & Das, 2012).

More research is needed to assess the extent to which these products affect human health. Public awareness should be created. There should be monitoring and control over the concentration of heavy metals in cosmetics. The existence of metals in nano form or otherwise should be determined. Toxicity of metals bearing nano particles is a domain where systematic research needs to be carried out to establish or negate toxic factors. Susceptibility to toxicity is influenced by age, physiological status, nutrition status and genetic factors. More research is needed to study these interactions, particularly since malnutrition is rampant in India. Where specific interactions are known *e.g.* lead and calcium, fluoride and calcium, populations exposed to these toxic substances (factory workers, communities living near the factories) should receive periodic health check-up and nutritional support. Health monitoring of workers engaged in industries handling toxic metals/ minerals should be carried out regularly and nutritional support where necessary provided. Since toxicity is insidious, mechanisms for early detection of the problem at subclinical level through proper surveillance systems are needed. More research is needed to identify and develop bacteria, plant, and fish-based tests. Functional consequences which may not be too obvious, like effects on reproductive, neurological-cognitive and other functions have to be identified, through more research on animals and humans under controlled conditions. A few recommendations are given below to reduce the heavy metal pollution.

Anthropogenic pollution can be at the stage of fabrication or end use. Instead of pollute and clean; mitigation strategies should receive high priority. Regulatory standards for emission and discharges from process plants should be strictly enforced. Recycling/reprocessing of wastes containing toxic metals needs to be given greater emphasis not only from environmental and health considerations but also as a resource conservation measure. Monitoring of air, water and soil in the vicinity of the toxic metal processing units needs to be carried out more rigorously for the specific metal. Regional accredited laboratories for analyzing pollutants in various environmental compartments should be set up to help regulatory bodies. Guidelines for proper management of tailings and slags containing toxic metals should be prepared taking into consideration techno- economic feasibility. Tailings dumps and process wastes lying in locations close to the processing units need to be remediated on priority. Phytorestoration enhances ecological capital and provides biodiversity of choice suitable for the region where such restoration measures are undertaken. Attempt should be made to replace CFL bulbs with LED (Light emitting diode) bulbs Mercury-based medical devices and equipment should be totally phased out, since digital options are available. Presently there is emphasis on production and use of private vehicles-two wheelers, cars. This should change with emphasis on cleaner public transport systems to reduce the burden of

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

road run off. CNG should replace petrol and diesel. Use of diesel should be confined to public transport and transport of goods. Manufacture of diesel cars should be stopped. Rich are taking the benefit of the subsidy on diesel. Periodic (six monthly) examination of water quality, particularly for detection of fluoride and arsenic is necessary in newer alluvium and flood plain areas in different parts of India. Water supplied by urban municipalities and rural panchayats, should be free of (or contain within safe levels) of biotic and abiotic toxicants including heavy metals and minerals. Inexpensive devises for purifying water at household level have to be developed. Creation of public awareness is very important. Greater interaction between scientists, technologists and media is needed to achieve that. School education can be a mechanism for creating awareness.

10. CONCLUSION

While anthropogenic activities are the major source of heavy metal pollution, natural sources contribute significantly to the burden of arsenic and fluoride. Apart from industries, road runoff is also an important source. The toxic elements enter the body mainly through water, food and air. Cosmetics, dental products, some drugs, particularly Ayurvaid and Unani drugs also contribute. Major pollutants are introduced into the aquatic systems significantly as a result of various industrial operations. The lack of technical and financial resources and the regulatory control for the management of hazardous wastes in the past had led to the unscientific disposal of hazardous wastes, which posed serious risks to human, animal and plant life. A huge quantity of pollutants in the form of domestic and industrial effluents is discharged directly or indirectly into the soil/water bodies, which has severe impacts on its biotic and abiotic environment. During rain, surface water with soil, mud and humus enter into the river, tanks and other water bodies. The inorganic minerals like sodium, potassium, calcium, magnesium and heavy metals like iron, manganese, lead, mercury, chromium, cadmium, nickel, cobalt, copper etc., when reach to the soil/river water caused pollution. Heavy metal contamination is becoming a great concern to the environmental awareness and government policies. Several heavy metal removal technologies including chemical precipitation, ion exchange, reverse osmosis, electrodialysis, ultrafiltration and phytoremediation are commonly used in industries. However, these technologies are becoming uneconomical and unfavourable to remove heavy metal from contaminated sites or wastewater. With increasing environmental attention and legal constraint on discharge effluents, a need of cost effective technology is essential. Therefore, the search for efficient, eco-friendly and cost effective remedies for wastewater treatment has been initiated. In recent years, research attention has been focused on biological method, *e.g.* bioremediation, is in the process of commercialization. Bioremediation provides a technique for cleaning up pollution by enhancing the natural biodegradation processes. The bioremediation is one of the most promising technological approaches to the problem of hazardous waste. This process relies on microorganisms such as bacteria or fungi to transform hazardous chemicals into less toxic or nontoxic substances. Such biological transformation is more attractive than direct chemical or physical treatment. Microorganisms directly degrade contaminants rather than merely transferring them from one medium to another, employ metabolic degradation pathways and can be used in situ to minimize disturbance of the cleanup site. Hence, microorganisms can be effective, economical and non disruptive tools for eliminating hazardous chemicals. There is no doubt that bioremediation is in the process of paving a way to greater pastures. This technology offers an efficient and cost effective way to treat contaminated soil, waste and water. Its advantage generally outweigh the disadvantage, therefore may be used as management tool.

Chapter 47
Leachate Treatment:
Case Studies in Selected European and Asian Countries

Irvan Dahlan
Universiti Sains Malaysia, Malaysia

ABSTRACT

Landfilling is one of the most important methods for disposal of solid waste in many countries. One of the most obvious problems associated with the landfilling practice is the generation of leachate. This chapter reviews case studies on the on-site treatment of leachates using various technologies in selected European and Asian countries. It was shown that the generation of leachate varies widely in both quantity and quality in European and Asian countries. Biological treatment and membrane technology show very high efficiencies in treating leachate generated from Odayeri landfill (in European side of Turkey) and Komurcuoda landfill (at Asian side of Turkey). Leachates from Arpley landfill (UK) and Bukit Tagar landfill (Malaysia) were successfully treated using sequence batch reactor (SBR). Fairly good treatment efficiencies were obtained using constructed wetlands (CWs) in treating Gdansk-Szadolki landfill leachate in Poland. Furthermore, the use of coagulation, filtration and membrane technologies has been proven effectively in treating Nonthaburi landfill leachate in Thailand.

INTRODUCTION

Landfill is one of the most popular and extensively used methods for the disposal of more than 90% of municipal solid waste (MSW) (Idris *et al*, 2009). Recent work done by Hoornweg and Bhada-Tata (2012) shows that the global MSW generation are expected to increase from the current 1.3 billion tonnes per year to approximately 2.2 billion tonnes per year by 2025. This corresponding to an increase in per capita waste generation rates from 1.2 to 1.42 kg per person per day in the next decade. The increasing trend represents for both developing and developed countries. Nevertheless, global averages are broad approximates only as rates may differ considerably by region, country, city, and even within cities.

Due to the generation of solid waste is inevitable in daily activity of humans and animals, it leads to the generation of highly polluted wastewater which is called landfill leachate. The open dump landfill approach still remains the predominant MSW disposal option in developing countries. On the other hand, in developed countries, even though the development of landfill technology from uncontrolled to sophisticated and highly developed facilities, the generation of contaminated landfill leachate consistently leaving an unavoidable issue of the practice of waste disposal in landfills.

The generation landfill leachate creates a negative long-term impact on the surrounding environment and public health since it contains substantial amounts of dissolved organics (BOD and COD), xenobiotic organic compound (XOCs), inorganic salts, ammonia, heavy metals and other toxicants (Poznyak *et al.*, 2007 & Emenike *et al*., 2012). Through direct leachate contact, it can contaminate the surface and ground water, as well as soil (Panagos *et al.*, 2013) and this has become a foremost environmental concern worldwide. Therefore, it can be concluded that landfill leachates are, and will continue to be, a serious threat to the environment and quality of life unless proper treatments are taken. Various technologies of wastewater treatment have been employed to treat leachate in full scale on-site treatment system. By applying full scale on-site treatment system, it can avoid the cost of transporting leachate to wastewater treatment plants (WWTPs) (*i.e.* off-site treatment) (Robertson *et al*., 1995; Tsuzuki *et al*., 2009).

When installing a leachate treatment plant at a landfill, it is essential to consider leachate production rates and alterations in quality of the leachate when sizing the plant. Specific landfill site will determine the nature of both quantity and quality of the leachate, and both of the criteria will also varies throughout the life of a landfill site. As waste changes with time, so does the leachate quality. This is particularly, an evident in non-hazardous landfills that have received MSW (IPPC, 2007). As a point of reference, Table 1 shows the difference in quality (or typical characteristic) of landfill leachate from large landfills in the selected region/country. It was shown that Southeast Asia has the highest COD, TOC, alkalinity, chloride, conductivity, sulphate and magnesium, while phosphate, nitrate, and nitrite were found to be high in Hong Kong. In UK, it was shown to have highest BOD, iron and sodium.

Although landfilling represents one of the oldest, economic and most common methods of MSW disposal, however the cost of treatment of leachate is still high. Based on the quantity of the raw leachate generated, the operating costs were estimated to be almost US$6–8 per cubic metre of leachate (Yaman *et al.*, 2012). The treatment cost and as well as the successful of leachate treatment depend strongly on the quantity and quality of the leachate produced at the landfill site. On-site leachate treatment has been extensively practiced for many years in many countries, especially in European countries as an alternative to reduce cost and environmental risk of transporting leachate to WWTPs or off-site treatment. Some Asian countries have also been practising on-site leachate treatment. Many applicable technologies for on-site leachate treatment have been employed including a variety of physical/chemical processes and as well as biological processes. The purpose of this chapter is to present and evaluate the performance of full scale on-site treatment of landfill leachates using various technologies in selected European and Asian countries.

OVERVIEW ON LEACHATE TREATMENT IN EUROPE

In 2010, about 252 million tonnes of total MSW was produced in European countries (EU-27), whereby the MSW generation per capita is about 502 kg/cap. The analysis indicates large differences in MSW management performance between European countries. The majority of this waste (45%) is still sent to

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Table 1. Typical characteristic of landfill leachate from large landfills in selected region/country (Kiser, 2004; Abubakar, 2006)

Parameter	Units	South east Asia	Hong Kong	UK
pH	-	6.0–8.4	7.4–8.6	7.4–8.5
COD	mg/l	1,600–13,000	650–2,800	2,600–8,500
BOD_5	mg/l	-	45–400	90–3,000
TOC	mg/l	400–10,000	-	400–3,400
Alkalinity	mg/l	8,000–40,000	3,000–12,000	7,000–17,000
NH_3-N	mg/l	1,200–3,000	1,200–3,000	1,100–2,500
Chloride	mg/l	2,500–6,300	500–3,000	1,700–5,200
Conductivity	µS/cm	14,000–42,000	14,000–30,000	14,000–30,000
Nitrate-N	mg/l	< 1–12	< 0.1–22	< 0.3–2
Nitrite-N	mg/l	< 1 – < 2	< 0.1–3.6	< 0.1–2
Phosphate (as P)	mg/l	2–50	3–125	4–20
Sulphate (as SO_4)	mg/l	< 5–1200	-	< 5–150
Sodium	mg/l	1,500–3,000	200–2,100	1,700–4,000
Magnesium	mg/l	60–500	18–50	17–150
Iron	mg/l	1,000–20,000	5,000–9,000	3,000–72,000
Zinc	mg/l	150–1500	200–2,200	30–330
Lead	mg/l	< 300 – <1000	-	< 40-600

landfill, but an increasing amount is recycled (42%) or incinerated (5%). The general increase in recycling of MSW has led to a reduction in the percentage of MSW landfilled. Most countries reduced landfilling in the period 2001–2010 (Saki, 2012; EEA Report, 2013). Although alternative disposal methods for example recycling, incineration and composting are being encouraged, landfilling of MSW is still remains the predominant and crucial issues for waste management across Europe and other countries in the world. Since the protection of surface waters used for drinking water supply has been ruled under Directive 75/440/EEC (EC, 1975), significant progress has been achieved in identifying the contamination of aquatic ecosystem. Subsequently, landfill leachate need to be treated on-site to meet certain standards before it can be discharged into a sewer system or direct disposal into surface water.

Currently, there are more than 150,000 landfill sites across European countries and considerable funds have been spent on leachate treatment with an estimated annual cost of EUR 10 billion to 17 billion. It is predicted that leachate treatment will become a larger industry as Environmental Directives are implemented to improve water quality. At the moment, modern landfills are highly engineered and developed facilities designed to remove or minimize the adverse impact of the waste on the surrounding environment (Egner, 2013).

A large number of widely adopted processes have been used on-site for leachate treatment, either a single or in combinations with other method. Physicochemical has been widely adopted for leachate treatment, for example by using coagulation-flocculation, chemical oxidation, activated carbon adsorption, and membrane technology (MF, UF, NF and RO). In addition, biological methods have been commonly applied to remove organic matter and ammonium nitrogen from landfill leachate, for instance activated

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

sludge process utilise an aerobic tank followed by a settlement tank. The sequence batch reactor (SBR) is one example of activated sludge treatment and this is the common technology used in the UK (Robinson, 2005). Furthermore, a specific treatment requirement for leachate may involve the use of primary, secondary, and tertiary processes. The use of on-site constructed wetland systems is might be one example. More than a decade ago, numerous on-site constructed wetland systems for landfill leachate treatment has been established in European countries (Wojciechowska, & Obarska-Pempkowiak, 2008). Three case studies of domestic on-site landfill leachates treatment in selected European countries are discussed in the next section in order to connect the processes effectiveness of full scale on-site treatment system to leachate characteristics and key contaminants treatability.

Case Study of Leachate Treatment Plant at the Odayeri Landfill Site on the European Side of Istanbul, Turkey

Istanbul is the largest city in Turkey. It is situated between the European and Asian regions, where about a third of its population lives in the Asian region. Having the largest population in Turkey, a large amount of solid wastes is being generated in Istanbul city. Currently, there are two operated landfill sites located both on its European (Odayeri landfill leachate treatment plant) and Asian (Komurcuoda landfill leachate treatment plant) regions (Yaman *et al*., 2012; Coban *et al.*, 2012). In this section, the case study of the European region of Istanbul city MSW landfill leachate treatment plant located at Odayeri, Turkey was discussed. Later, the case study of Komurcuoda landfill leachate treatment plant located at the Asian region will be discussed in this chapter.

Odayeri landfill site was originally opened in 1995 (Yaman *et al*., 2012) for the disposal of MSW generated from sixteen local residential wastes on the European side of Istanbul. Odayeri landfill site is 112-ha area covered with layers comprising gravel, coal, clay and sand in patches. The site continues to receive approximately 9,800 tons/daily of waste (Ozcan *et al*., 2006; Yaman, 2011). Over 2000 m^3 of leachate was generated from this Odayeri landfill site each day and the leachate collected was treated on site at the leachate treatment plant (Yaman *et al*., 2012). The analytical data of the raw leachate from Odayeri treatment plant shows that the leachate is characterized by high organics and ammonia concentration. Typical leachate characteristics measured in 2010 (in average) are COD (19,475 mg/l), TN (3,548 mg/l), NH_4-N (2,713 mg/l) and TP (14.8 mg/l) (Yaman *et al*., 2012). In addition, study reported by Campagna *et al.* (2013) shows that organic matter in raw Odayeri landfill leachate has hydrophilic character and approximately 37% of the COD in this raw leachate comprised of particulate/colloidal (>100 kDa) and 63% was soluble (<100 kDa). COD fractions were analysed to be 5%, 3%, 11% and 44% for molecular weight (MW) distributions of 100–10 kDa, 10–1 kDa, 1 kDa–500 Da and <500 Da, respectively. Based on the result obtained, it shows that significant parts of COD in Odayeri landfill leachate have very low MW distributions.

The units of the Odayeri landfill leachate treatment plant are consists of collecting basin (equalization basin), a pre-sedimentation unit, biological treatment (nitrification – denitrification), ultrafiltration membranes (UF), nanofiltration membranes (NF) and discharging channel. (Yaman, 2011; Yaman *et al*., 2012). As detailed out by Yaman *et al*. (2012), firstly, the raw leachate from collecting basin was pumped using three lift pumps (*i.e.* each have capacity of 125 m^3/l) to the pre-sedimentation unit (285 m^3) to eliminate settleable particulate matter from leachate. Then, the supernatant leachate at the top was sent to the biological treatment unit, which consists of anoxic and aerobic tanks. In the aerobic tank, ammonium in leachate with high concentrations will undergo nitrification process. In anoxic tank, deni-

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

trification process occurred. To attain efficient and optimum biological treatment, the removal of COD taking place simultaneously during nitrification and denitrification processes at optimum condition of 20°C and pH 7.5–8.5. To supply oxygen and to ensure a homogenous mixture in the tanks, ten units of surface aerators and eight units of jet aerators were installed. Afterward, the treated leachate was pumped to UF and NF units. The typical UF membrane used is tubular membrane with nominal pore size of 30 nm, membrane area of 27 m^2 and it operates at a flux of 77 l/m.h, pressure of 6.4 bar and permeate flow rate of about 90–100 m^3/h. This UF membrane unit has the capability to treat 50 m^3/h leachate. Whereas, two units of NF membranes (consists of nine modules each) were used to receive the treated leachate released from UF membrane. The configuration of this membrane is spiral membrane having pore size of less than 1 nm and membrane area of 34 m^2. With the permeate flux of 17 l/m.h, these NF membranes unit has the capability to treat 22-23 m^3/h of leachate.

During the study carried out by Yaman *et al*. (2012), significant part of COD, TN, NH_4-N, and TP is removed at the rate of 99%, 94.5%, 99%, and 93.8%, respectively by this Odayeri landfill leachate treatment plant. UF and NF units have capability to remove most of the carbonaceous organic matter. The COD values after treated with UF membranes were within the range of 648−1635 mg/l and these values reduced again to 20−775 mg/l after pass through NF membranes. The maximum COD removal efficiency after treated with NF membranes was analyzed to be 99.9% and the minimum efficiency was analyzed to be 95.1%. As the results, the COD, TN, NH_4-N, and TP values of the treated water discharged from leachate treatment plant is still below the discharge limits required by regulations enforced in Turkey. In expenditure evaluation of Odayeri leachate treatment plant, the treatment and operational costs were estimated to be US$4.6–5.3 m^{-3} and US$6–8 m^{-3} leachate, respectively.

Furthermore, further investigation by Campagna *et al*. (2013) indicates that TOC concentration in raw Odayeri landfill leachate (*i.e.* about 5,075 mg/l) is able to be removed at 89% (574 mg/l) after released from UF membranes. Finally, after treated with NF membranes, the TOC concentration value was analyzed to be 227 mg/l, which mean about 40% of TOC was removed by NF membrane units. The obtained results show that Odayeri landfill leachate treatment plant was operated with high efficiency.

Case Study of Leachate Treatment Plant at the Arpley Landfill, Warrington, England

Arpley landfill has been established since 1988. It is located around 2.5 miles to the west of Warrington, off Liverpool Road, in Sankey Bridges, England. It is situated between the River Mersey and the Manchester Ship Canal. The site covers an area of circa 160 ha of land and formerly used for the disposal of dredging from each stream. Presently, the total Arpley landfill area covers more than 200 ha. Since 1999, Arpley landfill has been managed and operated by Waste Recycling Group (WRG), which is one of the leading UK waste management and energy recovery companies, after being acquired from Cheshire County Council (3C Waste). From the design, Arpley landfill only accepts non-hazardous and inert wastes arising from municipal, commercial and industrial sources and as well as inert materials. Since from the opening, the site has received more than 15 million tons of wastes. Arpley landfill site will continue to accept more than 800,000 tons/year of primary domestic waste (Robinson *et al*., 2008; FCC Environment, 2010).

In 2001, WRG has installed a full scale on-site leachate treatment plant at Arpley. The treatment plant began to operate after a successful commissioned during late 2001. The installation of this facility can ensure the leachate from the site is being treated to the required water quality standards before being

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

released to the River Mersey. The plant is capable of treating raw landfill leachate containing of COD and NH_3-N of 8,000 mg/l and 2,500 mg/l, respectively. The plant capability can be increased up to 450 m^3/day for low characteristic of leachate generated from the site (Robinson *et al*., 2008).

The Arpley landfill leachate treatment plant consists of three large roofed sequencing batch reactors (SBR) tanks, each with automated control of nutrients dosing and pH value. The SBR treatment process has been developed and suitable for higher organic strength and NH_3-N concentrations as contained in raw landfill leachates. The higher volume of SBR tank makes the aeration process become more efficient, high rates of dilution of incoming leachates, and high resistance to the shock loading. Subsequently, the treated leachate from each SBR was pumped into the effluent balance tank, before being sent to dissolved air floatation (DAF) system to eliminate residual solids and colloidal materials. The installation of DAF system at Arpley landfill leachate treatment plant is the first UK application of DAF system to treat leachate. After being treated by DAF system, then it was pumped to a terraced reed beds (having an area of 3,000 m^2) for effluent polishing in order to achieve high effluent quality standards. Before being released to the River Mersey, the final effluent quality needs to fulfil the required limits (based on Water Resources Act 1991), such as the maximum daily rate is 600 m^3/day, pH value of 6−9, BOD_5 value of 30 mg/l, suspended solid of 45 mg/l, NH_3-N of 15 mg/l and non-detectable PCBs. BOD, COD, NH_3-N, iron, sodium and chloride are the example of substances that can be removed during the treatment processes (IPPC, 2007; Robinson *et al*., 2008).

According to Robinson *et al*. (2008), the main key factor of the leachate treatment process at Arpley is the pneumatic leachate collection system. This system is being designed to manage leachate levels through boreholes and wells at three distinct phases of the chosen sites, *i.e*. Birchwood, Lapwing and Walton. Different leachate strengths were measured at these three phases of the sites. At Birchwood phase, COD, NH_3-N and chloride fractions were analysed to be around 600 mg/l, 300-400 mg/l and 600 mg/l, respectively. While at Lapwing phase, the measured COD, NH_3-N and chloride fractions were about 5,000−10,000 mg/l, 1,000 mg/l and 2,500 mg/l, respectively. For Walton phase, approximately 6,000−20,000 mg/l, 1,500−2,200 mg/l and 3,500 mg/l were measured for COD, NH_3-N and chloride fractions, respectively.

From the major parameters measured during July 2007, Arpley landfill leachate treatment plant able to remove COD, BOD_5, TOC, and NH_3-N to give final effluent values of 835, 3.0, 140 and 0.4 mg/l, respectively. The pH and suspended values were around 8.03 and 3 mg/l, respectively. The treatment process was also able to reduce most of the heavy metals to below 0.5 mg/l. Results of the study conducted by Robinson *et al*. (2008) demonstrates that Arpley landfill leachate treatment plant was operated successfully to solve serious leachate problem in the UK.

Performance of Constructed Wetland Systems Treating Landfill Leachate in Gdansk-Szadolki, Northern Poland

In Poland, the extensive use of landfill is projected to continue and still the predominant waste management option in the future for disposal of MSW. Compared with other European countries, the composition of MSW produced in Poland is different. Due to the inadequately developed selection of waste materials, the generated MSW in Poland contains numerous organic components, metal, paper and hazardous materials as well (Slomczyńska & Slomczyński, 2004). In 2009, the majority collected MSW (85%) is still sent to landfill (Bialowiec, 2011). In the late 2005, there are about 762 legal landfills were operated in Poland. The available landfill sites in Poland need to be reduced to 200 landfill sites during 2005-

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

2014. By year 2010, biodegradable MSW disposed in landfills should be reduced to 75% of amounts generated in 1995 (4,381 tons), then reduced to 50% in 2013, and by the end 2020 it was estimated to be reduced to 35% (The World Bank, 2011).

There are many sophisticated and highly developed leachate treatment technologies, however, most of these technologies are capital intensive and require constant operation and maintenance cost, hence, they are not well-suited at many landfill sites, especially in rural areas. The treatment of landfill leachates using natural systems appears to be environmentally sustainable for contaminants removal. Constructed wetlands (CWs) are engineered treatment systems which have similar contaminant removal mechanisms as in natural wetlands. CWs provide inexpensive capital and maintenance costs, simple in operation, have potential to remove contaminants and can provide green space or wildlife habitat (Liehr & Sloop, 1996).

In Poland, an increasing interest in CWs for sewage treatment was observed almost a decade ago, particularly serving individual households in rural areas. However, in the case of landfill leachate treatment, CWs are still in the developing stage (Obarska-Pempkowiak *et al*., 2013). In this section, the performance of CW systems treating landfill leachate in Gdansk-Szadolki, northern Poland was highlighted. The Gdansk-Szadolki landfill site was originally opened in 1973 which covers an area of approximately 60 ha for the disposal of local residential wastes. The annual leachate generation rates from this landfill site are approximately 9,000–9,500 m^3/year and the daily collected leachate flow varies from 6 to 240 m^3. In 2001, an on-site CW for leachate treatment was fabricated in this Gdansk-Szadolki landfill. The CW in Gdansk-Szadolki contains two parallel horizontal flow (HF)-CW beds, having an equal area of 50 x 50 m for each bed and the depth is 0.6 m. Using the info from the basis of filtration coefficients and the beds dimensions, the calculated total hydraulic capacity was equal to 0.994 m^3/day for bed 1 and 0.213 m^3/day for bed 2. Each bed was planted with common reed (*P. australis*) (Wojciechowska *et al*., 2009; Wojciechowska *et al*., 2010; Obarska-Pempkowiak *et al*., 2013).

The leachate composition form Gdansk-Szadolki landfill is very unstable and fluctuated over the time. The characteristics of raw leachate measured in 2008 (*in means*) are COD (445.2 mg/l), BOD_5 (115.9 mg/l), BOD/COD ratio (0.26), pH (7.2), TSS (84.2 mg/l) and total nitrogen (395.8 mg/l). However, these characteristic values were lower compared to measured parameters in 2004, which were COD (1,616.2 mg/l), BOD_5 (792.1 mg/l), BOD/COD ratio (0.49), pH (7.5), TSS (150.5 mg/l) and total nitrogen (433.3 mg/l). This is because the raw leachate generated was mixed with rainwater. The raw landfill leachate was pumped directly to the CW, without pre-treatment at the sedimentation tank. Thus, the CW contained high BOD, COD and ammonia nitrogen concentrations; this definitely gave significant effect on the treatment results. The reed beds 1 and 2 used to treat Gdansk-Szadolki landfill leachate shows very effective for BOD_5 removal (*i.e.* 95.7% for bed 1 and 79% for bed 2). However, low COD removal was observed (*i.e.* 78.5% for bed 1 and only 32% for bed 2). This is most probably due to high refractory compounds exist in the raw leachate, which has been shown by low BOD_5/COD ratio. The results indicate that nitrification occurred in both beds, where the ammonia nitrogen was characterised by only 0.5% and 1% from the total nitrogen in the effluents of beds 1 and 2, respectively. On the other hand, denitrification only occurred in bed 1. Overall, the average concentrations of contaminants in the effluent of bed 1 fulfil the required limits set by Polish environmental standards. On the contrary, the concentrations of COD, TSS and the total nitrogen in bed 2 exceed the limits. As a results, the CW in Gdansk-Szadolki provided fairly good treatment efficiencies of BOD_5 (bed 1), total nitrogen and ammonia nitrogen, regardless of clogging problems (Wojciechowska *et al*., 2010; Obarska-Pempkowiak *et al*., 2013).

LEACHATE TREATMENT PRACTICES IN ASIA

In Asia, the major challenge in urban areas is solid waste management due to increasing generation rate of waste, especially MSW. The rate of MSW generation in rural areas can be as low as 0.15 kg/cap/day, while in the urban areas the rate can be above 1.0 kg/cap/day. In addition, due to economic growth, the quantitative and qualitative of MSW generated are difference between cities in Asian countries, especially if compared between smaller and major cities. For example, the rate of MSW generated in Katmandu city (Nepal) and Dhaka city (Bangladesh) is about 0.3 and 0.5 kg/cap/day, respectively. While in Singapore, Taipei city (Republic of China), and Penang (Malaysia), the MSW generation can more than 0.94, 0.95 and 0.98 kg/cap/day, respectively. Generally, the MSW contains more organic matters than other materials. The average percentages of organic matter can be ranged from 50% to 70% in major cities in Asian countries. The quantitative and qualitative of MSW are also be influenced by numerous factors like economics, culture, heritage, industrialization, and season (Hwa, 2007). In addition, most of MSW composition in the cities of developing countries is biodegradable organics (Dhokhikah & Trihadiningrum, 2012). On the other hand, in the Asian developed countries (such as in Japan, Singapore, Taiwan, and South Korea), the biodegradable organics composition commonly less than 45% (Shekdar, 2009).

At the moment, sanitary landfill seems to be the best option for Asian countries due to relatively simpler in technology. However, still many Asian developing countries practiced open dumping as their main disposal (70 – 90%), without to include on-site leachate treatment plant. The installation of leachate treatment plant is required in upgrading the existing dumpsites and landfills in Asia (Visvanathan *et al*., 2004). In this section, three case studies highlight the treatment technologies used in domestic on-site landfill leachates treatment facilities in selected Asian countries based on the characteristics of the leachate.

Case Study of Leachate Treatment Plant at the Komurcuoda Landfill Site on the Asian Side of Istanbul, Turkey

Komurcuoda landfill site is located at Anatolian (Asian) side of Istanbul and it has been under operation and receiving MSW since 1995. The site covers an area of approximately 89 ha of land. It is consists of six storage valleys and presently 17 million m^3 solid wastes have been collected and stored. Currently, it was estimated about 4.5 thousand tons of MSW is being collected daily (Yaman, 2011; Coban *et al*., 2012; Yuzer *et al*., 2012). The MSW collected in this landfill was received from the Hekimbasi and Aydinli transfer stations (Yazgan, 2013).

The on-site leachate treatment plant was built to receive and collect the leachate generated from Komurcuoda landfill site and has the capacity to treat about 1,200 m^3/day (Yaman, 2011; Coban *et al*., 2012). On daily average, the treatment plant was operated with a flowrate of 1,100 m^3/day (Yuzer *et al*., 2012). Similar with leachate treatment plant at the Odayeri landfill site, the current Komurcuoda on-site leachate treatment plant consists of ammonia stripping tank, primary sedimentation tank, aerobic/anoxic biological treatment followed by ultrafiltration membranes (UF) and nanofiltration membranes (NF) processes.

The characteristic of leachate form Komurcuoda landfill site is fluctuated over the time. From various parameters measured by Coban *et al*. (2012), it was found that COD, BOD_5, total nitrogen, and TSS were analysed to be around (with values ranging from minimum to maximum) 3,000−40,000 mg/l, 3,000−13,000 mg/l, 2,000−5,000 mg/l and 300−1,500 mg/l, respectively. The on-site Komurcuoda

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

leachate treatment plant shows a very effective treatment for COD removal, with the final removal rate of almost 99% after pass through NF membranes (*i.e.* treated to the level of 250 mg/l from the average influent COD of the leachate of around 24,000 mg/l). Apart from that, from the average influent of total nitrogen of around 2,890 mg/l, the total nitrogen was treated to the final level of 121 mg/l which gave the removal rate of around 96%. In addition, this Komurcuoda leachate treatment plant is also able to reduce NH_4-N from 2,313 mg/l (average influent) to 35 mg/l with the removal rate of about 98% (Coban *et al*., 2012). The results pointed out that Komurcuoda leachate treatment plant was operated with high efficiency, due to integrated membrane processes.

Case Study of Leachate Treatment Plant at the Nonthaburi Disposal Site, Thailand

Bangkok (as a capital city of Thailand) and also other urban areas in Thailand have generated about 61% MSW in 2010, while the remaining 39% of MSW was generated from the rural areas. Organic waste from food (64%) is the main component of MSW component in Thailand, followed by plastic (17%) and paper (8%) (Cherdsatirkul, 2012; Pollution Control Department, 2015a; Pollution Control Department, 2015b). In 2010, the generation of MSW in Thailand reached 15.11 million tons, of which 84% is being collected (*i.e.* 12.69 million tons). From that amount, 5.97 million tons of MSW (*i.e.* 47%) was disposed properly into sanitary landfills, while the rest was not disposed in a proper way. Further, the MSW generation in 2011 slightly increased to 15.97 tons (*i.e.* increase by 5.5%). While in Bangkok alone, it was estimated about 9,497 tons of MSW is being generated daily. From a number of MSW disposal facilities in Thailand, sanitary landfill (*i.e.* 131 sites) is still the most popular methods for the disposal of MSW (Jacob *et al*., 2013).

From many disposal sites, Nonthaburi landfill site (located in Sai Noi District, Nonthaburi Province) is one of largest solid waste disposal sites in Thailand. The site continues to receive more than 800 tons of MSW daily. The composition of collected MSW mainly consists of 27.9–56.6% of degraded organic wastes and 24.6–44.8% of plastic wastes (Chiemchaisri *et al*., 2010). The Nonthaburi landfill site was originally started in 1982 which covers an area of nearly 10.9 ha prior to the rehabilitation activities to occupy a total area of 38.6 ha. At the beginning, no integrated leachate treatment plant available at Nonthaburi landfill site. The leachate generated is not released from the site, but it is being collected through an open pipe system to be stored and treated in the stabilization pond located near the site. Until now, more than 300,000 m^3 of leachate is being generated (Theepharaksapan *et al*., 2011).

In order to treat the generated leachate, a full scale on-site leachate treatment with intake capacity of 1,000 m^3/day has been installed. This leachate treatment plant consists of coagulation unit, pressurized sand filtration unit, microfiltration (MF) unit and reverse osmosis (RO) membrane processes. In chemical coagulation unit, $FeCl_3$ in two open jet clarifiers (with a total volume of 113 m^3) was dosed to raw leachate. These clarifiers operated at an overflow velocity of 1.5 m/h and hydraulic retention time of 160 min. Then, the leachate was sent to the pressurized sand filtration units at a filtration rate of 6.4 m/h. The pressurized sand filter consisted of two tanks with total filter area of 6.6 m^2. Subsequently, after being pretreated using 5μm catridge MF unit, the treated leachate was pumped to RO unit. This unit consisted of six pressure vessels each containing seven RO membrane modules (0.20 m in diameter) and operated at a maximum pressure of 2.5 MPa with recovery rate of 50% (Theepharaksapan *et al*., 2011; Rukapan *et al*., 2012; Rukapan *et al*., 2014).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

During the analysis carried out by Theepharaksapan *et al*. (2011), the raw leachate contained very high organic matters in terms of COD, BOD_5, and TOC with values (in average) of 52,650 mg/l, 47,274 mg/l and 25,320 mg/l, respectively. It was also found that the raw leachate is very acidic (3.97) and contained high concentration of total dissolved solid (32,500 mg/l), suspended solid (27,500 mg/l) and total nitrogen (430 mg/l). After treated with chemical coagulation and pressurized sand filtration units, both biodegradable and recalcitrant compounds, in term of COD, BOD_5, TOC and as well as total nitrogen and suspended solid were reduced significantly to the level of 510 mg/l, 24 mg/l, 152 mg/l, 59 mg/l and 190 mg/l, respectively. Additional treatment with MF and RO units reduced again most contaminant concentrations to below the standard limit. From this full scale on-site leachate treatment, it was also noticed that most of the COD and ammonia were removed at chemical coagulation and membrane processes, respectively. At the final stage, the maximum COD, ammonia nitrogen and heavy metals removal efficiencies were measured more than 99%, 97% and 90%, respectively.

However, further investigation by Rukapan *et al*. (2012) and Rukapan *et al*. (2014) shows that membrane fouling is still the main task to be solved when reverse osmosis (RO) membrane is to be applied to full-scale on-site leachate treatment plant. Study by Rukapan *et al*. (2012) revealed that in long-term operation (2 years), the deposited foulants (*i.e.* ferric element with particle size of 0.45–0.70 μm) on RO membrane increased by 7–10 fold as compared to short-term operation (6 months). The degree of fouling was also higher on the first membrane module. Successive chemical cleaning using alkaline (NaOH) followed by acid solution (HCl) gave the best results in removing foulants on the membrane surface.

Case Study of Leachate Treatment Plant at Bukit Tagar Sanitary Landfill, Malaysia

Due to rapid development especially in urban areas, MSW generation in Malaysia has increased more than 91% over the past decade. The population in urban areas is the main waste generator which constitutes more than 65% of the total population (Periathamby *et al*., 2009). Currently, landfill is one of the most preferred methods for solid waste disposal in Malaysia. According to a report by JPSPN (2013), currently there are about 296 landfill sites in Malaysia of which 165 of them are currently operating and the rest are non-operational landfill sites. The site covers an area between 8 and 60 ha. Nevertheless, most of these sites are open dumpsites, and the capacity has been overloaded.

Among sanitary landfills operated in Malaysia, Bukit Tagar sanitary landfill (located in Hulu Selangor district) is one of the largest and modern landfills equipped with sophisticated and highly developed facilities. The landfill site occupied in a total 1,700 acres land area, surrounded by palm plantation and situated approximately 50 km from Kuala Lumpur. The site construction began in 2004 and opened in April 2005 to receive its first load of MSW of about 0.5 Mtonnes. Currently, Bukit Tagar sanitary landfill receives around 3,000 tons of waste per day. Bukit Tagar sanitary landfill has been classified as a fully engineered level IV landfill with complete high density polyethylene (HDPE) membrane liner. It was also equipped with leachate collection and treatment systems which accomplish all the standards according to the Malaysian Technical Guideline. The generated leachate was collected and treated on-site leachate treatment plant located not far away from the site in order to achieve the requirements of water quality standards required by the environmental agency. The treated effluent is flowed to plantation land within the landfill site (Kortegast *et al*., 2007; Zakaria, 2007; Taha *et al*., 2011; Ghazali *et al*., 2014). The

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

leachate treatment facility at the Bukit Tagar sanitary landfill has been designed to treat 1,000 m^3/day of raw leachate and allow modular expansion up to 3,000 m^3/day. At this time, this leachate treatment facility handles 300 to 500 m^3/day of leachate (Malek *et al*., 2008; Taha *et al*., 2011).

The generated leachate is collected and stored at four leachate holding ponds, having a total storage capacity of 180,000 m^3 and these ponds act as pre-treatment of the raw leachate. Then, four sequential batch reactor (SBR) lagoons (with a capacity of 5000 m^3 and equipped with 24 aerators in total) will be used for biological treatment to remove biodegradable COD and as well as nitrification of ammoniacal-N. These SBR lagoons are expected to operate in sequence on a 24-hour cycle, receiving inputs of leachate from a single large raw leachate balance tank (RLBT). The process was arranged for releasing the treated leachate for every 6 hours for each SBR lagoon into a treated leachate balance tank (TLBT). Thereafter, it was pumped to a dissolved air flotation (DAF) tank to eliminate all residual suspended solids and some colloidal COD compounds. Optimization of the process was carried out by on-site testing through dosing with polyelectrolyte and flocculent solution. Final polishing process take places in the reed beds (*i.e.* four reed beds with 1 ha of area in total), consists of *phragmites* plant which capable of absorbing the remaining contaminants in treated leachate in order to improve its quality (Kortegast *et al*., 2007; Malek *et al*., 2008).

From the study carried out by Kortegast *et al*. (2007), it was found that the raw leachate characteristics has been changed in composition during storage in the leachate holding ponds (*i.e.* Pond 3) due to development of methanogenic conditions occurred by anaerobic degradation which subsequently reduce the major contaminants values. After measured at four different times (*i.e.* from March 15, 2006 to December 12, 2006) the COD, BOD_5, TOC, suspended solid, and ammoniacal-N values were (from maximum to minimum) 33,268- 4,636 mg/l, 17,630- 1,834 mg/l, 6,804- 540 mg/l, 930- 350 mg/l and 1,923- 1,239 mg/l, respectively. The pH was also changed from 5.4 to 8.5. As a result, when transferring this storage raw leachate to the treatment process, it had transformed to methanogenic conditions. After went through biological process (SBR), the analysis at TLBT shows that COD, BOD_5, TOC, suspended solid, and ammoniacal-N values were decreased to 450 mg/l, 23 mg/l, 194 mg/l, 93 mg/l and 3.2 mg/l, respectively. Then, after treated with DAF and reed beds processes, the final effluent have the COD, BOD_5, TOC, suspended solid, ammoniacal-N, and pH values of 403 mg/l, 16 mg/l, 60 mg/l, 16 mg/l, 0.9 mg/l, and 6.8, respectively. The results demonstrated the effectiveness and reliable treatment for leachate to comply the required discharge standard. Although some parameter like COD has exceed the limit, thus, other methods using for example activated carbon or membrane process should be applied to reduce again this parameter.

PERFORMANCE COMPARISON OF ON-SITE LEACHATE TREATMENT

In summary, the comparison of on-site leachate treatment in selected European countries is given in Table 2. From the data obtained, it shows that the leachate generated from Odayeri landfill (Turkey) and Arpley landfill (UK) is characterized by high concentration of organics and ammonia, while the leachate generated from Gdansk-Szadolki landfill (Poland) is characterized by relatively low organics and ammonia concentration. These variations in leachate characteristics are caused mainly due to different type of solid wastes being disposed of, different climate conditions, site hydrogeology, and the landfill design and operation. From the view of on-site treatment, biological treatment combined with membrane based technology has been used successfully to treat leachate generated from Odayeri landfill (Turkey),whereas

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

the SBR treatment process has been developed and become the common technology used to treat leachate in UK. Leachate from Arpley landfill has been effectively treated using this technology in combination with DAF and reed beds. Constructed wetlands (CWs) are another type of on-site treatment that has been applied to treat leachate generated from Gdansk-Szadolki landfill (Poland). Although the results show that CWs provided quite good treatment efficiency, however, possibility of clogging are present which lead to reduce the hydraulic conductivity of the beds, resulted in slightly lower treatment efficiency in the second bed. Therefore, it is likely to be essential to have some type of pretreatment before passing leachate to a CW treatment system.

Table 2. Comparison of leachate characteristic and treatment performance at selected European countries

Furthermore, there are similarities between the on-site leachate treatment in selected European and Asian countries. Table 3 shows the summary of on-site leachate treatment in selected Asian countries. Komurcuoda landfill leachate treatment plant (at Asian side of Turkey) uses the same technology with Odayeri landfill leachate treatment plant (at European side of Turkey). Similar treatment performance was also observed from these treatment plants although Komurcuoda landfill leachate treatment plant has lower treatment capacity and the landfill only received nearly half of MSW as compared to Odayeri landfill. On the other hand, Bukit Tagar sanitary landfill (Malaysia) adopted the same technology with Arpley landfill leachate treatment plant (UK) to treat the leachate. With almost similar treatment capacity, Bukit Tagar sanitary landfill leachate treatment plant is capable to treat the leachate with higher treat-

ment efficiency (except for COD parameter), although having higher organics and ammonia concentration as compared to Arpley landfill leachate treatment plant. While in Nonthaburi landfill (Thailand), the generated leachate has higher concentration of organics and suspended solid, but lower ammonia concentration as compared to Komurcuoda landfill and Bukit Tagar landfill. Using coagulation and filtration processes together with membrane technology, Nonthaburi landfill leachate treatment plant able to achieve high and reliable treatment efficiencies for leachate to fulfil the required discharge standard.

CONCLUSION

Few case studies have been reported on the on-site treatment of landfill leachates using various technologies in selected European (*i.e.* Turkey at European side, England and Poland) and Asian countries (*i.e.* Turkey at Asian side, Thailand and Malaysia). This case study was reported in order to connect the various treatments effectiveness to leachate characteristics and key contaminants treatability. The characteristic and generation of leachate become the key elements in designing and performing on-site leachate treatment. From selected case studies, it was revealed that biological treatment combined with membrane based technology have been applied on-site leachate treatment plant and has high capability in treating leachate from Odayeri landfill (at European side of Turkey) and Komurcuoda landfill (at Asian side of Turkey). Biological treatment has also been combined with dissolved air floatation (DAF) system to successfully treat leachate from Arpley landfill (UK) and Bukit Tagar landfill (Malaysia), although have different leachate characteristics. Apart from that, significant efficiencies were shown when coagulation and filtration methods were used with membrane based technology to treat Nonthaburi landfill leachate in Thailand. Although there are increasing interests in constructed wetlands (CWs), however, it is important that the system is designed adequately for leachate treatment based on the site-specific leachate composition to comply the required discharge standard. In addition, few problems need to be solved, especially related to clogging problems and membrane fouling.

Chapter 48
On-Site Sanitation Systems for Low-Income Countries:
Technical Guidelines for Groundwater Pollution and Nuisance Control

ABSTRACT

On-site sanitation systems, the commonest sanitation technologies in low-income countries, are central to the elimination of open defecation in such countries. Nevertheless, their selection and application in the physical and socio-economic environment of low-income settings could be a complex and challenging task. Poorly designed and constructed facilities could pollute groundwater resources and create nuisances to the user and the general public. Meanwhile, local authorities in these countries often lack the human resource with the requisite technical capacity to analyse situations and recommend appropriate solutions. This calls for guidance in the most crucial technical decisions that affect the safe usage and environmental sustainability of on-site sanitation technologies. This Chapter reviews salient standards and guidelines for the selection of appropriate technologies, prevention of groundwater pollution, control of odor and fly nuisance, structural stability and safety of the latrine user.

INTRODUCTION

Improved sanitation technologies or latrines play a central role in public health management by serving as a barrier to the transmission of pathogenic agents (Mara et al., 2010). As a determinant of health, access to improved sanitation enhances poverty reduction and other Millennium Development Goals especially those related to gender and mortality (United Nations Department for Economic and Social Affairs [UNDESA], 2007). Nevertheless, some 2.5 billion people, mostly in low-income countries, lack access to improved sanitation (Joint Monitoring Program [JMP], 2014). This makes the sanitation MDG practically unachievable and exposes the health of these billions of people to the risks posed by open defecation (JMP, 2013).

In low-income countries, on-site sanitation systems are the most affordable and the most technically feasible for many households. When properly constructed, operated and maintained in accordance with appropriate technical standards and guidelines, they can offer most of the benefits of water-borne sewerage to their users. On the other hand, poorly constructed and maintained on-site sanitation systems could pose a major threat to groundwater resources. Groundwater happens to be a major source of drinking water for most households in these countries, especially those in peri-urban and rural areas that are often not connected to conventional water supply systems. Aside from groundwater pollution, poorly constructed and maintained on-site sanitation systems, especially simple pit latrines, tend to offer a very low level of hygiene that may be comparable to open defecation. Consequently, some prospective users of available facilities may avoid using them and resort to the practice of open defecation which is recognized as the riskiest sanitation practice (United Nations Children's Fund [UNICEF], 2010).

To serve their intended purpose, latrines should be constructed to fulfil basic scientific and engineering principles. Moreover, the choice of a technology should be such that its requirements for sustainable operation and maintenance could be met within a given environment or socio-economic context at an affordable cost. In view of this, various national and international institutions have developed standards and guidelines to assist technical practitioners and lay people in the choice of latrine technologies, their design and construction, as well as the best operation and maintenance practices. Such standards and guidelines are usually aimed at controlling the risks of pollution and nuisances to the general public, especially those of offensive odor and fly breeding.

Although rigid compliance to conservative design codes has been criticized as a setback to innovation in technology development and adaptation in resource-constraint settings (Jenkins & Sudgen, 2006), the availability of flexible standards and guidelines can enhance the technical judgment of sanitation professionals. This is especially imperative in low-income countries where governments are faced with challenges in developing or attracting adequate human resources with the required technical capacity for the sanitation sector. In Ghana, for instance, 2008 statistics indicated that out of 430 engineers and other professionals required in the various local authorities, only eight were available at post nationwide (Obeng & Filho, 2010). Consequently, the practice of environmental sanitation fell in the hands of sub-professionals and low-capacity technical officers. In such cases, the availability of technical guidelines and toolkits would make a significant contribution to the appropriateness of technical decision-making.

Furthermore, in low-income countries technical decisions are required to be taken within the boundaries of infrastructural and socio-economic limitations that make the technical decision-making process very complex and challenging (Katukiza et al., 2010). These challenges that are particularly more prevalent in peri-urban areas of low-income countries include poor physical planning, unreliable water supply and low income levels (Ministry of Water Resources Works and Housing [MWRWH], 2007; Ministry of Local

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Government and Rural Development [MLGRD], 2010; Katukiza et al., 2010). Where such constraints and low human resource capacity exist, there is the need for technical standards and guidelines to direct the implementation or adaptation of available technical solutions without compromising user safety or the integrity of the environment (Mara, 2006; Paterson et al., 2007).

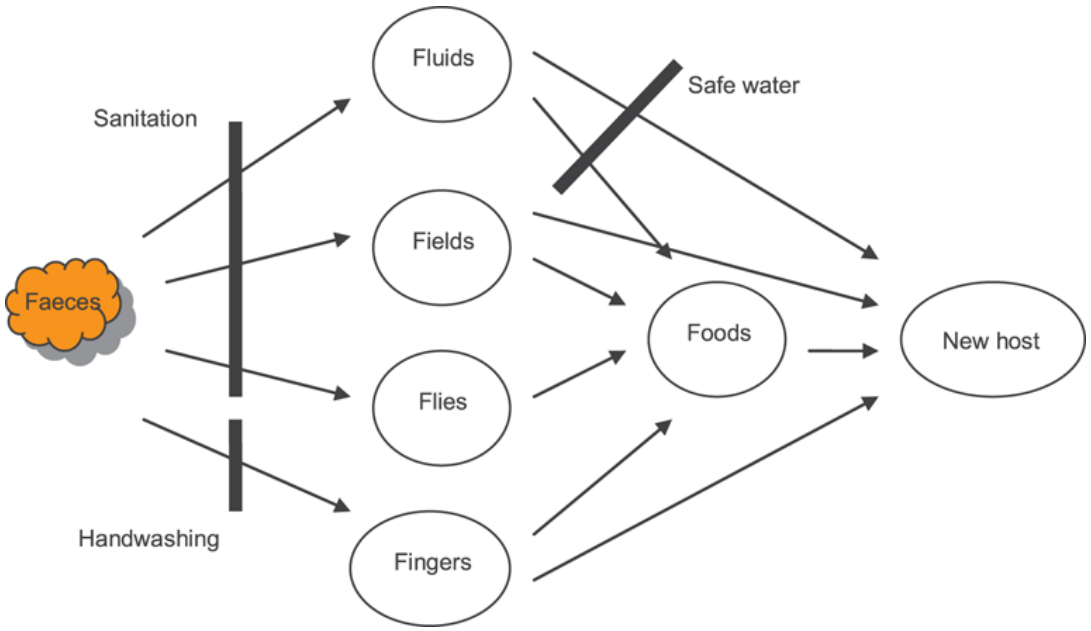
The purpose of this chapter is to review salient technical standards and guidelines for sanitation technologies commonly used in low-income countries with a specific focus on selection of appropriate technologies, prevention of groundwater pollution, control of odor and fly nuisances, structural stability and safety of the latrine user. The chapter identifies potential challenges that may be encountered in the application or enforcement of some standards and guidelines in specific difficult areas such as peri-urban settings and how they may be overcome. To facilitate an appreciation of the various standards and guidelines, the review is preceded with an overview of typologies and basic descriptions of the pro-poor sanitation technologies commonly used in low-income countries.

BACKGROUND

Sanitation Technology as a Barrier to Disease Transmission

Figure 1. illustrates the role of sanitation in breaking the routes of fecal-oral disease transmission. Of all types of human excreta, feces pose the greatest risk to health (Mara, 2010). It is estimated that one gram of fresh infected feces can contain 10^6—10^8 bacterial pathogens, 10^4 protozoan cysts or oocytes, 10^6 viral pathogens and 10—10^4 helminthes eggs (Feachem et al., 1983). When infected feces is indiscriminately disposed of, pathogens may be deposited in the soil, washed by water or carried by flies; it may also come into contact with human hands.

Figure 1. Sanitation technology as a barrier to fecal-oral disease transmission (Source: Mara et al. (2010))



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Through any of these routes, pathogens may be transferred to food and, ultimately, into the body of a new host. A person may also directly contract pathogens through contact with contaminated soil or drinking of polluted water. The result could be death or morbidity. Consequently, diarrheal diseases are the second cause of death in children under five years old, killing an estimated 760,000 yearly (World Health Organization [WHO], 2013).

Sanitation is a proven effective barrier that breaks these routes and prevents the transmission of gastro-intestinal diseases. Mara et al. (2010) accredits the first scientific notice of the relationship between disease transmission and the lack of sanitation to Chadwick's 'Report on an inquiry into the sanitary condition of the laboring population of Great Britain' (Chadwick, 1842). Since then, further scientific evidence has confirmed that gastro-intestinal diseases can be prevented or efficiently controlled through effective sanitation or its combination with water supply and hygiene. For instance, improved sanitation has been found to reduce the rate of diarrheal diseases by 32% – 37% (Waddington & Snilstveit, 2009; Fewtrell et al., 2005). Significantly, the impact of improved sanitation has been found to be even higher where baseline conditions were extremely poor. Examples of such cases were reported by Norman et al. (2010) and Barreto et al. (2007).

Emphasis on Simplicity and Affordability in Low-Income Countries

In low-income countries, cost and simplicity are key considered factors in choosing sanitation technology options (Murphy et al., 2009). On the basis of cost and simplicity, excreta disposal systems may be classified as either pro-poor or advanced (Heron, 2007; Paterson et al., 2007). Pro-poor or affordable sanitation technologies are often described by various terms such as low-cost technologies, appropriate technologies, sustainable technologies. Common examples include the pit latrines, the pour-flush latrine, the aqua privy and the septic tank with a water closet system. On the other hand, conventional sewerage is recognized as advanced or anti-poor (Paterson et al., 2007). Because some cost is saved by eliminating the need to transport excreta to a remote destination for completion of the sanitation chain, on-site sanitation technologies are commonly classified as pro-poor as compared to off-site technologies. However, it has been argued that simplified sewerage that relaxes the conservative design codes used in conventional sewerage can be cheaper than on-site sanitation in peri-urban areas where high population densities create economies of scale (Paterson et al., 2007). Notwithstanding, this chapter is restricted to on-site sanitation technology options.

The most important features of pro-poor sanitation technologies are that they are simple and inexpensive to construct, operate and maintain. It is important, however, that their simplicity and low-cost do not compromise the main sanitation function or the key requirement of an improved sanitation facility, i.e. the prevention of fecal-oral disease transmission (UN Millennium Project, 2005)

Basic Technology Options

Although recent attempts to adapt one technology or another to some specific local context have given rise to several technology options, sanitation systems commonly found in low-income countries are based on the following water-dependent and non-water-dependent technologies.

The most common non-water-dependent (dry) on-site sanitation systems are:

1. The simple pit latrine

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

2. The ventilated improved pit (VIP) latrine
3. The composting latrine

The water-dependent (wet) on-site sanitation systems have water-seals and these include:

1. The pour-flush latrine
2. The aqua privy latrine
3. The septic tank with water closet

Recent technological innovations include the development of the bucket and cartage and the worm digester toilet with water closet. The feasibility and technical performance of these recent technologies are still being researched and are not discussed further in this chapter. For the above listed dry and wet sanitation systems, detailed technical descriptions, advantages and disadvantages have been thoroughly discussed in several works (e.g. Brikke & Bredero, 2003; Cotton et al., 1995; Feacham et al., 1983; Franceys et al., 1992; Harvey al, 2003; Kalbermatten et al., 1980; Mara, 1984, 1985; Tilley et al., 2008). From these existing works, the salient features of the technologies are summarized below to facilitate an appreciation of the significance of the various technical guidelines applicable to them.

Simple Pit Latrines

As a basic characteristic of all types of pit latrines, the simple or traditional pit latrine retains excreta, anal cleansing material and, in some cases, sullage and refuse (Franceys et al., 1992) in a hole dug in the ground. Pathogens are killed as excreta decompose to produce humus-like solids, water and gases. Liquids in the pit are allowed to percolate into the surrounding soil while gases dissipate into the air, leaving a solid residue in the pit. To be regarded as an improved sanitation option, the pit is covered with a slab (JMP, 2006). The cover slab bears a hole or a seat through which the user defecates. A superstructure is provided to ensure user privacy and protection from the elements of the weather. When the pit is full, it is covered and another one constructed using as much of the previous latrine's materials as possible.

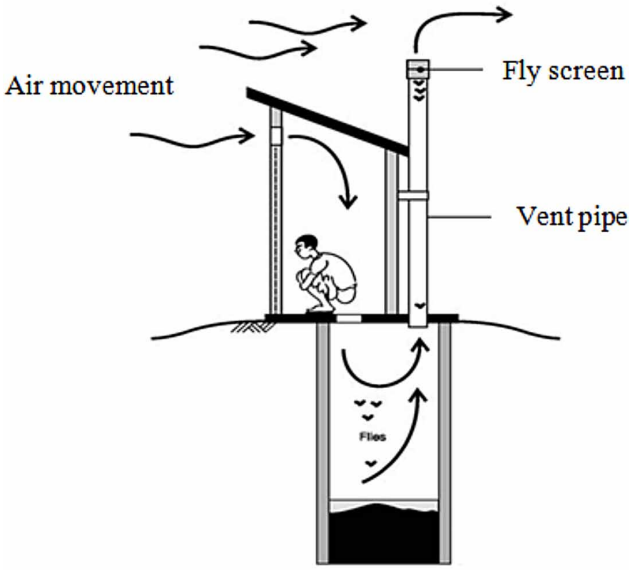
Pit latrines are widely used in low-income countries because of their affordability and simplicity in construction and operation. They represent the cheapest form of sanitation possible (Franceys et al., 1992). Their main disadvantage is that they generate offensive odors and are associated with the breeding of insects especially house flies, mosquitoes and cockroaches. At their worst, their level of sanitary hygiene is only a little better than open defecation (Cotton et al., 1995). Like all other pit latrines, they could also pose health risks to the use of groundwater as a drinking water source. Their use in urban slums and high density peri-urban areas is limited as land may not be available for digging a second pit when the first one is full.

Ventilated Improved Pit Latrines

Ventilated improved pit (VIP) latrines are designed to overcome the challenges of intense odor and fly nuisance associated with the simple pit latrine. The main difference with the simple pit latrine is that the pit cover slab is fitted with a vent pipe that is covered at the top with a fly screen to control odor and fly nuisance. Odor control is achieved through the chimney effect that allows the circulation of air from the superstructure into the pit via the squat hole and out via the vent pipe as shown in Figure 2. The vent

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 2. The chimney effect in a VIP latrine (Source: Harvey et al., 2002)



pipe is also responsible for directing flies produced in the pit to the external bright light at the top of the pipe. Flies are prevented from escaping through the vent pipe by the fly screen and die of dehydration (Brikke & Bredero, 2003) or fall back into the pit to die eventually. External flies attracted to the odor emitted from the top of the vent pipe are also denied entry by the fly screen.

The VIP latrine can be designed for permanent use by constructing a double pit (dividing a single pit with an impermeable wall), under the same superstructure, with each pit having its own squat hole and vent pipe. Developed in Kumasi, Ghana by staff of the Civil Engineering Department of the Kwame Nkrumah University of Science and Technology, it is popular in that country where it is locally known as the Kumasi Ventilated Improved Pit Latrine (KVIP). Only one pit is used at a time. When the first pit becomes full, it is covered and the second pit is used. Pit sizes are designed to allow adequate retention time, usually 2 years (Mara, 1984), so that by the time the second pit becomes full the content of the first pit would have decomposed and may be emptied by manual means. By alternating the two pits, the double-pit VIP can be used indefinitely. VIP latrines may also be designed with multiple pits under two or more cubicles.

With a proper superstructure and vent pipe design, odor and flies can be effectively controlled and the VIP can provide most of the health benefits and conveniences of conventional sewerage at a relatively much lower cost (Kalbermatten et al., 1980; Ryan & Mara, 1983). They are, however, more expensive to construct than simple pit latrines and require a greater operational input from the user, especially the double-pit VIPs (Franceys et al., 1992). As in simple pit latrines, the risk of groundwater pollution is a major concern. For low-income households, the additional materials required for the vent pipe and pit division may make the VIP less affordable as compared to the simple pit latrine.

Composting Latrines

There are two types of composting latrines depending on whether the latrine employs a continuous or a batch composting mechanism (Franceys et al., 1992; Kalbermatten, 1980). The continuous and batch composting latrines employ aerobic and anaerobic composting processes respectively (Harvey et al., 2002). The continuous composting latrine consists of a watertight sloping chamber directly below the drop hole, into which feces and urine fall. Inverted U- or V-shaped ducts and ventilation pipes are used to create aerobic conditions by promoting the passage of air through the mass of excreta and to allow excess moisture to evaporate (Franceys et al., 1992). After each use, the feces are covered with an absorbent usually in the form of dry organic wastes such as sawdust, ash, grass or household refuse. The absorbent deodorizes the decomposing feces, absorbs excess moisture and maintains an appropriate carbon-nitrogen ratio suitable for composting. As new material enters at the top, old material gradually slides on the sloppy floor into a humus vault from where the humus is periodically collected and used as a soil conditioner.

In the batch or anaerobic composting latrine, the decomposing excreta is retained in the chamber without periodic removal until the chamber is about three-fourths full. At this stage, it is topped with earth and sealed for the composting process to continue under anaerobic conditions. In many cases, urine is collected separately and used as a fertilizer. The most common type of the batch composting latrine is the double-vault composting latrine that employs two chambers or vaults used alternatively like a double-pit VIP latrine.

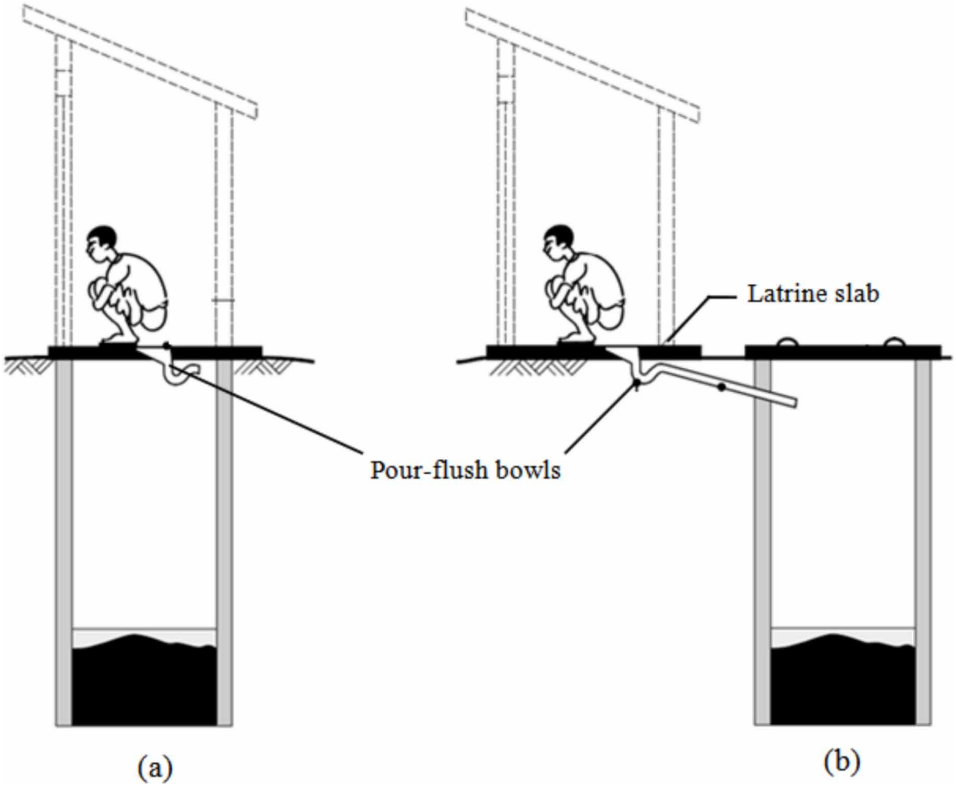
The obvious advantage of the composting latrine is the production of a soil conditioner that may be a useful farm input where it is socially acceptable and a demand exists. Besides, the use of watertight chambers substantially minimizes the risk of groundwater pollution as compared to the pit latrines. This makes the technology more suitable where the water table is high or groundwater is a major source of drinking water. Nevertheless, the technology requires a careful operation to prevent excessive odors and fly proliferation (Franceys et al., 1992). There is the need for household awareness on the rate of absorbent addition and, in the case of the continuous composting latrine, the rate at which the compost is removed. Besides, the requirement for organic wastes or grass limits their use to areas where households may have gardens and the compost may be required for agriculture. Even in these areas, their use may still be limited unless excreta reuse in agriculture is culturally acceptable.

Pour-Flush Latrines

The simplest form of the pour-flush latrine is a modification of the simple pit latrine which incorporates into the latrine cover slab a pan (commonly referred to as a pour-flush bowl) fitted with a shallow U-bend trap that provides a water seal as shown in Fig. 3a. After defecation, a few liters of water, about 1—4 liters depending on the geometry of the bowl and trap (Franceys et al., 1992), is poured into the bowl to flush the excreta into the pit. In another design, referred to as the offset pour-flush latrine, the pit is completely displaced from the latrine superstructure, as shown in Fig. 3b, and the bowl is connected to the pit with a short pipe of about 100 millimeter diameter (Kalabermatten et al., 1980). In its simplest form, the pit is sealed when it becomes full and another one is dug, but the offset design allows two pits to be used alternatively as in the double-pit VIP.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 3. Pour-flush latrines (Source: Adapted from Harvey et al., 2002)



If properly constructed and maintained, the pour flush latrine can effectively reduce the nuisance of odor and flies. The offset pour-flush latrine can be conveniently provided inside a dwelling with the pit located outside (Heron, 2006). They are particularly suitable where water is used for anal cleansing and squatting to defecate is preferred. However, poor design or improper use can easily lead to blockage of the water trap. Besides, the requirement of water for flushing can be a setback where water is fetched from a communal source.

Aqua Privy Latrines

An aqua privy latrine (Figure 4) has a watertight underground tank directly below the latrine floor. The tank is filled with water above the level of excreta to maintain a water seal. Excreta are dropped into the tank through a chute which is fitted to the base of the drop hole and extends into the water in the tank. The user needs to flush sufficient water to replace any water losses due to leakages and evaporation in order to maintain the water level in the tank and to clear out the chute of any blockage by excreta. The aqua privy operates essentially as a small septic tank. Usually, effluent is allowed to infiltrate into the soil through a soak pit while the sludge in the tank is removed periodically by a cesspit emptier.

If the level of water in the tank is properly maintained, i.e. above the sludge, the aqua privy eliminates the problems of odor and flies. In practice, however, the water level is often found to be improperly maintained either because users are not aware of its relevance to the operation of the system or are reluctant

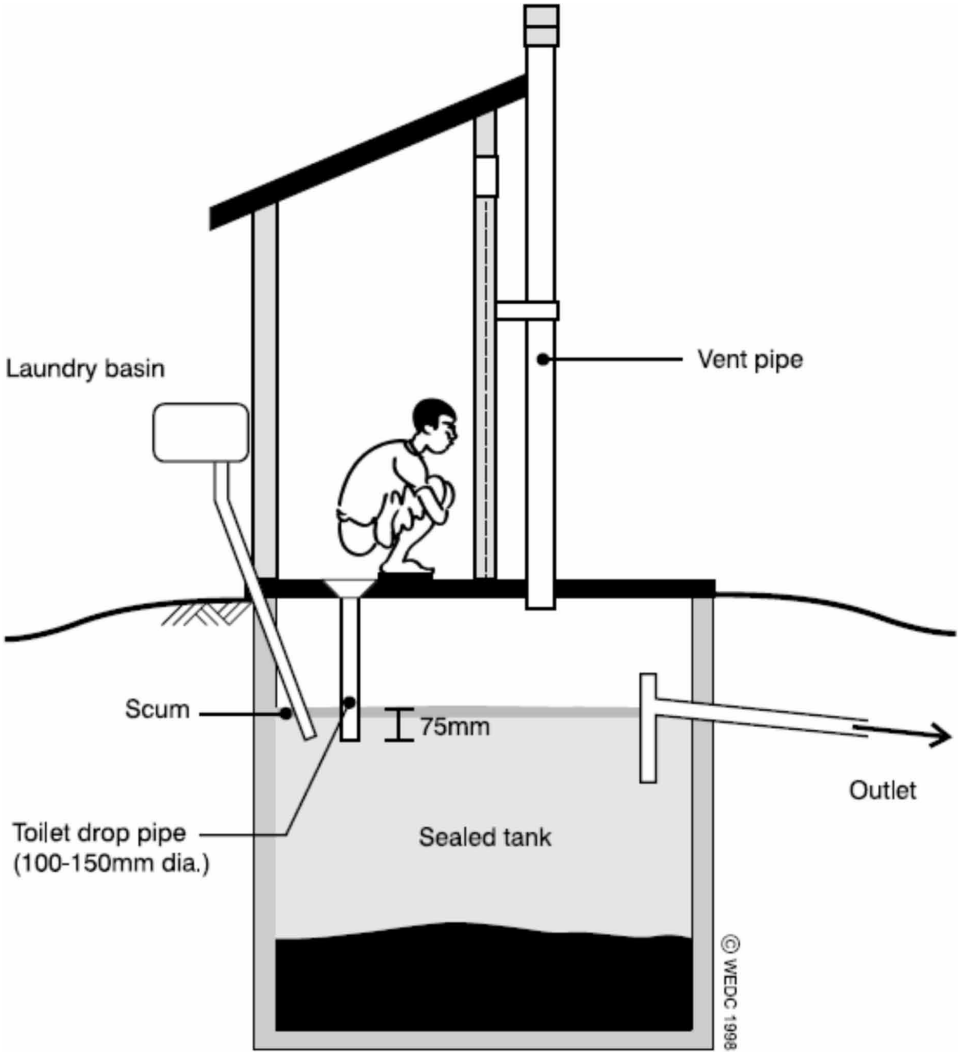
Figure 4. Aqua privy latrine (Source: Harvey et al., 2002)



to expend or carry the water to the toilet (Kalbermatten, 1980). Besides, the requirement of a watertight tank and regular use of water make the aqua privy a more expensive technology to construct and operate than the dry sanitation systems described above or the pour-flush latrine (Franceys et al., 1992; Heron, 2007). Furthermore, the use of a soak pit or a drain field could pollute groundwater resources.

The Septic Tank with Water Closet

The septic tank is a watertight settling chamber built just below the ground level to receive raw sewage via a pipe connected to a water closet toilet with a water seal. It is suitable where the volume of wastewater produced is too large to be disposed of in pit latrines and a central sewerage system is unaffordable (Harvey et al., 2002). The solids in the sewage settle in about 1—3 days of hydraulic retention time and are digested anaerobically in the tank (Kabermatten et al., 1980). Sludge and scum are required to be

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

removed periodically using a cesspit emptier but the liquid effluent is usually disposed of by infiltration in a soak pit or drain field. Hence, the system works more efficiently where the soil is well permeable and not prone to flooding or waterlogging. The main difference with an aqua privy is that the septic tank is completely offset from the toilet superstructure while the aqua privy is built directly under the superstructure (Heron, 2007).

A well maintained septic tank with a water closet system provides all the convenience of conventional sewerage. However, about 7—12 liters of water is required for flushing when full-flush water closet systems are used. This, coupled with the large space requirement and high cost of construction, makes the septic tank the most expensive on-site sanitation system (Brikke & Bredero, 2003).

GUIDELINES FOR TECHNOLOGY SELECTION

Frequently, the failure of sanitation facilities leading to environmental pollution and cause for nuisance can be traced to the wrong choice of technology for the given context. Generally, guidelines for selection of sanitation technologies emphasize the need for the chosen technology option to be sustainable. This means the technology can be constructed with readily available materials; will be accepted and regularly used by the intended users; and can be operated to achieve the overall goal of preventing fecal-oral transmission at an affordable cost (Howard et al., 2003; Ngoc and Schnitzer, 2009; Ottoson and Stenström, 2003). To achieve this goal, some general and specific guidelines need to be observed.

General Guidelines for Selecting Sustainable Sanitation Technologies

To select sustainable sanitation technology options for any given locality or household, the following general guidelines have to be observed:

Performance of the Basic Sanitation Function

Within the conditions of the existing natural and built environment, the chosen technology should be able to satisfy the basic requirement of disposing of excreta in a manner that reduces the risk of fecal-oral transmission to its users and the environment (Mara et al., 2010, UN Millennium Project, 2005). On this basis, bucket latrines, pit latrines without slab, flush or pour–flush to the open environment and open defecation in bushes or beaches are ruled out as improved sanitation options (JMP, 2006).

Acceptance by the Intended Users

For a given sanitation technology to be regularly used, it should be acceptable in the light of the cultural values of the intended user groups (Garfi & Ferrer-Marti, 2011). In view of this, it is highly recommended to involve the intended users in the process of technology selection (Ntim, 1988).

Use of Locally Available Materials

As a general rule, technology options that make use of locally available materials are more sustainable than those that require importation of materials (Mitchell, 1980). This is because the use of locally avail-

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

able materials eliminates dependence on external sources of material supply and mostly reduces the cost of the technology (Murphy et al., 2009). Besides, facilities constructed with locally available materials by local tradesmen can be easily repaired in the event of any breakdown (Garfi & Ferrer-Marti, 2011).

Affordability

Affordability is a basic requirement for technology uptake because most people who need sanitation in low-income countries are poor (Jenkins & Sugden, 2006). Therefore, a sustainable sanitation option for a low-income setting should be affordable to the majority of intended users (Murphy et al., 2009). However, a sustainable technology option for a given context need not necessarily represent the least-cost solution. The most important consideration is to ensure that the cost of the technology is closely matched to how much the intended users are willing and capable of paying (Murphy, 2009).

Requirements of Operation and Maintenance

To ensure constant availability and regular usage, the skills and services required for operation and maintenance should be readily available. Priority should be given to technologies that local people will be capable of maintaining and repairing (Darrow & Saxenian, 1993; Garfi & Ferrer-Marti, 2011). Maintenance support services, where necessary, should be accessible. For instance, the use of a septic tank should only be recommended where cesspit emptying services are available and the proposed latrine location will be accessible to a cesspit emptier.

Guidelines on Specific Factors Affecting Technology Selection

In addition to the above general guidelines for selecting sustainable sanitation technologies, guidelines are available to support sanitation practitioners on how the following specific factors may influence the choice of technology options:

Water Consumption/Availability

It is widely accepted that a minimum of 20 liters per person per day is required for drinking and personal hygiene in order to derive maximum benefits from hygienic excreta disposal irrespective of the sanitation technology chosen (JMP, 2006; WHO, 2008). Thus, wet sanitation systems should only be considered when available water supply is in excess of 20 liters per capita per day. Table 1 shows guidelines for minimum water requirements for various wet sanitation technologies:

In the absence of data on water consumption or availability, it is recommend that wet systems are avoided where water is only available from communal sources but not within individual compounds, with the exception of the pour-flush technology that may be feasible in such situations if water is used for anal cleansing (Kalbermatten et al., 1980). A yard or compound connection makes systems employing a water-seal feasible but caution must be exercised against the use of full-flush cistern systems (Kalbermatten et al., 1980). This may be attributed to their inefficient operation under conditions where water is not piped directly to the toilet location in the house.

Table 1. Minimum water requirement for wet on-site sanitation systems

Sanitation technology	Minimum water requirement for flushing (liters per person per day)
Pour-flush (direct on pit)	3—6
Pour flush (offset)	6—10
Aqua privy	6—10
Septic tank with cistern flush water closet	10—20

Sources: Kalbermatten et al., 1980; Mara, 1985; Gleick, 1996

Housing Density

As a guide, the pit latrines, pour-flush and septic tanks with soakaways are not suitable in densely populated areas where the population density exceeds 300 persons per hectare (approximately 110,000 square feet) for single-story homes (Kalbermatten et al., 1980; Mara, 1984). It should be noted that the low-population status of peri-urban areas of low-income countries can no longer be taken for granted due to recent rises in their population densities (Barrios et al., 2006; Paterson et al., 2007).

Nature of Soils

Generally, all systems requiring on-site effluent disposal by infiltration such as the pit latrines, pour-flush latrines and septic tanks require permeable soils for efficient operation (Brikke & Bredero, 2003; Fraceys et al., 1992; Kalbermaaten, 1980). Mara, 1984 recommends a minimum of 2 millimeters per hour for VIP latrines. Obviously, wet systems such as pour-flush and septic tanks or aqua privies with soakaways would require no less infiltration rate than this.

PREVENTION OF GROUNDWATER POLLUTION

General Guidelines for Prevention of Groundwater Pollution

Groundwater pollution is perhaps the most crucial concern for the use of on-site sanitation systems, especially pit latrines and other systems in which liquids are allowed to seep into the surrounding soil (Graham & Polizzotto, 2013; Katukiza et al., 2012). To prevent groundwater pollution, minimum distances are recommended for the vertical clearance between pit bases and the groundwater table, as well as the lateral clearance between the latrine location and groundwater abstraction points. To prevent groundwater pollution, the section of unconsolidated soils between the bottom of a pit latrine and the groundwater table has been identified as the most important line of defense against bacteria and viruses (Mara, 1984). There is a general consensus that a minimum of 2 meters of this section offers protection against pathogenic organisms (Banks et al., 2002; Franceys et al., 1992; Lewis et al., 1982). However, it has been suggested that 1.5 meters may be tolerated (Banks et al., 2002).

Guidelines on the minimum lateral distance between latrine locations and groundwater abstraction points are widely varied, ranging between 8 and 75 meters. A minimum distance of 15 meters was found

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

by Lewis et al. (1982) in a comprehensive review as being safe and traditional. Shorter distances have been recommended for some more favorable conditions. According to the WHO, 15 meters is satisfactory where the latrine is upstream to the groundwater abstraction point but could be reduced if the latrine is located downstream, though no minimum distance is suggested by the WHO for the latter case (Franceys et al., 1992). Also, where the soil is fine, it has been suggested that the distance could be reduced to 8 meters (Wegelin-Schuringa, 1991). Moreover, Cotton et al. (1995) note that where a minimum of 2 meters of unsaturated zone can be maintained between the pit base and the water table throughout the year, a well or borehole may be cited a few meters away from a latrine but no specific minimum distance has been specified for such situations. Nevertheless, some national agencies require that latrines are located at longer distances from drinking water sources. Examples include 30 meters for Haiti (Reed, 2010), 50 meters for Ghana (CWSA, 2010) and 75 meters for South Africa (Still & Nash, 2002). For areas with rocky soils and shallow groundwater tables, it has been recommended that pit latrines should not be used at all (Nichols et al., 1983; Pujari, et al., 2012).

Special Measures Under Difficult Conditions

For some localities such as peri-urban settings in low-income areas, it may be a challenge to meet a minimum distance between latrine locations and groundwater abstraction points. This is due to the likelihood of the need to site both groundwater sources and latrines on the same compound. Low-income peri-urban areas receive a disproportionately inadequate piped water supply (Paterson et al., 2007) that makes most households rely on usually untreated groundwater via wells and boreholes (Cotton et al., 1995; Rosa & Clasen, 2010; United Nations, 2008). Meanwhile, restrictions are often placed on the siting of latrines by lack of space that may be attributable to high population densities and poor physical planning (Paterson et al., 2007). Consequently, it may be challenging accommodating a latrine and a groundwater abstraction point at 15 meters apart on the compound of a household.

In such difficult situations, a possible solution may be the raising of latrines above the ground level to increase the vertical separation between the pit base and the water table to a minimum of 2 meters (Dzwairo et al., 2007; Graham & Polizzotto, 2013) to compensate for a shorter lateral separation between latrine location and a water source. If the effective size (E.S.) of soil particles is 0.2 mm or less and an unsaturated section of 2 meters can be maintained throughout the year, even pour-flush latrines that discharge more effluent than pit latrines can be located at 3 meters away from water sources (Roy et al., 1984). The same distance can be maintained for soils of an effective size larger than 0.2 millimeters, provided the bottom of the pit is sealed off with an impervious material such as a plastic sheet or puddle clay while an envelope of fine sand (E.S. $<$ 0.2 millimeters) is provided around the pit up to a thickness of 500 millimeters (Harvey et al., 2002; Roy et al., 1984). A greater challenge may be faced in coastal peri-urban settings and other places where a higher water table may make it impossible to maintain 2 meters of the unsaturated zone above the water table. In such cases, a minimum distance of 10 meters instead of 3 meters should be maintained with the same precautions taken as described above if the soil sizes are larger than 0.2 millimeters (Roy et al., 1984).

CONTROL OF ODOR AND FLY NUISANCES

Odor Control Mechanisms

Intense odor is one of the major challenges associated with the most basic sanitation technologies such as the simple pit latrine (Brikke & Bredero, 2003; Franceys et al., 1992). To control the emission of odor, both structural and operational solutions have been recommended. Identified odor control solutions include structural designs to improve ventilation, use of a water seal and addition of substances. Relevant guidelines for these solutions are discussed below:

Structural Designs for Improving Ventilation

The problem of intense odor with the simple pit latrine is addressed in the ventilated improved pit latrine (VIP) with structural modifications that enhance the exchange of air between the pit and the external environment via the superstructure and vent pipe. The VIP achieves odorless conditions when airflow rate through the vent pipe reaches 10 cubic meters per hour, but 20 cubic meters per hour is recommended for permanent (emptiable) toilets sited close to homes in urban centers (Ryan & Mara, 1983). Table 2 summarizes the sizes of vent pipes recommended to achieve these levels of ventilation while additional guidelines are summarized in Box 1.

Although adherence to these technical recommendations in Table 2 and Box 1 has been found to effectively control odor (Feacham et al., 1983; Franceys et al., 1992), their level of complexity may be above the capacity of many households in low-income peri-urban areas. The double-pit VIP developed with these guidelines in Ghana where it is locally known as the Kumasi Ventilated Improved Pit (KVIP) latrine has been particularly noted as being too complex and expensive (Jenkins & Sudgen, 2006). Such level of complexity may lead to poorly constructed latrines as households may lack knowledge of all relevant guidelines or seek to minimize cost. Poorly constructed latrines that fail to adequately control odor would discourage regular patronage by the prospective users and adoption by other households. To address these concerns, it would be necessary to assist households with technical support services through the local government system or use of community structures to train local artisans in latrine construction.

The above guidelines were found to achieve good odor control, mostly based on the feedback of users of the latrines studied. However, no studies have reported the use of modern gas detectors to quantify the actual levels of various odorous gases that can be maintained in latrines constructed in accordance with these guidelines. This could make research on odor control less subjective and contribute to the development of permissible levels for public health regulation, especially monitoring of public toilets in low-income countries.

Table 2. Minimum sizes of vent pipes

Type of vent pipe	Minimum size for 10 cubic meters per hour ventilation rate	Minimum size for 20 cubic meters per hour ventilation rate
Asbestos cement (AC) or polyvinyl chloride (PVC) pipe	100 millimeter diameter	150 millimeter diameter
Cement-rendered, bamboo or other rural vent pipes	200 millimeter diameter	230 millimeter diameter
Brickwork	180 millimeter square	230 millimeter square

Sources: Ryan & Mara, 1983; Mara, 1984

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Box 1. Guidelines for odor control in VIP latrines

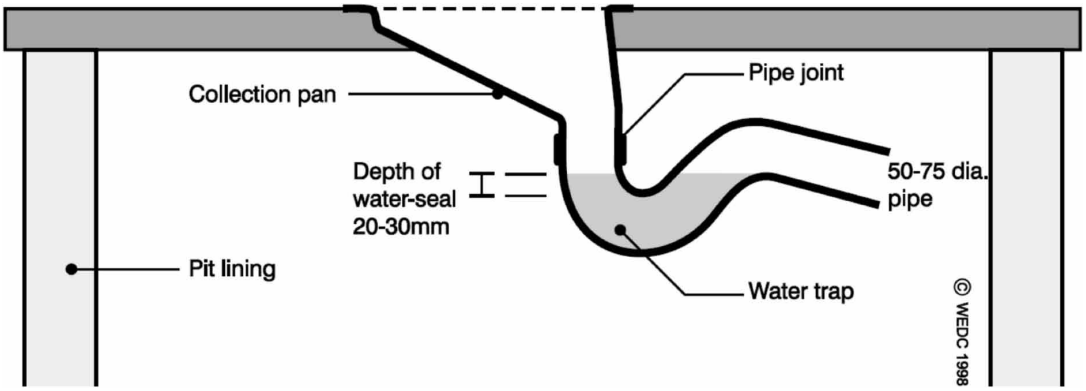
1. The vent pipe should be installed to a minimum height of 500 millimeters above a flat roof or the highest point of a sloping roof; for conical roofs, the vent pipe should be at least as high as the apex of the roof.
2. Where local wind speeds exceed 3 meters per second, the diameter of asbestos cement (AC) and polyvinyl (PVC) vent pipes may be reduced to 100 millimeters while those of other types may be reduced to 200 millimeters instead of the dimensions stated in Table 2 for a 20 cubic meter per hour ventilation rate.
3. For vent pipes serving two adjacent pits as in double-pit VIPs, the dimensions stated in Table 2 for a 20 cubic meter per hour ventilation should be maintained irrespective of the local wind speed.
4. For multiple alternating pits such as those used as communal latrines, a minimum of 200 millimeter diameter AC or PVC vent pipe should be provided
5. Where local wind speeds are less than 0.5 meter per second, the vent pipe should be painted black to enhance thermally induced ventilation.
6. The vent pipe should be located on the windward side of the superstructure.
7. Openings of a total area not less than 3 times the cross-sectional area of the vent pipe should be provided on the windward side of the superstructure; if both openings and vent pipe cannot be located on the windward size, preference should be given to openings on the windward side.
8. Openings in the opposite side to the windward direction should be avoided to avoid a drastic reduction in the pressure difference required to cause up-draught in the vent pipe.
9. The squat hole or toilet seat should not be covered to allow air flow through the superstructure into the pit.
(Cotton et al., 1995; Feacham et al., 1983; Franceys et al., 1992; Mara, 1984; Ryan & Mara, 1983)

Use of a Water Seal

Technologies such as the pour-flush, aqua privies and septic tanks make use of a water seal to prevent odorous gases from reaching the superstructure. For effective odor prevention, the following recommendations have been made:

1. The depth of the water seal, in a pour-flush latrine should be 20—30 millimeters in a 50—70 millimeter diameter water trap as shown in Figure 5 (Harvey et al., 2002; Roy et al., 1984)
2. The chute of an aqua privy latrine should extend to 50—75 millimeters below the water surface in the tank to effectively seal off odors (Brikke & Bredero, 2003; Franceys et al., 1992; Harvey et al., 2002). This requires that the water level above the sludge should be at least 75 millimeters (Brikke & Bredero, 2003).

Figure 5. Cross-section of a typical pour-flush pan with a water-trap (Source: Harvey et al., 2002)



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Addition of Substances

Various substances have been reported as being added to excreta by latrine owners in low-income countries to reduce odor (Rheinlander et al., 2013). Substances that have been recognized by experts as inhibiting odors and commonly recommended for use in composting latrines are mostly absorbents such as sawdust, wood ash, dry grass, husks, peat moss, etc. (Brikke & Bredero, 2003; Fraceys et al., 1992; Kalbermatten et al., 1980). Most of these substances were thought to be readily available at an affordable price or at no cost in the peri-urban environment where latrine owners may keep gardens (Kalbermatten et al., 1980). However, recent sharp rises in population densities in peri-urban areas (Barrios et al., 2006; Paterson et al., 2007) make this claim contestable.

No guidelines were found on the optimum quantities of the various substances required to achieve an acceptable level of odor control for any given excreta loading rate. Such data would be useful to help households achieve a good level of odor control with minimal material doses. Given the bulky nature of some of these materials, applying optimum quantities is absolutely necessary to avoid compromising the excreta storage capacity of latrines.

Fly Control Measures

The installation of a vent pipe and water traps as discussed above are also meant to control the proliferation of flies in latrines. For the VIP latrine, the following specific measures are recommended for controlling flies and other insects (Curtis & Hawkins, 1982; Franceys et al., 1992; Mara, 1984; Ryan & Mara, 1983):

1. The vent pipe should be installed as vertical as possible to easily direct flies in the pit to the light of the sky.
2. The top of the vent pipe should be covered with an insect screen having apertures not exceeding 1.2 x 1.5 millimeters to prevent entry of flies and mosquitoes.
3. The toilet room should be kept as dark as possible so that flies in the pit would not be attracted to light in the toilet room.
4. The door should be closed when the toilet is not in use to keep the room dark.
5. An insect screen may be used to cover the squat hole when not in use.

In recent times, efforts to improve the VIP have replaced masonry seats with prefabricated porcelain bowls fitted with plastic seats and covers like those used in water closet toilets. In addition to its aesthetic value, the smooth surface of the porcelain bowl allows easy cleaning while the plastic seat offers a more comfortable seating arrangement. Also, the plastic cover supposedly prevents flies from entering or leaving the bowl or pit. However, complete covering of the toilet seat is known to disrupt the chimney effect as noted above. Based on successful use of insect traps over VIP squat holes in Tanzania (Curtis, 1981), a potential improvement could be the replacement of the solid cover with an insect screen fitted in a plastic frame. However, the introduction of screened seat covers could also interfere with the chimney effect due to the reduced flow area and head losses associated with airflow through the fly screen (Ryan & Mara, 1983). Such interference may be compensated for by a revision of existing guidelines on vent pipe dimensions but no such investigation has been reported.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

STRUCTURAL STABILITY AND USER SAFETY

Safety concerns over the use of on-site sanitation mostly arise from possible collapse of the pit, the cover slab or superstructure. Structural stability is of a greater concern where the latrine is built in unstable soils. Beside these, there is also the fear of entry by rodents and reptiles and the risk of the user falling into the pit through the squat hole. Relevant guidelines on assessing soil stability and addressing safety concerns are discussed in this section.

Soil Stability Criteria

Soil stability may be assessed in terms of the particle size distribution or undrained sheer strength as described in, for example, British Standards BS 2004: 1972 (Mara, 1984). Soils are considered stable if they contain more than 30 per cent clay (E.S < 0.002 millimeters) or a combined sand and silt (E.S. > 0.002 millimeters) fraction not exceeding 70 per cent; on the other hand, soils with undrained shear strength of 20 kilonewton per square meter or above can be considered stable enough to support normal superstructures and cover slab loads (Mara, 1984).

In low-income countries, such scientific assessments of soil stability would most likely be unaffordable to individual households. In such situations, Mara (1984) recommends a simple improvised evaluation of the soil's stability by collecting samples by hand-auguring at 0.5 meter intervals to a depth of 3 meters. A rough cylinder of approximately 5 centimeters in length and 2 centimeter diameter is then formed from each sample by hand-rolling. When the sample is gently crushed between the thumb and fingers after sun-drying for two days (or oven-drying at 100 degrees Celsius for two hours where possible), unstable soils are found to crush easily while stable, cohesive ones do not. Obviously, this test is subjective and requires experience after practice with soils of known particle size distribution and undrained sheer strength.

In addition to the above, it can be reasonably assumed that if other excavations in the locality such as hand-dug wells have not been lined and they have been self-supporting for a number of years, then it will be fairly safe to leave pit latrines unlined (Franceys et al., 1992, Harvey et al., 2002).

Pit Lining

Aside from systems such as septic tanks and aqua privies that require watertight chambers that must always be lined (Franceys et al., 1992), pit lining is recommended as a safety measure where the soils are unstable (Fraceys et al., 1992; Mara, 1984). Even in stable soils, it is recommended to always line the top 0.5 meter of the pit as a precautionary measure against pit collapse due to, for example, gradual release of pore water pressure (Franceys et al., 1992; Harvey et al., 2002; Mara, 1984). According to Mara (1984), this could be in the form of partial lining by plastering the soil faces with 10 millimeter thick cement mortar using 1 part cement and 5 parts sand. However, Franceys et al. (1992) recommend full lining at the top 0.3—0.5 meter to support the slab in all cases.

In unstable soils, pits should be fully lined with suitable materials such as fired bricks, concrete blocks, cast in-situ concrete, perforated oil drums, ferrocement, etc, with perforations or unmortared joints left below a depth of 0.5 meter to allow for infiltration (Franceys et al., 1992; Harvey et al., 2002; Mara, 1984). In wet pits, lining can be done by inserting short-length concrete pipes as excavation proceeds (Mara, 1984).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Stability of the Cover Slab

The cover slab may be made of concrete, wood, ferrocement and plastic but concrete is the most preferred material due to its durability, low cost and ease of cleaning (Harvey et al., 2002). As a basic requirement, the cover slab should not deflect noticeably and should be strong enough to support the weight of the superstructure, a vent pipe (in the case of VIPs), a pedestal seat (if used) and the user (Franceys et al., 1992; Mara, 1984). When concrete is used, it is necessary to reinforce it with steel bars placed at the lower side of the slab to prevent the development of tension cracks and eventual collapse. Adequate strength may be achieved with different combinations of slab thickness, diameter of steel bars and spacing intervals. The spacing of steel bars to be provided along the length and breadth of the cover slab are shown for different steel bar diameters and slab thickness in Table 3.

In low-income settings, the cost of reinforcing the cover slab, which is usually the most expensive component of a pit latrine (Harvey et al., 2002), can be a major setback to households. As an alternative to reinforcement, the concrete may be cast in a dome shape which transmits the imposed weights to the supporting ground, leaving the underside of the slab in compression and therefore requires no reinforcement (Franceys et al., 1992; Harvey et al., 2002; Mara, 1984)

Size of Drop Holes

To minimize the risk of falling into the pit, especially for children, Mara (1984) recommends the use of a key- or pear-shaped opening with a maximum width of 200 millimeters. Harvey et al., however, recommend a maximum of 250 millimeters and a minimum of 160 millimeters to avoid users fouling the floor with feces and urine. Perhaps, latrines to be used by children should have a maximum drop hole width of 200 millimeters. Further research in the determination of an appropriate size of drop holes need to consider the squatting positions of men, women and children of different ages, height and weight.

Prevention of Entry by Rodents and Reptiles

In Nepal, rats have been reported to burrow into double-pit latrines through holes allowed in the lining for infiltration (Fraceys et al., 1992). Rodents and reptiles may also enter the superstructure through openings allowed for ventilation. Although a full lining of the top 0.5—1 meter of pits has been recommended for preventing entry by rats (Franceys et al., 1992), not much detailed guidelines exist on how to effectively prevent other rodents and reptiles from entering the superstructure through openings

Table 3. Spacing for steel reinforcement bars in pit latrine cover slabs

Slab thickness (millimeters)	Steel bar diameter (millimeters)	Spacing of steel bars (millimeters) in each direction for minimum slab span of:				
		1 meter	*1.25 meters*	*1.5 meters*	*1.75 meters*	*2 meters*
65	6	150	150	125	75	50
	8	250	250	200	150	125
80	6	150	150	150	125	75
	8	250	250	250	200	150

Source: Franceys et al., 1992; Harvey et al., 2002

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

provided for ventilation. Provision of special netting at openings could be a solution but its effect on the rate of ventilation due to loss of air pressure across the net needs to be investigated. It also calls for an investigation into the necessary compensation in the recommended size of openings, i.e. three times the cross-sectional area of the vent pipe, as recommended by Mara (1984).

FUTURE RESEARCH DIRECTION

Adapting existing guidelines on on-site sanitation systems to the evolving conditions of urban slums and peri-urban areas of low-income areas requires much attention in future research. Future research needs to explore opportunities for relaxing or modifying existing design codes to respond to the infrastructural limitations of these areas. Notably, population explosions in these areas and the inability of governments to match population growth with public infrastructure, especially water supply, place constraints on the selection and design of some sanitation technologies. For instance, lack of regular water supply implies that most households have to depend on dry sanitation systems, with the ventilated improved pit (VIP) latrine becoming increasingly popular in these areas. However, the performance of this technology is very sensitive to environmental factors such as wind speed and direction that are influenced by uncontrolled land development. Particularly, multiple extensions to houses in response to increasing demand for residential accommodation tend to alter the circulation of air within the neighborhood and lead to situations where existing VIP latrines that were originally built with openings facing the wind direction later become disoriented as the wind direction changes. In such cases, future research needs to explore the feasibility of a 'direction-free' VIP that would be independent of the direction of wind as well as improved designs of dry sanitation systems, in general, to eliminate or minimize the development of odors.

CONCLUSION

On-site sanitation technologies can effectively perform the basic function of raising a barrier against fecal-oral disease transmission and afford households in low-income countries all the health benefits of conventional sewerage provided relevant technical guidelines are observed in the choice of technology options, the design and construction of facilities and their operation and maintenance. Perhaps, the most crucial requirement for the long-term sustainability of facilities is the appropriate choice of a technology option to suit a given physical and socio-cultural environment. This chapter provides the most critical principles and considerations. Thus, the technology option should be capable of raising an effective barrier to disease transmission; it should be accepted and used regularly by the intended users; and it should be affordable in terms of the cost of construction and maintenance. To safeguard human health and environmental sustainability, the prevention of groundwater pollution is an overriding factor. This chapter has discussed minimum distances recommended for the vertical clearance between pit bases and the groundwater table, as well as the lateral clearance between the latrine location and groundwater abstraction points. Beside these, issues relating to the comfort and safety of the latrine user are key to consistent usage of facilities and, hence, the prevention of open defecation. Guidelines have been discussed for the control of odor and fly nuisances and the structural stability of facilities.

However, the guidelines provided in this chapter should not be taken as being exhaustive or the final word of authority. Frequently, local experiences may require the development of specific guidelines by local experts in response to prevailing needs and challenges. In applying these guidelines, there is the need for flexibility and innovation. Nevertheless, such innovation should not compromise the safety of the latrine user and the prevention of fecal-oral disease transmission.

KEY TERMS AND DEFINITIONS

Bucket and Cartage Toilet: A reinvention of the age-old sanitation system in which excreta are stored in the home in waste buckets or other containers that are collected regularly by a cleaning team and carted or transported to a central disposal or treatment site. The new system, which is referred to as porta potty in some countries, has a specially designed container that allows the separation of urine from feces.

Chimney Effect: The movement of air through chimneys and vent pipes as a result of buoyancy or difference in the densities of hot and cold air. In a ventilated improved pit latrine, external cold air entering the pit through the superstructure displaces hot air in the pit of a relatively lower density. The hot air then rises through the vent pipe.

Ferrocement: A thin-shell construction material consisting of cement mortar reinforced with wire mesh or small-diameter steel rods.

Guideline: A principle, code or recommendation to inspire a sound practice. Following guidelines is usually advisory rather than mandatory.

On-Site Sanitation: A type of sanitation system that retains all the components of a sanitation system within the premises or surroundings of the excreta generating entity. It may, however, require periodic removal of fecal sludge from the holding tank, pit or vault.

Sanitation System: An assemblage of structures and appurtenances for the collection, storage, transportation, treatment and disposal of excreta. Some sanitation systems may not involve all of the above components. In a broader sense, sanitation may be defined as the protection of human settlements from diseases associated with waste generated by humans. However, this chapter focused on sanitation as safe disposal of human excreta.

Shear Strength: The property of a material which measures its ability to resist forces that attempt to cause its internal structure to slide against itself in a plane that is parallel to the direction of the force.

Soakaway: A constructed drain field, usually consisting of a pit or a channel filled with crushed rock, in which waste water slowly infiltrates into the adjoining ground.

Soil Stability: The property of a soil that determines its tendency to be self-supporting, especially in the absence of an embankment.

Standard: A mandatory code of practice required to be followed in a particular vocation or service. A standard is meant to be enforced by an appropriate authority.

Structural Stability: The property of being stable or resistant to collapse.

Sullage: Any type of domestic wastewater generated from cooking, washing and cleaning that does not contain excreta. It is sometimes referred to as grey water.

Water Seal: A layer or section of water used to trap volatile substances or prevent them from escaping from a closed system.

Worm Digester with Water Closet Toilet: A sanitation system in which a digester containing macro-invertebrates (red worms) is connected to a micro-flush or full-flush water closet system to provide stabilization and reduction of excreta. The effluent is disposed of in a drain field or soakaway pit.

Chapter 49
Mining Spatial Patterns of Distribution of Uranium in Surface and Ground Waters in Ukraine

Michael Govorov
Vancouver Island University, Canada

Viktor Putrenko
National Technical University of Ukraine "Kyiv Polytechnic Institute", Ukraine

Gennady Gienko
University of Alaska Anchorage, USA

ABSTRACT

A variety of geovisualization and spatial statistical methods can reveal spatial patterns in the distribution of chemical elements in surface and groundwater, and also identify major factors which define those patterns. This chapter describes a combination of modeling techniques to enhance understanding of large-scale spatial distribution of uranium in groundwater in Ukraine, by linking spatial patterns of several indicators and predictors. Factor, correlation, and regression analysis, including their spatial implementations, were used to describe the impacts of several environmental variables on spatial distribution of uranium. Local factor analysis (or Geographically Weighted Factor Analysis, GWFA) was proposed to identify major environmental factors which define the distribution of uranium, and to discover and map their spatial relationships. The study resulted in a series of maps to help visualize and explore the relationships between uranium and several environmental indicators.

INTRODUCTION

Surface and ground waters are important resources for drinking water supplies. Ukraine river flow is 1,000 m^3 per capita, which is one of the lowest indicators in Europe, so availability of quality drinking water is a very important issue for the country. Drinking water quality is determined by chemical and biological content of the water and depends on several factors, including radioactivity of surface and groundwater associated with various natural and anthropogenic processes.

Natural radioactivity and groundwater contamination is often studied in areas of the extraction and processing of minerals, including uranium and oil. Natural radioactivity of oil and gas was first registered in 1904 in Canada, and later found in many places worldwide (Schneider, 1990; Makarenko, 2000). Several areas in Ukraine have high concentrations of uranium, so surface and groundwater in these areas can be potentially unsafe as a source of drinking water. Concentrations of uranium of 0.08 Mg/L and higher are potentially dangerous to human health, therefore, investigation of the impacts of uranium on groundwater (and thus, on the quality of drinking water) is an important scientific problem (Canadian soil quality, 2007; Nacional'nij atlas, 2007; Uranium in Drinking-water, 2011).

Multiple studies suggest that geological structure is the main natural factor which determines the content of natural radionuclides in ground and surface waters (Hakonson-Hayes et. al., 2002; Myers et. al., 1982; Sami & Druzynski, 2003; Skeppstrom & Olofsson, 2007). There is a wide body of research on this topic, but the most relevant to Ukraine are studies implemented in Sweden, Finland, and Canada, as geological structures in these countries are similar to those in Ukraine; they are all located on Precambrian crystalline shields, Baltic and Canadian.

Ukraine is located in the central and southeast regions of Central Europe, with a population of about 47 million people. It spreads from the southwest of the Eastern European Plain, through the Ukrainian Carpathians and the Crimean Mountains, with its shores in the south washed by the Black and Azov Seas. About 95% of the country is relatively flat (with an average elevation of about 170m), and the Carpathians and Crimean Mountains occupy about 5% of its territory.

Ukraine is located within two major tectonic structures: the East European platform and the Alpine geosynclinal (folded) region. The plateau part of Ukraine is a rigid, slightly shifting tectonic structure with ancient crystalline rock covered by sediments (sand, clay, limestone, etc.). The Alpine geosynclinal region is dominated by sedimentary rocks. The system is relatively young (25-100 million years), and exhibits intense tectonic movements.

Ukraine has a complicated geological structure, comprising the following genetically related geostructural regions: the Ukrainian Shield, Volyn-Podolsk Upland, Dnieper-Donetsk Basin, Donetsk folded structure within the East European Platform, and Carpathian and Crimean folded systems and Scythian Platform within the Alpine geosynclinal region. An interesting geological structure, the Black Sea Depression, stands out in the entire system. The structure lies in the merging areas of the old East European and younger Scythian Platform.

Apart from radioactive elements in rocks, concentration of radioactive elements in natural waters is defined by hydrogeological and climatic conditions, physical properties of rocks, chemical composition and electrochemical properties of natural waters, migration of radioactive isotopes during their transition from rocks into the water and further transportation with water, as occurs mostly in faults or other permeable surfaces. On average, river water has less total natural radioactivity than the sea and underground waters, except for rivers in regions with highly radioactive rocks (Uranium in Drinking-water, 2011). Levels of radioactivity in rivers vary depending on seasonal changes; levels reduce in spring and rise

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

during the low-water periods of summer due to an increase in the concentration of natural radionuclides. Higher levels of uranium are found in rivers with catchment areas composed of granites.

Another significant factor affecting water quality is climate. Climate change impacts all components of the environment, resulting in reorganization of geochemical processes. Climate plays a major role in rock weathering, and rocks, in turn, serve as a transportation channel for radioactive elements in natural water. For example, a large amount of precipitation leads to leaching of uranium from radioactive minerals, dilution of groundwater enriched with radioactive elements, and transportation of radioisotopes away from the source of natural concentration. Substantial saturation of rocks containing radioactive elements may result in accumulations of uranium and radon in groundwater. Chemical composition of water is another important factor. Acidity, gas composition, and oxidation are important elements defining the mineralization of water, which is directly related to concentration of uranium in groundwater.

In summary, major environmental and natural indicators affecting concentration of uranium in ground and surface waters can be grouped into four categories: geological structure and geomorphology, geochemical composition, mineralogical composition, and climate (Salih et. al., 2002). Geological and geomorphological factors include types and mineral structure of rocks, relief of the territory (elevation), structure of the relief (slope, exposure), and deepness of bedrock. Geochemical factors are characterized by distribution of rare earth elements in the water, which are often found in conjunction with uranium. These include arsenic, fluoride, chromium, copper, and zinc. Mineralogical indicators are divided into two groups: characteristics of water and those of soil. These indicators are the product of interaction between climate and geological structures. Mineralogical markers in water include common indicators of mineralization, hardness, chloride, sulphate, magnesium, and calcium. Concentrations of humus were used to characterize soil. Climatic factors studied were characterized by average annual rainfall, and average annual values of temperature and evaporation.

Figure 1 illustrates distribution of uranium in Ukraine. Two different symbolization methods for categorization of the source data were used to illustrate spatial distribution of uranium. While the areas of low concentration (below 0.04 Mg/L) and transitional types of uranium have been clearly identified using quintile categorization (Figure 1, center), geometric interval-based categorization were used to illustrate the distribution of high levels of uranium concentration (0.04-0.145 Mg/L, Figure 1, right). Zones of low concentration (Polesia, the Carpathian Montains, and Transcarpathia) are characterized by a percolative water regime and high level of precipitation. Low concentrations of uranium were observed in the Dnieper River valley in northern Ukraine and near the delta in the south. The highest concentrations were associated with the structures of the Ukrainian Crystalline Shield in central Ukraine and also observed near the coast of the Azov Sea.

Geographical distribution of uranium in surface and ground waters in Ukraine indicates that concentration increases from North-West to South-East. This trend is associated with arrangement of geologic structures (granite) in the Ukrainian Crystalline Shield, mineralization of water, and certain fluctuations of climate, such as increased evaporation (Shiraishi et.al., 1994). There are six uranium provinces in Ukraine with different geologic structures and features of concentration of uranium in rocks (Nacional'nij atlas Ukraïni, 2007). The northern and western regions of Ukraine are characterized by relatively low amounts of uranium. The main concentration of uranium is found in the Ukrainian Crystalline Shield, with the mining industry located mainly in Kirovohrad and Dnipropetrovsk regions. These areas exhibit high concentrations of uranium deposits. Another area of high concentration of uranium in waters is in eastern Ukraine, in the Donetsk fold region and partly in the Black Sea lowlands. Surface and ground water in this area are characterized by high levels of mineralization (Makarenko, 2000).

Data courtesy of State Enterprise "Kirovgeologiya" (Prirodni ta antropogenni, 2004)

The goal of this study is to explore various geostatistical methods to model spatial dependencies between several environmental variables and distribution of uranium in groundwater. The study is focused on comparative analysis of using several techniques to identify the most robust method to describe spatial distribution of uranium in groundwater in Ukraine. The analysis was conducted using tools available in SPSS, ArcGIS, and GeoDa packages.

BACKGROUND

This study is based on the results of geological surveys in Ukraine carried out by State Enterprise "Kirovgeologiya" (Prirodni ta antropogenni, 2004; Makarenko, 2000). The database consists of 23 environmental indicators collected in 9353 sample points in Ukraine and neighboring territories of Russia, Belarus, and Moldova. Unfortunately, not all environmental indicators are available for all neighboring territories, limiting the research by using only the complete dataset available for Ukraine (6546 sample points).Variables included in the source dataset are listed in Table 1. Several spatial statistical methods were used to discover patterns of spatial distribution of natural uranium. (Note on terminology: the terms 'natural variables,' or 'environmental indicators,' are widely used in this study to describe various natural and environmental factors, for example, mineralization, precipitation, relief, and many others. Some models use 'predictors' with the same meaning as 'variables.')

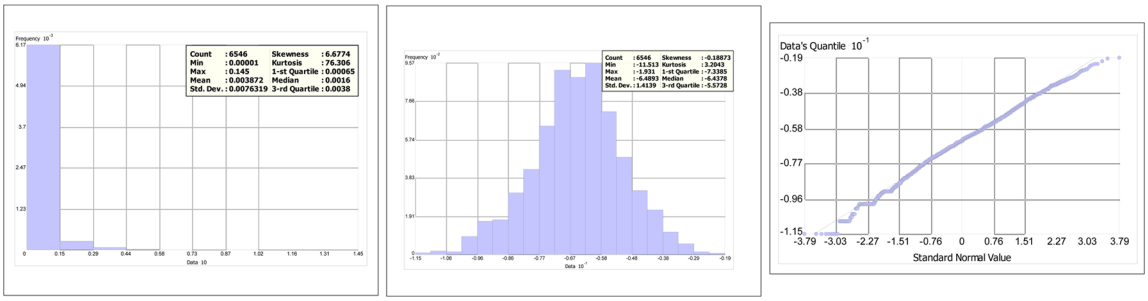
The following spatial analyses and cartographic visualization workflow was used to describe the impact of several environmental variables on spatial distribution of uranium.

Exploratory spatial data analysis (ESDA) was used for initial data analysis, such as checking for statistical distribution, linearity, multicollinearity, and presence (or absence) of a pattern (both in spatial and non-spatial domains). Based on initial hypotheses and results of ESDA, further statistical data exploration can be developed by building correlation, regression, and factor models.

Many methods of regression are based on the assumption that the distribution of the dependent variable is normal. Figure 2 displays the histogram of uranium concentration (left), which clearly shows that statistical distribution of the source data does not meet criteria for normality. However, logarithmic transformation brings the dataset closer to normal (Figure 2, center and right).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 2. Histograms of the source (left), and normalized data (center), and normal QQPlot after applying logarithmic transformation (right)



For linear regression models, the relationship between a dependent variable and each independent variable should be linear. For example, the curve estimation procedure shows that the relationship between uranium and mineralization of waters is more exponential than linear; this would require nonlinear regression modeling. (However, implementation of multiple nonlinear regressions for these variables can be problematic.)

Independent variables can be significantly correlated (multicollinear) and produce unstable and unreliable multiple regression models. Several variables in the source dataset exhibit multicollinearity and require appropriate treatment.

Spatial autocorrelation methods were used to identify patterns in spatial measurements of uranium concentration. According to Moran's *I* and Getis-Ord analysis (Getis & Ord, 1992; Moran, 1950), the distribution of uranium can be described as highly clustered with statistical significance. Moran's *I* index is 0.5475 (p-value = 0.0) and Observed General G = 0.00007 (p-value = 0.0). There is positive spatial autocorrelation, as Moran's *I* is positive and greater than expected IndexE(*I*) = -0.00015. Thus, spatial patterns in observations of uranium should be taken into account in correlation, regression, and factors models to avoid bias due to over-counting (Anselin, 1995).

In the second step, quantitative measure of global correlation is used to confirm or reject several hypotheses of relationship between the dependent variable (uranium) and independent variables (environmental indicators). The analysis should identify natural variables which define high concentration of uranium, taking into account multicollineaity and clustered nature of the data.

The classical global Pearson correlation coefficient *r* is used as a measure of global correlation. The coefficient is defined as:

$$r = \frac{\sum_{i=1}^{n}\left(u_i - \overline{u}\right) * \left(v_i - \overline{v}\right)}{(n-1) * S_u * S_v}, \tag{1}$$

where *r* is the correlation coefficient; u_i and v_i are the individual observations; $\overline{u}$ and $\overline{v}$ are the means of the two variables; *n* is the sample size; and S_u and S_v are the standard deviations of the two variables.

In the next step, global factor analysis is applied as an attempt to identify underlying indicators and factors that explain the pattern of correlations within a set of natural variables. Factor analysis is used

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

to identify a smaller number of natural variables that define most of the variance of uranium distribution. This study utilizes factor analysis based on the principal components using Varimax rotation with Kaiser normalization (Harman, 1976).

In the factor analysis model based on factor *p* is:

$$\Lambda_p = \Omega_p \Gamma_p^{1/2}, \tag{2}$$

where Λ_p is the matrix of factor loadings based on factor *p;* Ω_p is the diagonal matrix of ϖ_i that are the corresponding eigenvectors of *R*, where *R* is the correlation *n*×*n* matrix *or* eigenvectors of Σ, where $\Sigma=[\sigma_{ij}]_{n\times n}$ is the covariance *n*×*n* matrix of natural variables; and Γ is the matrix of eigenvalues. Here, *n* represents the number of variables and *p* is the number of factors. It is also assumed that each factor has unit variance and the factors are independent of each other.

After a varimax rotation, each original variable tends to be associated with one (or a small number) of components, and each component represents only a small number of variables. This simplifies interpretation of resultant factors and their associations with the variables. In addition, components can often be interpreted from the opposition of few variables with positive loadings to few variables with negative loadings. Varimax searches for a linear combination of the original factors, such that the variance of the squared loadings, are maximized, which amounts to maximizing (Harman, 1976).

The most significant natural variables, as identified from factor and global correlation analysis, were used to demonstrate spatial non-stationarity of correlation between uranium and natural variables. This was done by implementing local correlation analysis (or geographically weighted correlation, GWC). In this study, a local form of bilinear regression with optimized bandwidth was used to model spatially-varying relationships between uranium and natural variables.

The geographically weighted local Pearson correlation coefficient $r_i(x_k,y_k)$ is used, and defined as:

$$r_i(x_k, y_k) = \frac{\sum_{j=1}^{n} \varpi_j * \left(u_j - \overline{u}\right) * \left(v_j - \overline{v}\right)}{(n-1) * S_u * S_v} = \beta_1(x_k, y_k) \frac{S_u}{S_v}, \tag{3}$$

where $r_i(x_k,y_k)$ is the correlation coefficient, x_k,y_k is the location of observation *i*; u_j and v_j are the individual observations; $\overline{u}$ and $\overline{v}$ are the means of the two variables, ϖ_j is the weight assigned to each observation that based on a distance decay function centered on the observation *i; n* is the sample size; and S_u and S_v are the standard deviations of the two variables; $\beta_1(x_k,y_k)$ is the estimated parameter for the bivariate local least-squares regression on observation *i.*

Relationships between the dependent variable and all explanatory variables, as identified from the factor analysis, were modeled by using stepwise linear multivariate regression analysis (or ordinary least squares regression, OLS regression). Then, several most significant explanatory variables identified from the stepwise multivariate regression analysis were used to build local linear multivariate regression models (or geographically weighted regression, GWR) with the optimized bandwidth (Fotheringham et. al., 2002).

Explanatory variables in the spatial regression model have consistent relationships with the dependent variables both in geographic space and in data space. The following requirements of linear multiple regression have to be addressed (Tabachnick & Fidell, 2012):

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

- Variables have a linear association.
- It is important not to miss significant explanatory variables (misspecification must be avoided).
- Explanatory variables should not be redundant (multicollinearity must be avoided).
- For every value of a dependent variable, the distribution of its residuals should be normal, and the mean of the residuals should equal zero.
- Residuals have a constant variance across all the values of the statistical variables (non-stationarity or spatial heterogeneity must be considered).
- The value of each residual is independent of all other residual values (spatial autocorrelation must be considered).

The OLS global regression formula was applied to the explanatory independent variables v_p to best predict the dependent variable *u*, and defined as:

$$u = \beta_0 + \beta_1 * v_1 + \beta_2 * v_2 + ... + \beta_p * v_p + \varepsilon \,, \tag{4}$$

where *y* is the dependent variable, x_p are the explanatory variables, β_p are global regression coefficients, *p* is number of variables, and $\varepsilon$is random error or residual.

A stepwise approach was used to build multivariate regression models. At each step, the independent variable not included in the equation had the smallest probability of *F-statistic*, if that probability is sufficiently small. Variables already in the regression equation are removed if their probability of *F-statistic* becomes sufficiently large. The method terminates when no more variables are eligible for inclusion or removal. The Akaike Information Criterion and *adjusted* R^2 are used to estimate the models' performance. The method also insures that Variance Inflation Factors among explanatory variables are low, to avoid measures redundancy or multicollinearity among explanatory variables.

There is a possibility to improve model results by applying local Geographically Weighted Regression (GWR), which takes into account the effect of heteroskedasticity (Fotheringham et. al., 2002; Ord & Getis, 1995).

The geographically weighted local regression (Fotheringham et. al., 2002), defined as:

$$u_i(x_k, y_k) = \beta_{0i}(x_k, y_k) + \beta_{1i}(x_k, y_k) * v_{1i} + \beta_{2i}(x_k, y_k) * v_{2i} + ... + \beta_{pi}(x_k, y_k) * v_{pi} + \varepsilon_i \,, \tag{5}$$

on observation *i*, where $u_i(x_k,y_k)$ is the dependent variable estimated in location *i*; v_{pi} are the explanatory variables; $\beta_p(x_k,y_k)$ are the local regression coefficients; *p* is the number of variables, and ε_i is the residual estimated in location *i*. Each local regression $u_i(x_k,y_k)$ equation is solved using a different weighting of the observations that based on a distance decay function centered on observation *i.*

GWR accounts for spatial non-stationarity in parameter estimates, but it does not directly address autocorrelation (Jetz, 2005). In addition, GWR models tend to have large numbers of parameters, which are not easy to empirically estimate.

If strong autocorrelation is present in the residuals of global multivariate regression models, further actions can be taken by using autoregressive models of spatial econometrics. The spatial lag model and spatial error model were used (Anselin, 2006).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

General expression for the spatial lag model is:

$$u = \rho * W * u + \beta * v + \varepsilon, \tag{6}$$

where u is a vector of dependent observations, W is a spatial weight matrix, ρ is a spatial autoregressive parameter, v is a matrix of explanatory variables, β are the respective regression coefficients, and ε is a vector of independent disturbances.

General expression for the spatial error model is:

$$u=\beta*v+\varepsilon \text{ with } \varepsilon=\lambda*W*\varepsilon+\zeta, \tag{7}$$

where λ is the coefficient of spatially lagged autoregressive errors and ζ is a vector of independently distributed errors.

A spatial error model is appropriate when there appears to be structure in the residual term, and a spatial lag model is appropriate when spatial structure is present in the variables of the model (Anselin, 2001, 2006).

Finally, local factor analysis (or geographically weighted factor analysis, GWFA) with the optimized bandwidth (Harris et. al., 2011) was used to generate linear multivariate regression models for the dependent variable (uranium), and six major factors were produced in the global factor analysis.

The geographically weighted local factor/regression models, defined as:

$$u_i(x_k, y_k) = \beta_{0i}(x_k, y_k) + \beta_{1i}(x_k, y_k) * F_{1i} + \beta_2(x_k, y_k) * F_{2i} + ... + \beta_{pi}(x_k, y_k) * F_{pi} + \varepsilon_i, \tag{8}$$

on observation i, where $u_i(x_k,y_k)$ is the dependent variable estimated in location i; F_p are the factors from principal components extraction; $\beta_p(x_k,y_k)$ are the local regression coefficients; p is the number of variables, and ε_i is the residual estimated in location i. Each local regression $u_i(x_k,y_k)$ equation is solved using a different weighting of the observations.

GLOBAL AND LOCAL SPATIAL CORRELATION ANALYSIS OF DISTRIBUTION OF URANIUM

The overall distribution of uranium depends on several factors defined by geographical conditions of the area. The most significant factors can be identified using global correlation of uranium with all indicators from the four defined groups: geological, geochemical, mineralogical, and climatic (see Table 1).

The highest global correlation coefficients of uranium were obtained for humus (r=0.52), temperature (r=0.51), precipitation (r=-0.50), and volume of natural groundwater resources (r=-0.56). Uranium also has significant correlation with the overall water mineralization (r=0.49) and its components: SO_4 (r=0.45), Cl (r=0.44), and hardness of water (r=0.49). These indicators are interdependent and highly correlated. Geomorphic indicators, which include relief (r=-0.24), sediment thickness (r=0.02), and slope of terrain (r=-0.08), were less associated with the distribution of uranium. Although there is a

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

direct association between granite rocks represented in relief uplifts and uranium concentration in water, correlation analysis identifies certain relationships between uranium and mineralization of water and variations in climatic conditions.

Each factor affecting concentration of uranium has its own spatial distribution, forming certain allocations in geographic space. Local correlations for different indicators can form complex spatial patterns and anomalies. Moran's I and Getis-Ord analyses confirm that the distribution pattern of uranium is highly clustered. Thus, values of correlation coefficients inherit high non-stationarity and should be modeled by using local methods. For example, global coefficient of correlation shows very low relationship between uranium and isopachs (only r=0.02), but local coefficients of correlation range from -0.71 up to 0.42 indicating very high association between these two variables (see southwest area of Bessarabia region in Figure 3).

Global Factor Analysis of the Relationship Between Natural Variables and Uranium

There are many natural variables which influence the distribution of uranium. Factor analysis has been used to find the impact of a particular variable on the distribution of uranium in Ukraine. Analysis of 23 different natural variables has revealed six principal components which shape the distribution of uranium (see Table 1). In this case, the analysis involved the independent variables excluding uranium.

The first major component is characterized by mineralization of water, with the most important issue being the total salinity and hardness of water. The second component largely comprises metals dissolved in water (copper, iron, magnesium, and zinc). The third component describes climatic conditions of the territory and formation of surface and ground water. The fourth component is associated with the presence of organic compounds in water. The fifth component describes geomorphological characteristics, and the sixth component is associated with mineral compounds and metals which often accompany uranium ('satellites').

The analysis shows that all six identified principal components largely coincide with the four groups of natural variables outlined in the hypothesis of uranium distribution in Ukraine (see Table 2).

It should be mentioned, that factor analysis on all variables including uranium indicates that uranium belongs to the first mineralogical group.

Figure 3. Uranium (left), isopachs (center), and their correlation (right). This is an example of low global correlation (r=-0.02) with high values in local variations (r=-0.70, blue, and r=-0.42, red)

Local Spatial Correlation

Results of factor analysis were used to explore patterns of local spatial correlation of particular indicators with uranium. The local correlation analysis was carried out for the most significant elements from each component (highlighted in Table 1).

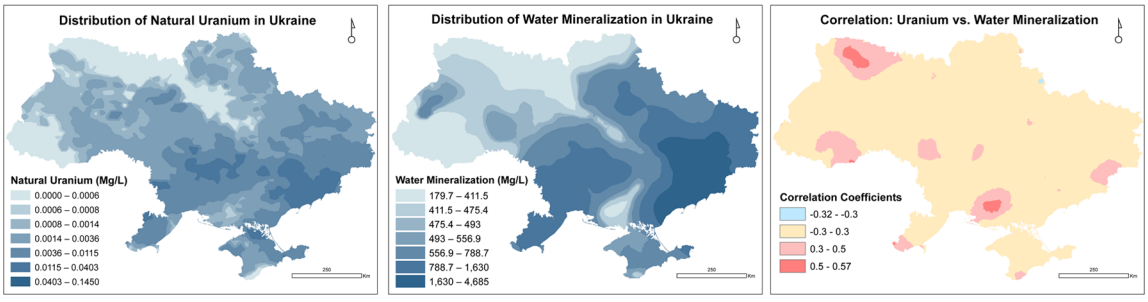
Component 1

Uranium exhibits positive correlation with total mineralization of water reaching r=0.56 in certain areas (Figure 4). The relationships strengthen in the north, center, and south of Ukraine, and weaken in the forest-steppe zone.

The total salinity of surface and groundwater gradually increases from the northwest to the southeast (Gorev, et. al., 1995), which is associated with climatic changes of the balance between precipitation and evaporation. Atlantic air masses soften the climate of the western part of Ukraine, increasing rainfall, and decreasing the temperature range and the total number of active temperatures. This is clearly articulated in the area of the Carpathian Mountains, where active migration of Atlantic air brings the maximum precipitation to Ukraine and the Western Polesie. The eastern Ukraine has more continental climate, defined by continental air masses of the eastern European part of Russia, and even Siberia. These air masses are characterized by low humidity and predominant anticyclonic activity when the balance between precipitation and evaporation is shifted towards evaporation. There is also a natural zonal increase in insolation from the north to the south.

Both mineralization and uranium are less exposed in the northern and western parts of Ukraine, but still exhibit relatively high correlation. The amount of mineralization of water in the forest-steppe zone is increased, but uranium does not show the same pattern, which results in weakening of correlation. High concentration of uranium in the area of the Ukrainian Crystalline Shield contributes to higher correlation with mineralization of water. In the south, the correlation is increased due to the increase of mineralization and concentration of uranium. However, correlation weakens in the western part of the Black Sea Lowland. High mineralization is associated with low values of uranium, which is found in small quantities in these sedimentary rocks. Overall, the correlation analysis highlights significant global association between uranium and water mineralization, with strong local correlation in certain

Figure 4. Uranium (left), water mineralization (center), and distribution of local correlation (right). Global correlation r=0.49



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

areas in Ukraine. A strong relationship is defined mostly by climate parameters, geological formation, and distribution of large river basins. Weakening of correlation is associated with transition from the mixed forest to steppe zone with specific balance of temperature and precipitation.

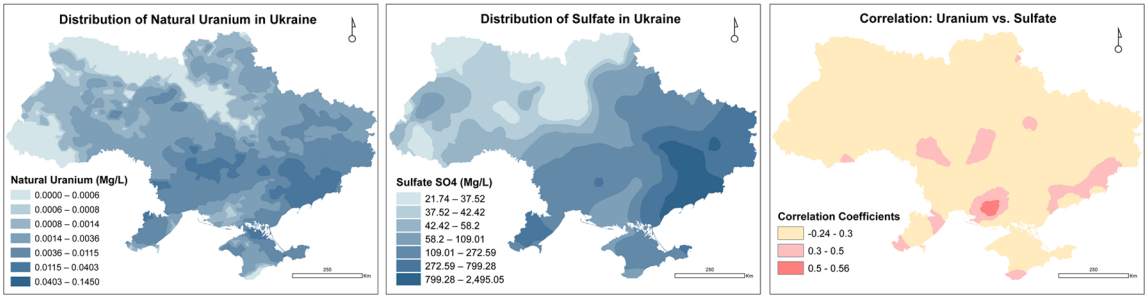
Total mineralization of water is closely related to water hardness, SO_4, and Cl. Water hardness exhibits correlation patterns very similar to that of mineralization, but with slightly higher maximum values of the local correlation (r=0.59). There is also a clearly defined relationship of uranium with folded structures of the Donetsk range in the east part of Ukraine, which may be associated with higher natural hardness of groundwater in this area.

Group SO_4 is characterized by a somewhat more evident zonal relationship with uranium, which strengthens in the Ukrainian Crystalline Shield and Azov Upland (Figure 5). This indicates that this group is more dependent on the geochemistry of the environment than the total mineralization, and so it is not a significant factor in local geochemical anomalies.

Uranium can probably correlate with sulfate in the karst areas (for example, in the west Ukraine or in the Crimea). The distribution of uranium and sulfates in groundwater in the Dnieper-Donets Basin is influenced by deposits of hydrocarbon (Penkov, 1989) that occur in sedimentary rocks of the geological depression along the Eastern wing of the Ukrainian shield. Oil fields are mostly found in the northern part of the region; the central and southeastern areas are rich with natural gas. (Note on the physical processes in areas of hydrocarbon deposits: anaerobic bacteria cause desulfurization of groundwater (decrease of SO_4^{2-}), enrichment of carbon dioxide and hydrocarbons. This pattern has been found in local shale gas in the Kirovograd region. Concentration of ammonium sulfide, hydrogen sulfide, and the total gas saturation can decrease with the distance from the area of hydrocarbon deposits.)

Local correlation of uranium with chlorides is similar to the patterns of correlation with mineralization. The difference in values of global correlation and maximum coefficients of local correlation is less than in the case of mineralization, which indicates a relatively weak connection with uranium. Areas of high correlation with chloride are smaller and, there, distribution does not have any pronounced trend to the south. This may indicate that the chlorides can better explain the general patterns of distribution of uranium, but do not reflect local geochemical anomalies.

Figure 5. Uranium (left), SO_4 (center), and distribution of local correlation (right). Global correlation r=0.45



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Component 2

The second component is largely formed by metals with the highest global correlation of uranium with iron (r=-0.15), and the widest range in local correlation revealed by magnesium (r=-0.34…0.63). In association with uranium, metals exhibit noticeable local correlation in relatively small areas, associating mainly with bedrocks and geochemical anomalies. Another feature of environmental variables in this component group is that the main element is usually accompanied by a constellation of certain metals ('satellites'). Copper has been placed in the first place in this component group, but has the lowest global correlation with uranium (r=-0.07). Iron shows low global correlation (r=-0.15), but the local correlation spans from r=-0.40 to r=0.49 (Figure 6). Iron shows moderate to high correlation with uranium in the Black Sea Lowland, which may be related to iron ore deposits in the Ukrainian Crystalline Shield.

Elevated concentration of iron in Northern Ukraine (Polesye) can be associated with large wetland areas. Swamp waters are rich with iron and other microelements. The correlation between the iron and uranium here depends on the type of wetland. In Southern Ukraine, areas of increased concentration of iron and accompanying uranium are likely impacted by iron ore mining and processing industry of the Kryvyi Rih iron ore basin. This area has a significant number of registered cancer patients (in the town of Yellow Waters in particular) (Bagriy et. al., 2005). Concentration of iron in the mountain rivers of the Crimea is low (0.00-0.05 mg/dm^3), increasing to 0.6 mg/dm^3 during the floods. This can also indicate the impact of karst.

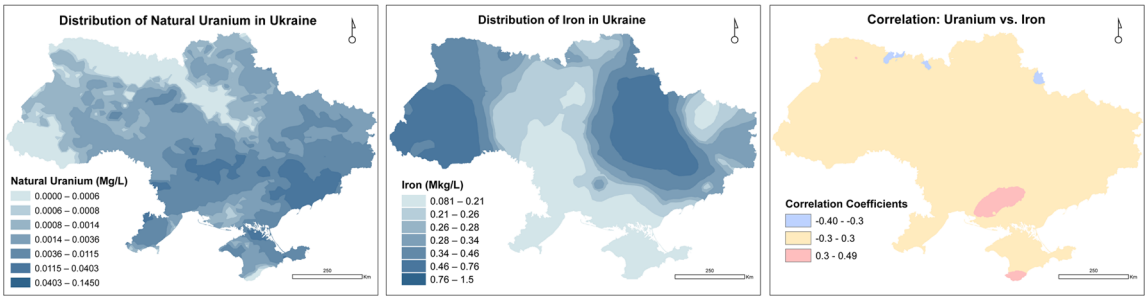
Similar patterns were observed for copper and zinc.

Magnesium shows strong correlation with uranium only in the southern part of Ukraine, with the maximum value r=0.63 (Figure 7). This clustered pattern might be associated with the proximity of the sea, and as a predictor, magnesium can be taken into account only in the Black Sea province.

Component 3

Among the natural variables of the second largest component, precipitation and temperature play important roles, but are highly correlated between themselves. Temperature shows the highest global correlation coefficient (r=0.51), and displays distribution with the highest values in local correlation (r=-0.52…0.53). Temperature is highly correlated with uranium in the southeast areas (Figure 8).

Figure 6. Uranium (left), iron (center), and distribution of local correlation (right). Global correlation r=-0.15



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 7. Uranium (left), magnesium (center), and distribution of local correlation (right). Global correlation r=0.12

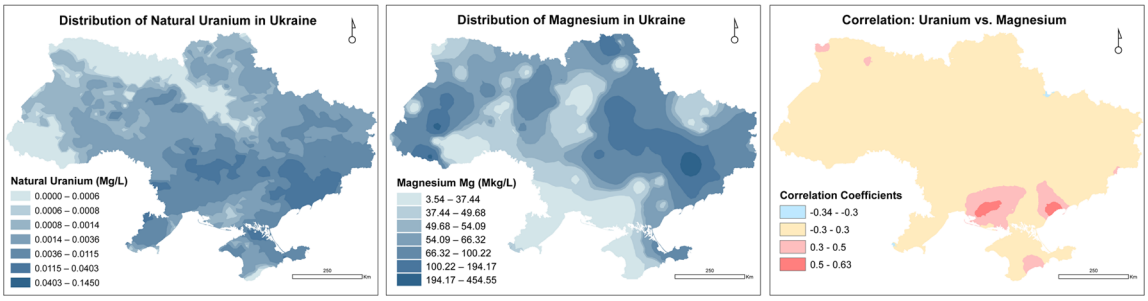


Figure 8. Uranium (left), temperature (center), and distribution of local correlation (right). Global correlation r=0.51

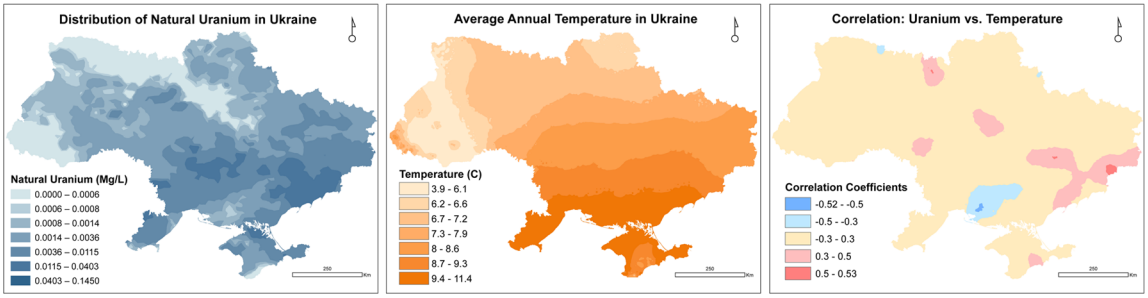


Correlation of uranium with temperature has a clearly distinguishable zonal pattern stretching along the Dnieper River. On the one hand, the Dnieper affects the microclimate in the surrounding regions; on the other, it accumulates uranium from surface and groundwater runoff in the entire river basin.

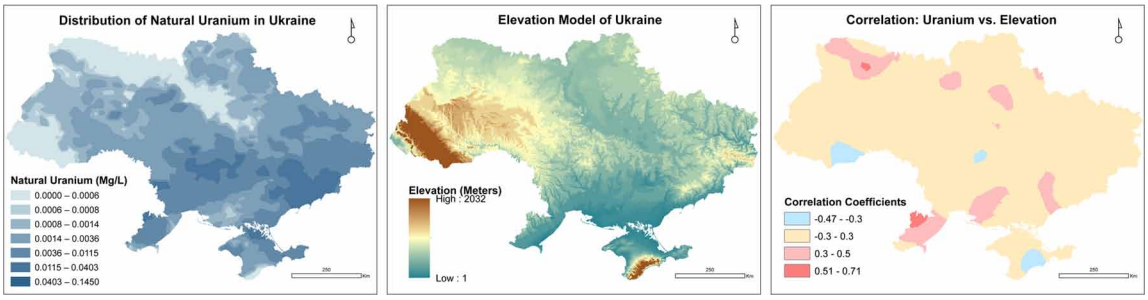
Significant correlation between air temperature and uranium in the southeastern region corresponds to arrangement of watersheds in the Azov Sea basin. Air temperature and evaporation increases from north to south, while the tendency for average annual rainfall is the opposite. Reduced rainfall with an increased amount of groundwater in areas of elevated concentration of uranium can indicate the "depth" of groundwater.

Precipitation is characterized by a positive correlation in the north and northwest, with the predominance of negative relationships in the center, where associations between the concentration of uranium and geological factors are stronger and the relationships with climate are weaker.

Geomorphological factors have low global correlation coefficients, but could be well used to predict phenomenon at the local level. Local correlation coefficients range from -0.47 to 0.71 for relief (Figure 9), and from -0.71 to 0.42 for isopachs (thickness of sedimentary rocks). Determining factors in this case are the associations of convex landforms in central Ukraine, with granite foundations and folding structures, as well as lower heights in Polesie, where uranium concentrations are minimal. This pattern is not observed for the young mountain systems (the Carpathian and Crimean Mountains). The same problem exists for analysis of the depth of bedrock under sedimentary layers, where the association of uranium with granitic rocks is not always evident.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 9. Uranium (left), relief (center), and their local correlation (right). Global correlation r=-0.24



Component 4

The fourth component comprises a group of organic compounds, accompanied by chromium which exhibits the maximum global correlation with uranium in this group (r=-0.39, Figure 10), with the local correlation spanning from r=-0.54 to r=0.45.

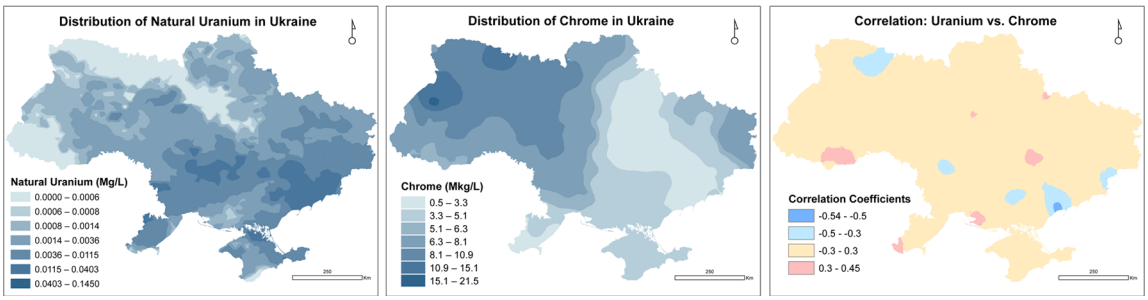
The fourth component may reflect processes specific to surface waters, in particular, the oxygen regime. NH_4 is unstable in oxidizing conditions, as the oxygen and bacteria force ammonium to oxidize in nitrite and nitrates as follows:

NH_4 + oxygen + water = nitrites

Nitrite + oxygen = nitrates

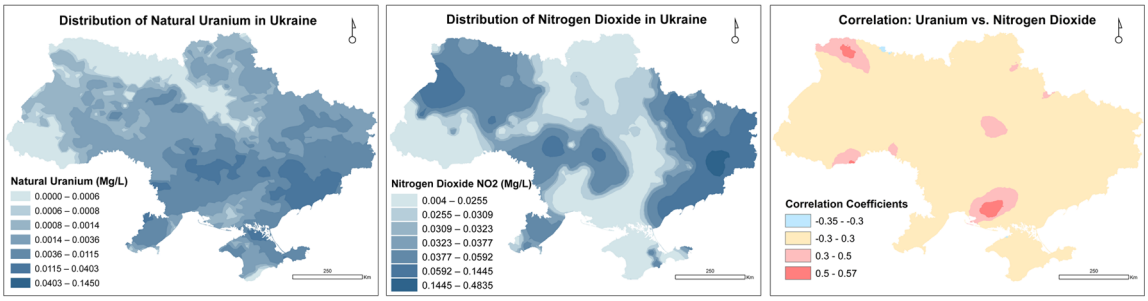
Deficiency of oxygen causes a reversible process of denitrification. While NH_4 is the first element in this component group, it shows the lowest global correlation with uranium (r=-0.12). At the same time, the relationships of uranium with NO_2 are stronger with global correlation r=0.29 and local correlation coefficients ranging from r=-0.35 to r=0.57 (Figure 11). Such relations can be explained by the composition of elements in water and geochemical characteristics of migration of metals in water. It has been found that nitrogen oxide bonds stand out from the rest of the environmental variables in this component group. The nitrogen oxide group is also associated with anthropogenic pollutants such as sewage or agricultural fertilization.

Figure 10. Uranium (left), Cr (center), and distribution of local correlation (right). Global correlation r=-0.39



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 11. Uranium (left), NO_2 (center), and distribution of local correlation (right). Global correlation r=0.29



Component 5

As discussed above, geomorphological factors can be well used to predict phenomenon at the local level. Global correlation of uranium with isopachs on the global level is weak (r=0.02), but local coefficients of correlation range from -0.71 up to 0.42 indicating very strong associations with uranium (Figure 12).

Humus, a product of climate and biota, creates a specific environment for migration of chemical elements. Concentrations of humus reflect general trends of distribution of uranium and explains some particular characteristics of distribution (Figure 13). Accumulation of humus is associated with absorption of uranium compounds, and a decrease in concentration of humus is observed in areas with high migration of chemical elements.

Component 6

The last component is formed by bicarbonate, fluoride, and arsenic. Bicarbonate is at the top in this group, but has the lowest global correlation with uranium. Fluoride and bicarbonate correlate with uranium with global coefficients r=0.35 and r=0.16 respectively, and show relatively high local correlation with uranium (-0.34…0.72 for fluoride, and -0.22…0.66 for bicarbonate). Geographically, local correlation of uranium with fluoride is clustered in the Crimea and the Poltava region (Figure 14), while bicarbon-

Figure 12. Uranium (left), isopachs (center), and their correlation (right). This is an example of low global correlation (r=0.02) with high values in local variations (r=-0.71, blue, and r=0.42, red)

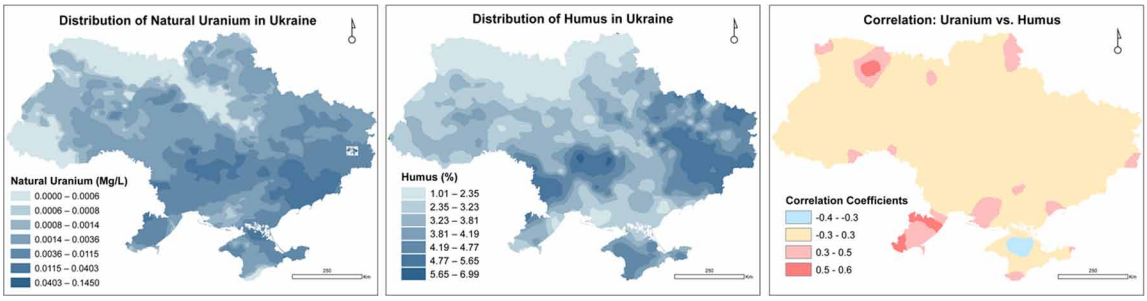
Figure 13. Uranium (left), humus (center), and distribution of local correlation (right). Global correlation r=0.52



ate is highly correlated with uranium in Western Ukraine. Arsenic has relatively low global correlation (r=0.23) and relatively high values of local correlation (from r=-0.28 to r=0.48), which can be explained by geochemical anomalies in relationships between the two elements.

Global and Local Spatial Multiple Regressions and Autoregressive Models

While correlation and factor analyses allowed for identification of significant environmental variables which impact the distribution of uranium in ground waters in Ukraine, contributions of each factor can be better understood by carrying out a multiple regression analysis. The main steps for analysis were: selection of indicators for multiple regression, assessment of their relevance and contribution to the distribution of uranium, and calculation of parameters of regression. Table 3 outlines environmental variables chosen as predictors for building several multiple linear regression models. A summary of multiple regression models is provided in Table 4 and graphically illustrated in Figure 15.

Regression residuals of global multiple regression were tested for spatial autocorrelation. A Moran's I index = 0.4182 on the residuals indicates significant autocorrelation. Spatial autocorrelation among residuals could imply the presence of nonlinear relations between the dependent and independent variables, the omission of one or more regressors, and/or that the regression model should have an autoregressive structure (Cliff & Ord, 1973). Action needs to be taken, e.g., use of spatial local multiple regression or autoregressive models, etc.

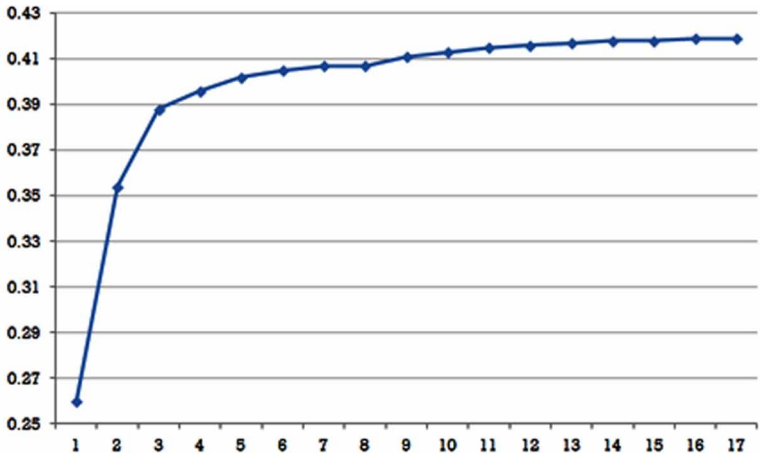
A global linear regression model has been used to describe the contributions of several environmental variables on spatial distribution of uranium in ground waters. Calculation of global regression was followed by spatial local multiple regression or GWR.

Fifteen multiple regression models were built incrementally using predictors outlined in Table 4. The first five most significant predictors (precipitation, humus, water hardness, F, and Fe) contribute 40.2% to the overall model. Examination of individual and cumulative contributions of environmental variables is provided below.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

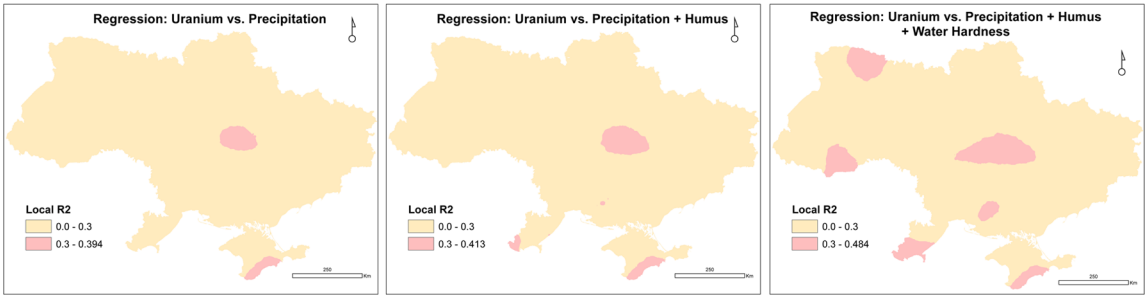
Figure 15. Global multiple regression model summary, R-square vs. model



Analysis of environmental relationships indicates that the most significant environmental variable is precipitation. The second most significant predicting variable is humus content in the top soil. Although this indicator is not a major factor in determining the distribution of uranium, it has a high degree of association to conditions of the geochemical migration of uranium. Soil is a product of interaction of all components of the environment, and has a direct relationship with underlying rocks, mineral composition, climate, and biota. As a result, the humus content in the soil reflects climate and geochemical characteristics of the migration of chemical elements, including uranium. Local r-square coefficients for multiple regression model, built only on the precipitation variable, are shown in Figure 16, left. Adding the humus component and then hardness of water improves the model (Figure 16, center and right correspondingly).

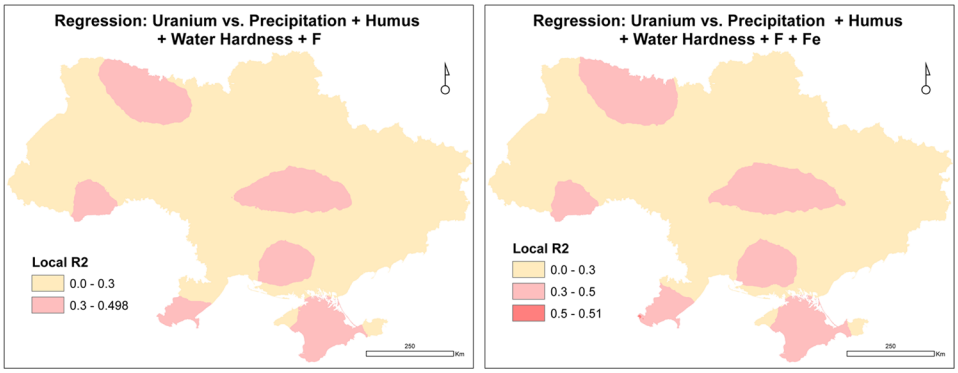
Fluorine (F), iron (Fe), and arsenic (As) add only 1.7% to the variability of the data, but still contribute to the cumulative regression model (Figure 17). None of the rest of environmental variables contributed more than 0.2% in the final model, which indicates their very low impact on the total distribution of uranium. This can be partially explained by the fact that many of these variables depend on each other, and thus, are highly correlated.

Figure 16. Local R^2-square coefficients for geographically weighted regression models: precipitation (left), precipitation + humus (center), precipitation + humus + water hardness (right)



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 17. Local R^2-square coefficients for geographically weighted regression models: precipitation + humus + water hardness + F (left); precipitation + humus + water hardness + F + Fe (right)



Overall R^2-square of the six explanatory variables from the GWR model reaches 0.5997. The improved performance of GWR over the global regression models was demonstrated by significantly higher values of R^2-square.

Geographical analysis of the results of local multiple regression indicate that the impact of precipitation and humus on distribution of uranium is mostly noticeable in the southern areas of Ukraine. Inclusion of hardness of water in the model spreads the relationship in the center and northwest. Adding one more variable (F) improves the model and extends it to the central part of the Ukrainian Crystalline Shield and in the southwest. Multiple regression with all six factors strengthens the model, especially in the south and northwest. The local correlation achieved r=0.51, which confirms that the inclusion of all six indicators in the model was sensible. It is also worth mentioning that several variables have shown high local correlation in the spatial multiple regression model. In particular, fluoride and magnesium have a high degree of correlation with uranium in the south of Ukraine.

Results from the models which include both the spatial lag and error term reveal that the spatial lag coefficients are significantly different from zero. The spatial lag model with maximum likelihood estimation produces R-squared of 0.6079, and the spatial error model with maximum likelihood estimation produces R-squared of 0.6054. These results provide strong evidence that spatial correlation exists in uranium distribution. Based on the AIC and R-squared, all of the autoregressive models are preferred to the OLS specification. The spatial lag model that utilizes the distance weights matrix provides the best fit of the data (see Figure 18). Spatial correlation in uranium distribution may be best modeled using a spatial lag. Moran's I index on the residuals from the autoregressive models still indicates significant autocorrelation. However, Moran's I index on the residuals is lower compared to the OLS residuals and equals 0.2013 for the lag model.

Combining geological, geochemical, and climatic factors allows for creation of spatial distribution models which describe associations with uranium as well as identify areas with potentially problematic groundwater quality. The model indicates a high level of uranium in groundwater in central and southeast areas of Ukraine, where historically, there is a high density of population and low supply of drinking water.

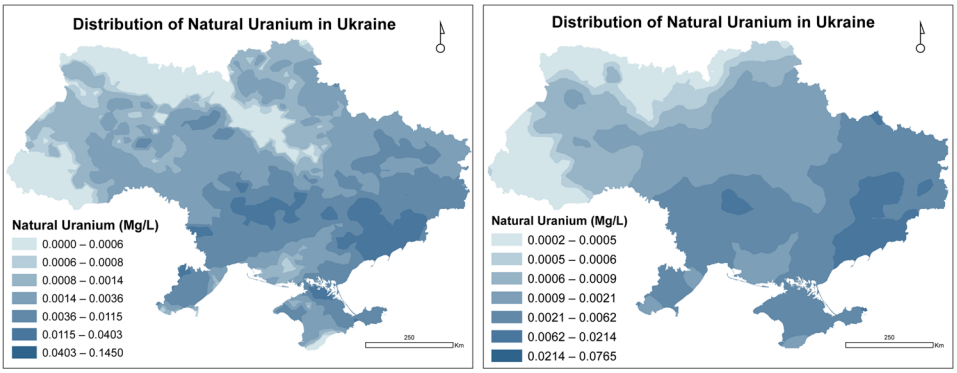
Figure 18. Distribution of natural uranium in Ukraine: source data (left) and prediction map from the lag model (right)



Multiple Regressions Based on Principal Components

Multiple regression analysis in the previous section was based on selection of the most significant environmental variables (predictors), and consecutively adding those individual predictors to incrementally improve the model. An alternative approach is to build the models using principal components. In this approach, all variables constituting the first group of principle components (Component 1, Table 1) are used to create the first multiple regression model. The model is further improved by adding all elements forming the second groups (Component 2). The final regression model will constitute all six principal components (Figure 19). Figure 20 illustrates successive steps in building the multiple regression models using principal components.

Overall R^2-square of the six factors used as explanatory variables from the GWR model reaches 0.5683. Comparison of two multiple regression models based on six principal components and six individual environmental indicators shows that, in general, both models indicate similar associations with the distribution of uranium in groundwater. However, the maximum coefficient of local correlation for the model, based on the principal components, is only 0.48, while the same correlation for the latter model is 0.51. This indicates that the zones of high regression are identified objectively, and the model of the five environmental variables shows stronger local associations compared to the component model which takes into account all studied indicators.

SOLUTIONS AND RECOMMENDATIONS

Several spatial statistics and cartographic visualization methods were used in this study to explore spatial distribution of uranium in groundwater in Ukraine. There is a general trend toward an increase in the concentration of uranium from the northwest to the southeast. Factor analysis reveals six principal components and several environmental variables which describe major factors influencing the distribution of uranium in Ukraine. These components, which often accompany uranium, include total mineralization of water, climatic conditions, metals, anions nitrate and phosphate, geomorphology of terrain, and chemical elements. The model explains nearly 72.5% of the variability in the original 23 independent variables.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

The multiple global regression model defines eighteen environmental variables that describe 42% of the variability of the data. The first six most significant predictors (precipitation, humus, water hardness, F, Fe, and As) contribute 40.5% to the overall model. Local spatial correlation and multiple regression analyses show significant spatial differentiation of factors influencing distribution of uranium.

The use of local correlation improves assessment of relationships between environmental variables. Local multiple regression was used to estimate the contribution of individual environmental variables in the resulting concentrations of uranium. The GWR model with six explanatory variables explained 59.97% of variability in the data, and GWR model with six factors used as explanatory variables described 56.83% of variability in the data. However, an autoregressive model yielded better results, with the spatial lag model explaining nearly 60.79% of the variability in the main six independent variables.

The study reconfirms a strong association between climate and distribution of uranium in groundwater. Local correlation reaches 0.55 in the central and southeastern part of Ukraine. Over the past century, there has been a clear tendency of change in the climate conditions in Ukraine. The average annual temperature in the central and northeastern part has increased by 1°C, and precipitation exhibits 110% of the climatological norm in the southeast territories. This may trigger certain alterations in geochemical processes in the landscape, which may have an impact on the concentration of uranium in groundwater. The main consequences can be an increase in the number of uranium-containing compounds in the forest-steppe zone and expansion of the areas of high concentration of uranium in the southeastern part of Ukraine.

CONCLUSION AND FUTURE RESEARCH

The chapter demonstrates the use of a combination of different modeling techniques to better understand large-scale distributions of environmental indicators (such as uranium) by exploring spatial associations and patterns of associated natural variables and predictors. The methods presented in this study (global vs. local for regression and factor analysis) do not always provide overly objective ground for making conclusive inferences, and outcomes from different models sometimes do not match. For example, some explanatory variables have low correlation with the dependent variable, but at the same time have a high percentage of explained variance in factor analysis. Global regression modeling in a large-scale spatial analysis can be unsuitable for the local inference.

Spatial autoregressive modeling and local multiple regression can be successfully used for prediction of uranium concentration in different scenarios for changing climatic conditions in different parts of Ukraine and other territories. One intriguing association discovered from the modeling is the relationship between uranium and climatic variables. Concentration of uranium has strong local correlation with precipitation, temperature, and humus. Precipitation and humus are the first two variables in the regression models for uranium. At the same time, precipitation has very high correlation with temperature ($r=-0.825$). Variation in temperature and precipitation due to global climate change can alter their contributions to the uranium content. Those scenarios can be explored using the proposed spatial regression models. It is necessary to emphasize that the modeling results presented in this chapter, including their cartographic representations, remain mainly descriptive and require detailed analysis and interpretation by experts from various environmental disciplines.

Further research is envisioned to refine relationships among environmental indicators and improve numerical forecasts by expanding the range of applied spatial statistical methods. Study is planned to explore spatial-clustering techniques to improve the robustness of the developed statistical model.

KEY TERMS AND DEFINITIONS

Environmental Mapping: Field of cartographic sciences dedicated to mapping environmental processes and phenomena.

Exploratory Spatial Data Analysis (ESDA): Statistical techniques used for initial data analysis, such those used for checking statistical distribution, linearity, multicollinearity, etc. Based on results of an ESDA, initial hypotheses and further statistical data exploration can be developed, for example, by carrying out correlation, regression, and factor analyses.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Factor Analysis: Statistical methods which reduce a set of source variables to a smaller number of new variables, where each new variable is a function of one or more of the original variables.

Geographically Weighted Analysis: Statistical methods used when geographic location of an observed characteristic is one of the key factors; often used to define local spatial variation in relationships between data.

Geographically Weighted Factor Analysis: Spatial statistical method that uses factor analysis (for example, PCA) to estimate principal local factors in location of each observation.

Geographically Weighted Regression (GWR) Analysis: Spatial statistical method used as a regression technique to estimate a local regression in the location of each observation.

Geovisualization: Computer-based methods for mapping and visual presentation of geographical and social phenomena; evolved from classical cartography and can be used to visualize static two- and three-dimensional phenomena, as well as dynamically changing processes.

Multivariate Regression: A statistical method where a set of independent variables is used to explain a single dependent variable; offers a logical extension to the simple, two-variable regression procedure.

Principal Component Analysis (PCA): Mathematical method which transforms a number of variables (possible correlated) into a number of uncorrelated variables called principal components.

Spatial Autocorrelation: Correlation between observations of a variable separated in space; takes into account distances (and/or directions) between sample points. Spatial autocorrelation can be described by "the first law of geography," which states that "everything is related to everything else, but near things are more related than distant things" (Tobler, 1970).

Spatial Correlation: Correlation of geographically distributed data; used to find relationships and dependencies between various geographical objects or environmental characteristics. For example, correlation of certain species of vegetation with a particular type of soil, or the relationship of temperature and relief (elevation).

Spatial Dependence: Spatial phenomenon that occurs when the value of a variable at a point in space is related to its value at nearby points; knowing the value of these points allows us to predict (with some degree of certainty) the value at the chosen point.

Spatial Econometrics: Spatial econometrics is a subfield of econometrics which deals with spatial autocorrelation and spatial structure (spatial heterogeneity) in regression models.

Spatial Heterogeneity: A property of a spatial phenomenon which describes uniformity of characteristics or relationships between geographically distributed variables. Relates to spatial dependence.

Spatial Regression Analysis: Statistical method which, taking into consideration the location of each observation, measures the strength and direction of relationships between a dependent spatial variable and independent spatial variables.

Spatial Statistics: Statistical methods applied to geographically distributed phenomena.

Spatial Structure: The nature of the spatial relationship between points, i.e., how far and in which direction, is the spatial dependence? How does the spatial dependence vary with distance and direction between points?

Uranium in Groundwater: The naturally-distributed concentration of a radioactive element (Uranium) in ground waters, lakes and rivers; one of the key elements defining drinking water quality.

Chapter 50
Supercritical Fluids as a Tool for Green Energy and Chemicals

Maša Knez Hrnčič
University of Maribor, Slovenia

Darija Cör
University of Maribor, Slovenia

Željko Knez
University of Maribor, Slovenia

ABSTRACT

Hydrothermal conversion of biomass is a promising technology for the conversion of biomass into biofuels and biobased chemicals. This chapter is focused on the waste biomass conversion for production of biofuels and chemicals by applying sub- and supercritical fluids. One of the biggest disadvantages in biomass conversion by SCF is the extremely high energy requirement for heating the media above the water critical point (374 °C, 221 bar). The idea behind the recent research is to reduce the operating temperature and energy requirements by processing biomass with water at much higher pressures. The importance of knowledge on behavior of multicomponent systems at elevated pressures and temperatures is underlined. Methods, developed by the authors of this chapter for determination of thermodynamic and transport properties for multicomponent systems of different solid compounds and supercritical fluid under extreme conditions are described. Future perspective of hydrothermal technology as a tool to obtain advanced materials and the possible scope for future research is also discussed.

INTRODUCTION

Large amounts of waste biomass produced offer a great opportunity to convert this volume of plant material and animal waste to a huge amount of energy. The conversion of biomass to biofuels and biobased chemicals has attracted a lot of attention recently, largely due to the environmental and socio-economic problems associated with the use of fossil fuels. In recent time, many novel technologies have been

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

introduced for conversion of biomass to energy and chemicals. Biomass can be converted to energy by biochemical and thermochemical processes. The two main thermochemical conversion processes to produce biofuel from biomass are the pyrolysis process and the hydrothermal process as promising technologies for the conversion of biomass into biofuels and biobased chemicals. In recent years, hydrothermal energy was accepted as a possible energy resource with a high potential already in the beginning of the previous century. Hydrothermal conversion of biomass has consequently attracted considerable attention. This chapter will therefore focus on the waste biomass conversion for production of biofuels (liquid or gaseous) and biochemicals (furfurals, organic acids, aldehydes, ketones) by applying sub- and supercritical fluids at pressures up to 1000 bar. Operating at high pressures may result in processes that require much lower amounts of energy and maybe also in new processes which are capable of performing new types of reactions that produce completely new bio-based products.

The production of value-added products from waste biomass, such as waste from agriculture, food or forestry industry, will be mostly considered. A topic of the intense research is to reduce the operating temperature and energy requirements by processing biomass with water at much higher pressures or adding supercritical CO_2 to the reaction mixture. Nevertheless, biomass conversion processes at high-temperature and pressures exceeding 300 bar are, for now, a completely new aspect of high-pressure technology for biomass conversion and literature regarding the reactions taking place in such systems practically does not exist. There are also several advantages of supercritical fluid processing under "real" high pressure like new product formulations and economic production of high value products due to the fact that the solubility of several dense gases in low soluble substances increases with increasing pressure and temperature. Most of the commercial supercritical water processes today are limited to pressures, where the complete solubility of water and CO_2 is not achievable. By elevating pressure, the total miscibility of water and CO_2 is already achieved at considerably lower temperatures. Another possibility is lowering the energy barrier by the addition of catalysts. Such treatment of biomass would be a completely new process. However, the data on the mechanisms and kinetics of reactions are scarce. Additionally, the total yields of the final products are practically unknown for these unconventionally high-pressures and temperatures for the multi-component systems.

Considering the above mentioned facts, it is highly important to investigate how of water and CO_2 in such a system would affect the biomass conversion reactions and what products would form, how different ratios and conditions affect the conversion and if it is possible to perform the reactions that normally occur above critical point at milder conditions. This knowledge will open completely new possibilities in biomass conversion, which could also lead to new types of reactions and products. Fundamental data obtained from such research could therefore revolutionize the concept of biomass conversion facilities or could open routes to completely new types of process intensification. Limitations of processes operating at the mentioned high temperatures and unconventionally high pressures are their investment costs that are significantly higher compared to ambient pressure technologies. Nevertheless, many recent studies have suggested that classical large-scale reactors needed for biomass conversion are maybe not necessary for processes involving supercritical water as reaction medium. It has been proven, that reaction kinetics of near-critical water and supercritical water with organic compounds are extremely fast and that long contact times should therefore be avoided.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

BACKGROUND

The ability to produce solvent-free products and handle high viscous materials makes the SCFs technologies unique. Such novel technologies are emerging, for instance for particle design, sterilization, and separation of enantiomers (Brunner, 2005). Particulate products with the desired characteristics can be obtained (Kiran, 1994). The development of a process technology comprises the application of fundamentals to processes and has been a topic of an intense research in the past decades (Brennecke & Eckert, 1989; de Swaan Arons & Diepen, 1963).

Phase equilibria and reaction kinetics, the verification of process steps, as for example in specific reactors, and the design of process sequences to produce a product (energy) from raw materials are the main hindrances concerning the SCF applications. Some important bioconversions have decreased interest today, but other conversions gain interest or will gain interest, so that the fundamentals will somehow have to find its way. Detailed investigations on the basic thermodynamical and transport data like phase equilibria, density, viscosity, dielectric constant and diffusion coefficient have to be carried out to obtain the data fundamental for the design of a process in order to fulfil consumer and economic requirements (Brunner, 2015). Supercritical fluids have been widely applied in several processes developed to the commercial scale; – from pharmacy, food sciences to the textile industry, but however, pilot plant and industrial scale applications in the field of energy are still in its infancy. Solubility of the substance in SC or SubC fluid is the main parameter controlling the feasibility of the process. Determination of solubility of several compounds in SCFs is already reported in scientific literature. However, contributions reporting phase equilibria of systems with CO_2 are offered in particular (Fonseca, Dohrn, & Peper, 2011). Knowledge about phase equilibria and thermodynamic data is essential to design a process with a well-considered union between economic feasibility and safety.

A wide literature review showed that different authors suggest various, mainly well-established methods, to investigate thermodynamic data of binary systems of substances in presence of SCF (Aionicesei, Škerget, & Knez, 2008; Corma, García, & Leyva, 2005; Dindar & Kiran, 2002; Gourgouillon, Avelino, Fareleira, & Da Ponte, 1998; Gutiérrez, Rodríguez, Gracia, De Lucas, & García, 2013; Markočič, Škerget, & Knez, 2011; Mukherjee, Bhattacharyya, & Bagchi, 2002; Pantoula & Panayiotou, 2006). Those methods are either time consuming or require expensive, advanced equipment. Additionally, most of the methods may only be used for pure compounds, and may not be adopted to the diversity of the systems occurring in industry that include materials of a complex composition like biomass, bio oils, etc. There are only few articles dealing with the development of new methods (Calvignac, Rodier, Letourneau, Almeida dos Santos, & Fages, 2010; Calvignac, et al., 2010; Elvassore, Vezzù, & Bertucco, 2005; Knez Hrnčič, Markočič, Trupej, Škerget, & Knez, 2014). Solubility data, density, viscosity, dielectric constant, diffusion coefficient and interfacial tension certainly play a key role in a design of an efficient fractionation process of components of pyrolysis oil that are a product of fast pyrolysis or liquefaction of biomass and are dark brown organic liquids, which are chemically a complex mixture and/or emulsion of water and degradation products of lignin. and also open the innovative routes to completely new types of process intensification.

MAIN FOCUS OF THE CHAPTER

Issues, Controversies, Problems: Environmental Issues Relating Energy Consumption

The importance of the problem regrading environmental issues reflects also in the field of science popularization. Several conferences are organized worldwide. United Nations Conference on Climate Change was organized in France in the beginning of December 2015. Energy demand is still increasing and the use of fossil fuels still remains the principle energy source which may lead to uncontrolled net global warming and to an increased number of extreme climate events (Paris COP21, 2015).

In the past SCFs were used mainly as solvents in extraction processes such as decaffeination of coffee and tea, spices extraction, extraction of antioxidants from (Knez, Škerget, & Knez Hrňič, 2010), oil from seeds etc..., however in recent time technologies using SCFs as a processing media received new challenges. SCFs present a promising new alternative as a media for biomass conversion to green chemicals and energy. Currently over 80% of energy demand is still met by fossil fuels (oil, gas and coal) but these resources are finite. Beside the impact on the environment, the price of crude oil is fluctuating. However, fossil fuels are still the main source of energy and chemicals. Research on alternative sources of chemicals and fuel and production technologies has therefore attracted a great deal of attention (Barnes, 2015). Several investigations are recently performed in the field of supercritical fluids as a tool for energy production (Brunner, 2015). Biomass conversion processes applying sub- critical water and supercritical water are promising basis for processing of various intermediates to be used for energy and chemical purposes. Water as a reaction media opens new possibilities compared to "dry processes", allowing lower reaction temperatures.

From Sustainable Energy Resources to Energy and Fuel

Nowadays, there is a growing interest in the development of alternative technological processes with minimized environmental impact, such as reduced energy consumption, less toxic residues, better use of by-products and also better quality and safety of the final products (Knez et al., 2014). Currently, chemicals and energy are mainly derived from fossil fuels, what is challenged by the rapidly declined reserves, fluctuating price of crude oil and impact on the environment. Research on alternative sources of chemicals and fuel and production technologies has therefore attracted a great deal of attention Feng, Cheng, Yuan, Leitch, & Xu, 2013). Biomass energy is derived from distinct organic matter that can re-grow over a relatively short period of time compared with the hundreds of millions of years that it took for fossil fuels to form (Kullaiah Byrappa & Masahiro Yoshimura, 2013). Much effort is therefore oriented to the utilization of waste biomass for production of energy and chemicals. Figure 1 presents hierarchy of waste management as advised by the European Union (Wasteshipment, 2016). Residues produced by the agricultural and food industries contain valuable functionalized molecules such as flavonoids, waxes, biopolymers or fatty acids. Food supply chain waste has a high potential to be utilized as a feedstock for electricity generation (i.e. through anaerobic digestion), fuel generation (i.e. conversion of cellulosic biomass to bioethanol) or the production of animal feed (Pfaltzgraff, Cooper, Budarin, & Clark, 2013). Waste biomass and biomass of nature and agricultural cultivation are valuable organic reservoirs of raw materials and must be used in accordance with their organic composition (Kamm, Gruber, & Kamm, 2007).

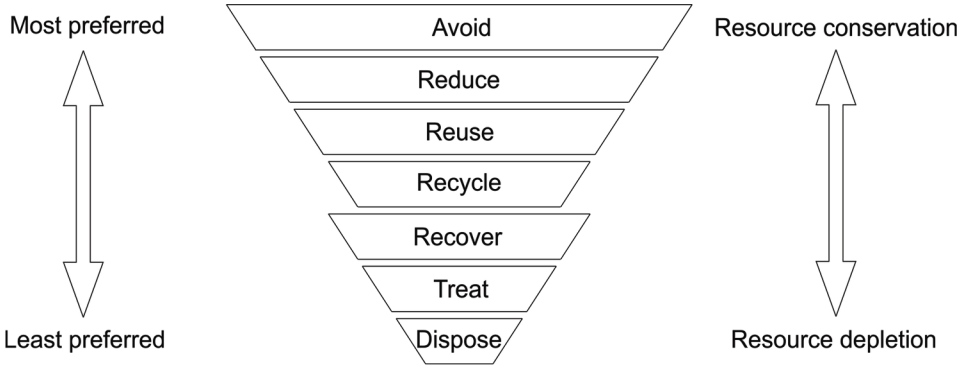
Figure 1. Hierarchy of waste management as advised by the European Union
Wasteshipment, 2016.



Anyhow, harvesting biomass to produce energy may result in reduced soil productivity by depletion of carbon and nutrients and may therefore not be sustainable (Woolf, Amonette, Street-Perrott, Lehmann, & Joseph, 2010). By biomass pyrolysis waste products may be utilized (Woolf et al., 2010).

The vital difference between biomass and fossil fuels as energy sources is the time scale. If it is managed on a sustainable basis, biomass is harvested as part of constantly replenished plants or crops in which the new growth in the re-plantation takes up CO_2 from the atmosphere at the same time as it is released by an energy conversion process (e.g. combustion) of the previous harvest. This maintains a closed carbon cycle with no net increase in atmospheric CO_2 levels, in contrast to that of fossil fuels, and therefore biomass is considered as a renewable energy resource. The large amounts of waste biomass, which is a renewable resource, cause serious problems when not being processed, which is a severe problem facing especially the countries of the third world that do not have strong regulatory instruments to control the environmental challenges.

Biofuels are liquid or gaseous fuels that are predominantly produced from biomass for transport sector applications. As biofuels are renewable, sustainable, carbon neutral and environmentally benign, they have been proposed as promising alternative fuels for gasoline and diesel engines (Hoogwijk et al., 2003). For different biomass types as a renewable resource there are a number of conversion technologies available (Cartmell et al., 2006). Primarily, the options are divided into two groups, namely thermal and chemical conversion. In general, the conversion technologies may release the energy directly, in the form of heat or electricity, or may be converted to another form, such as liquid biofuel (bioethanol, biodiesel), combustible biogas (H_2, CH_4) or charcoal-like solids (biochar). While for some classes of biomass resources there may be a number of usage options, for others there may only be one appropriate technology (Cabeza et al., 2015). Optimization of biomass supply chains could help in commercializing this sustainable energy source by reducing costs (Shabani, Akhtari, & Sowlati, 2013).

Conversion of Waste Biomass to Energy

Nevertheless, biomass derived energents have several pros and cons. Besides, several obstacles that have to be overcome to convert waste biomass to biomass fuels. Finding new methods to convert biomass energy resources to usable energy resources is inevitable (Mazaheri, Lee, Bhatia, & Mohamed, 2010; Van Bennekom et al., 2009) since there are several issues, such as some technical challenges, facing

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

biodiesel production via transesterification, which include long residence times, high operating costs and energy consumption and on the other hand low production efficiency. Problems facing biodiesel production have to be solved in order to make the process more efficient and economical. Many efforts are proposed to convert biomass to bio fuel (Kruse, 2011). Green revolution focuses on the development of biodiesel production based on the use of non-catalytic esterification under high pressure and temperature, or with supercritical methanol (Glisic & Skala, 2009; Kesić et al., 2012; Qiu, Liu, & Riffat, 2011). General approach is to process the biomass in an aqueous phase. The specific implementation of this approach of interest is supercritical water gasification (SCWG), which involves the conversion of organic compounds to gaseous products (H_2, CO, CO_2, and CH_4) via reactions in and with water at a temperature and pressure exceeding the thermodynamic critical point ($T_c = 374$ ∘C and $P_c = 221$ bar) and therefore knowledge about the behavior of these gases with liquid products, obtained by fast pyrolysis of biomass under different conditions of temperature and pressure is essential in designing the separation processes following the conversion reactions. Figure 2 presents phase diagram of water with area of application for hydrothermal treatment. HT pretreatment could not only improve the mechanical dewatering of parent materials, but also the fuel quality, such as the carbon content and energy density (Zhao, Shen, Ge, Chen, & Yoshikawa, 2014). Anyhow, heating value of biomass depends on its composition. For instance, dry woody biomass consists of cellulose, hemicelluloses, lignin and ash. Its heating value can therefore be estimated from the heating value and weight fraction of each constituent.

Overview of High Pressure Processes for Biomass Treatment

Several applications have been proposed in the past years using hot compressed water as a reaction media, e.g. destruction of hazardous materials, synthesis of inorganic and organic materials, recovery of valuables from wastes recycling of polymers and energy recovery of biomass (Cabeza et al., 2015; Jain, Balasubramanian, & Srinivasan, 2016). There are certain drawbacks regarding utilization of waste bio-

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

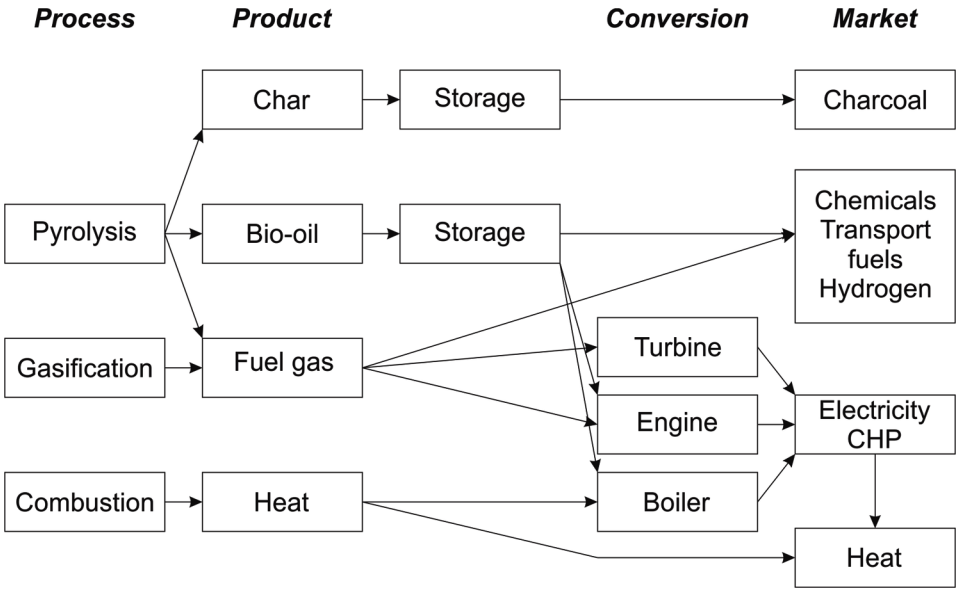
mass materials and forestry residues as sources of energy due to their uneven and troublesome properties and characteristics. Several beneficiation technologies which basically improve the physical and thermal characteristics of the original biomass materials by changing shape, size, size, distribution, density, water content, etc. Amongst these processes, the most important are: sizing and shaping, separation, drying, dewatering, densification (Baling, Pelletization and Briquetting) and torrefaction (Sugathapala, 2013). In many situations, more than one of the above types is required.

Generally, HT processes could be divided into four main processes, as demonstrated in Figure 3: carbonization (HTC), aqueous phase reforming (APR), liquefaction (HTL), and gasification (HTG).

An ancillary advantage of the uncongenially high processing conditions is that product streams are completely sterilized with respect to any possible pathogens including biotoxins, bacteria or viruses (Peterson et al., 2008). Hydrothermal carbonization is normally carried out at moderate conditions (250°C and 20 bar) "Hydro char" as the main product can be generated at even higher temperatures (250-800°C) based on wet pyrolysis. Reaction was tested with several types of biomass (Kruse, Funke, & Titirici, 2013; Liu, Quek, Kent Hoekman, & Balasubramanian, 2013; Titirici, Thomas, & Antonietti, 2007). When performing the process under moderate temperature, reaction rate is lower, normally it takes some hours. However, when applying high temperature, the reactive gasses are produced parallel with other pyrolysis products (bio-oils) resulting in interesting carbon structures like: nanotubes, films, microspheres, advance carbon materials.

The most widely investigated hydrothermal reaction over the past decade has been hydrothermal liquefaction involving conversion of waste biomass into chemicals and biofuels under medium temperature and high pressure (280-370°C, 100-250 bar). Water should be kept in a liquid state. The main product is water-insoluble bio-oil (called also bio-crude) with small quantities of water soluble products like char (solid residue) and light gases (e.g. H_2, CO, CO_2, CH_4). Both, liquefaction and gasification can be minimized at a comparably low temperatures ranging from 160 to 250 °C in order to increase the yield

Figure 3. Applications of biomass thermochemical conversion processes
Kamm et al., 2007.



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

of solid biofuel (Huber, Iborra, & Corma, 2006). Produced fuel has a high C/H ratio beside a higher stability and energy content. Various types of biomass have been subjected to the conversion concept, e.g., agricultural residues (Toor, Rosendahl, & Rudolf, 2011), forest residues as well as sewage sludge (Akizuki, Fujii, Hayashi, & Oshima, 2014). Three main types of supercritical water gasification are reported, depending on the temperature range: catalyzed near-critical gasification to methane and aqueous phase reforming (Pavlovič, Knez, & Škerget, 2013).Catalyzed near-critical gasification is conducted under lower near critical temperature range at 300-500°C with addition of heterogeneous catalysts, which is increase selectivity to CH_4-rich gas product and carbon dioxide (Devi, Ptasinski, & Janssen, 2003; Yoshida, Oshima, & Matsumura, 2004). The reaction mechanisms are intensively investigated for different catalysts. Pt-based catalysts exhibit high H_2 selectivity but low conversion of the alcohols. Ni-based catalysts exhibit high activity and conversion but low H_2 selectivity and yield (Chen, Li, Chen & Yan, 2015). The reaction takes place at relatively mild reaction conditions within temperature 220-250°C and pressures typical of 15-50 bar. One of the most important factors of an economic analysis is the expected cost of the end product or products and the total energy efficiency of waste biomass conversion process with SCFs.

SOLUTIONS AND RECOMMENDATIONS

Techniques, applying supercritical fluids as a processing media certainly have a high potentiality for future large-scale biofuel production, especially for biodiesel production from waste oil and waste fat due to a number of advantages that include fast kinetics, high fuel production rate, ease of continuous operation and in some cases even elimination of the necessity of catalysts. The sub-chapter presents high pressure processes for treatment of biomass as a perspective concept for production of energy and chemicals as well as emphasizes the importance of fundamental studies of phase equilibria of substances in the presence of supercritical fluids. Main product of hydrothermal liquefaction, which is one of the most investigated process for converting waste biomass into chemicals and biofuels, is water-insoluble bio-oil (called also bio-crude) with small quantities of water soluble products like char (solid residue) and light gases (e.g H_2, CO, CO_2, CH_4). Bio oil, commonly termed as pyrolysis oil, chemically consist of a complex mixture and/or emulsion of water and degradation products of lignin (e.g. guaiacols, catechols, syringols. vanillins), cellulose (such as levoglucosan, dehydrated sugars, di-sugars, furancarboxaldehydes), and hemicellulose (such as acetic acid, formic acid). Their composition varies depending on the type of biomass feedstock and conditions of pyrolysis process. As these free-flowing organic liquids are composed of numerous highly oxygenated components, which are reactive, a suitable way to stabilize the oil (and allowing production of hydrocarbons) should be considered. A possible solution may be in hydrotreating (Venderbosch, Ardiyanti, Wildschut, Oasmaa, & Heeres, 2010). Hydrogenation of bio oil yield products less prone to produce carbon during oxidation process. Water content of the bio-oil may differ considerably. Organic acids form esters with olefins and esters and water with alcohols, aldehydes form oligomers and resins. With water, aldehydes form hydrates. Combination of aldehydes and alcohols is suitable to form hemiacetals, or acetals and water. Products in thermodynamic equilibrium with the reactants are formed, which means that a change in temperature or relative amounts of water and other reactive compounds will upset the equilibrium and initiate compositional changes. Some reactions may form resins or polyolefins and may be irreversible under likely bio-oil storage conditions. Another important issue is air oxidation that tends to form more acids and reactive peroxides that catalyse the

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

polymerization of unsaturated compounds. In a complex, real bio-oil, the number of possible chemical reactions is very high, especially considering the large number of complex oligomers. The reactions between the oligomers are responsible for nearly all the viscosity increases observed during aging of bio-oil (Diebold, 2000).

Several research groups performed experiments and obtained mixtures of gaseous and liquid products. Phase equilibrium data for ternary system bio oil/ diesel/CO_2 and bio oil/tail water/ CO_2 was determined in the frame of our previous research (Knez Hrnčič, Venderbosch, Škerget, & Knez, 2013a). Data for the system H_2/pyrolysis oil and H_2/hydrogenated pyrolysis oil was reported by Knez Hrnčič and co-authors (Knez Hrnčič, Venderbosch, Škerget, Ilić, & Knez, 2013b).

Hydrogen is expected to become an important fuel in the long-term since in combination with fuel cells it offers the opportunity of an intrinsically clean energy supply. Compared with the conventional methods, SCWG process is characterized by its high reaction efficiency and H_2 selectivity. Water plays a role of reaction medium. A high moisture content material can be applied (Wang, Wang, Zhao, Guo, & Guo, 2016). Compared with conventional biomass gasification technologies, supercritical water gasification possesses a number of advantages which are derived from the unique thermodynamic and fluid dynamic properties of water in supercritical state. Dielectric constant of water is besides being a function of temperature, a strong function of pressure. At normal temperature and pressure, dielectric constant of water is relatively large, approximately 80. The main reason the strong effect of hydrogen bond in water. With increasing temperature and pressure, dielectric constant of water decreases and is around 5 at critical point. Several benefits compared to conventional gasification procedures include high thermochemical conversion rate, high pressure products that are easy for future transportation and usage, opportunities for carbon capture, sequestration and storage, as well as to further pure hydrogen production via a further steam-methane reforming process.

During the past two decades, over 100 journal papers have been published regarding different aspects of heterogeneous catalysis in the SCWG process. These studies include both commercial as well as catalysts tailored for gasification in SCW (Wang et al., 2016). A variety of real biomasses including lignocellulosic biomass from different sources, sewage sludge, chicken manure, food wastes, algae, and fermentation residue have been successfully gasified in SCW (Azadi & Farnood, 2011; Matsumura et al., 2005). Performance of a gasification process is generally influenced by operating pressure and temperature, different catalysts and feedstock type and concentration, catalyst and loading, and the contact time between the catalyst and the feed.

Several obstacles are present on the way of scaling-up of a biomass gasification process. High energy requirements are present already in the first step of the process. Water must be heated from ambient to supercritical conditions and above. Another drawback is the highly aggressive nature of water, which is even more evident in combination with an oxidant, leading to corrosion related issues. In addition to the above mentioned drawbacks, salt deposition on the reactor walls as a result of very low solubility of inorganic compounds at supercritical conditions should be considered (Vadillo, Sánchez-Oneto, Portela, & Martínez de la Ossa, 2013). These are the main hindrances that should be removed to enable a wider exploitation of biomass conversion processes applying water in supercritical state on industrial (Kamm et al., 2007). In continuous processes, pumpability of the biomass slurry is a problem. As the dry matter content of the biomass slurry exceeds the pumpability limits, several clogging problems may appear. On the other hand, a high dry matter content contributes to a higher gas production which increases the energy efficiency and the profitability of the plant (Yakaboylu, Harinck, Smit, & de Jong, 2015). A detailed investigation of phase equilibrium for the systems gas/water and gas mixtures/water was carried

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

out to provide the fundamental data for the design and operation of the pilot plant and dissemination of the concept to the industrial scale (Knez Hrnčič, Markočič, Kramberger, & Knez, 2011; Knez Hrnčič et al., 2013b; Kramberger, Markočič, & Knez, 2013; Markočič, Kramberger, van Bennekom, Heeres, Vos, & Knez, 2013). In the frame of the past research on reforming in supercritical water, a unit for the conversion of organic compounds to gaseous products was constructed (Figure 4). The main goal of the research was to increase the content of H_2 and CO and to reduce the hydrocarbon concentration, application of catalysts was proposed. Experimental conditions presented here covered a wide range of reaction temperature and types of catalysts. Reactions were performed at high pressure in the range of temperatures between 100°C and 600°C. Results were interpreted on a common basis in terms of carbon conversion and hydrogen and methane yields. No significant change in the composition of the substrate over the entire range of the investigated conditions has been observed. The possible explanation may be that all the catalyst reacted already with the surface of the reactor even before the reaction took place. There were only small changes in the concentration of the gases, which depended on the working pressure, during the experiments performed at a constant temperature of 750°C.

In Table 1, some applications of gasification as pilot scale and semi-industrial scale processes are summarized. Comparison between hydrothermal liquefaction (HTL), hydrothermal carbonization (HTC) and hydrothermal gasification (HTG) processes in last 5 years is presented in the Table 2.

Reaction mechanisms and kinetics of the process are another issues that have to be addressed. Due to the sufficient heat energy all of the biomass feed, including char, is normally converted to gasification products in a single pass through a gasifier system (Sugathapala, 2013). The overall combustion reaction is taking place in the combustion zone. The air introduced contains, besides oxygen, water vapor and inert gases such as nitrogen and argon. The inert gases are normally assumed to be non-reactive with the fuel constituents. However, the water vapor reacts with the hot carbon according to the heterogeneous water gas reaction ($CO + H_2O \Leftrightarrow CO_2 + H_2$). In the subsequent reaction, CO_2 is reduced to CO according to the Boudouard reaction. Salts, usually in the biomass, act as catalyst/promoter for the water-gas shift reaction, producing up to half of the hydrogen (Kruse, Bernolle, Dahmen, Dinjus, & Maniam, 2010). Another important reaction taking place in the reduction zone is the water shift reaction (Sugathapala, 2013). Instead of a deeper understanding of the reaction paths occurring during gasification, thermody-

Table 1. Applications of the concept as pilot scale and semi-industrial scale processes in the last years

Plant	Brief Description	Reaction Conditions	Presence of Catalyst	Process Type	
woody biomass gasification	A high temperature air-blown gasification scale-up model for woody biomass gasification. The down-flow gasifier was used. In large-scale units, the cold gas has ability to achieve 80% efficiency in the air-blown gasification. The cold gas efficiency was over 80%, and the heating value of the produced gas was 6.6 MJ/ m_N^3 .	Feeding rate 1000 kg/h, input air temperature 427 °C. (Maximum achievable temperature is over 1100 °C the O/C is from 1.26 to 1.84).	-	Continuous	(Kobayashi et al., 2009)
CHP Agnion Biomasse Heizkraftwerk Pfaffenhofen	TRL 4-5 - Laboratory Component Testing - Component Prototype Development Pilot CHP - Combinate heat and power technology The Heatpipe-Reformer developed by agnion is an innovative plant for production of renewable energy. Production of high-quality syngas.	Input: Waste Wood (80,000.000 t/y) Output: syngas (32.500 MWth) power (electricity) (6.100 MWel) at temperatures around 800°C – to form a gas mixture made up of hydrogen and carbon monoxide	-	Continuous	(Bioenergy, 2015)
Skive CHP plant	TRL 9 - Full scale commercial deployment A bubbling fluidized bed (BFB) gasifier is used to produce gas from wood-based biomass. This gas is then used in of reciprocating engines in a combined heat and power (CHP) application.	wood pellets (100.000 t/d) power (electricity) (6.000 MWel) heat (20.000 MWth) pressurized, bubbling fluidized bed, bed material dolomite, operated 850°C	monolith catalysts	Continuous fully automated	(Bioenergy, 2015)
Urbas Calvello	A combustible gas, wood gas, is drawn from wood through a thermochemical processes. The raw gas is then separated of dust and tars through a filtering system. Such cleaned gas is afterward used to produce combined heat and power through a gas engine and generator.	Input: wood output: chips power (electricity) (0.199 MWel)	-	-	(Bioenergy, 2015)
Vaskiluodon Voima Biomass Gasification Plant	The biomass feedstock is dried in a belt dryer and gasified in a large CFB-gasifier. Produces biogas from wood, comprising mainly of forest residue, to generate electricity and provide district heating to the local community.	Input: biomass substituting coal Output: power (electricity) (140.000 MW)	-	Continuous Fully automated	(Bioenergy, 2015)
Synthesis Tembec Chemical Quebec	TRL 6-7 Component Prototype Demonstration-Pilot Plant	Input: spent sulphite liquor feedstock Output: ethanol (13,000.000 t/y)	-	Continuous	(Bioenergy, 2015)
FICFB Oberwart	TRL-9 Full-Scale Commercial Deployment High electrical efficiency (almost 30% with combined gas engine and ORC process) No problematic solid residues (only ash, carbon content) Length of District Heating System ca. 5200 m Temperature District Heating System VL 95°C / RL 65°C	Input: wood chips (8.700 MW) Output: - power (electricity) (2.800 MWel) - heat (4.100 MWth)	-	Continuous	(Bioenergy, 2015)
Synthesis Enerkem Sherbrooke	Pilot plant TRL 4-5 Gasification based process technology that transforms sorted municipal solid waste (MSW) and residues from the forest and agricultural industries into transportation fuels, high value chemicals and electricity. Steps: 1.feedstock pre-treatmant, 2. Gasification, 3. Synthetic gas conditioning, 4. Conversion into liquid fuel	Input: municipal solid waste, wood chips, treated wood, sludge, petroleum coke, spent plastics and wheat straw Output: ethanol (375.000 t/y), methanol (475.000 m^3/y), syngas	-	Continuous	(Bioenergy, 2015)

Plant	Brief Description	Reaction Conditions	Presence of Catalyst	Process Type	
Synthesis Demonstration Plant, Westbury	TRL 6-7 Demonstration Pilot Plant	Input: waste wood, clean wood, saw mill residues (12,000.000 t/y) Output: FT liquids (0.568 m^3/h)	-	Continuous	(Bioenergy, 2015)
CHP Urbas Eberndorf	TRL 9 Full Scale Commercial Power / CHP technology A combustible gas, wood gas, is drawn from wood through thermochemical processes. The raw gas is then separated of dust and tars through a filtering system. Advantage: wood gas cogeneration requires no intermediate medium thus resulting in a higher electrical efficiency throughout the entire system.	Input: waste wood Output: power (electricity) (0.300 MWel)	-	Continuous	(Bioenergy, 2015)
GoBiGas	TRL 6-7 Demonstration Fuel synthesis The gasification technology is based on indirect gasification, which is supllemented by gas upgrading and SNG synthesis.	Input: Wood pellets (6.500 t/h), Forest residues (6.500 t/h) Output: SNG (20.000 MW), heat (5.000 MWth)	-	Continuous	(Bioenergy, 2015)
Holzgasanlage 2 Kaeser Gasel	TRL 9 Full-scale plant commercial Power / CHP technology; CHP gasifier unit with connection to heating device and power.	Input: wood chips (133.000 kg/h) Output: power (electricity) (0.140 MWel), heat (0.240 MWth)	-	Continuous	(Bioenergy, 2015)
BioSynergi CHP demonstration plant	TRL 6-7 Demonstration Pilot Plant Staged Open Core gasifier fuelled with forest wood chips (45-50% moisture on wet basis), as a part of a Internal combustion engine based CHP plant. The annual generation at the plant is expected to be 2,000 MWh electricity and 5,000 MWh heat.	Input: Wood chips Output: power (electricity) (0.300 MWel), heat (0.750 MWth)	-	Continuous	(Bioenergy, 2015)
Holzverstromungsanlage Bucher Escholzmatt	Full-scale Plant includes: feedstock and handling devices with heat and power gasifier unit, connection to district heating and power.	Input: wood chips (4,700.000 m3/y) Output: power (electricity) (0.130 MWel), heat (0.260 MWth)	-	Continuous	(Bioenergy, 2015)
Gasification plant fuelled with olive industry wastes	The energy recovery from olive industry wastes. The pilot plant contains a downdraft gasifier, gas cooling-cleaning stage and spark ignition engine with an adjusted carburettor. Cold gas efficiencies in the range of 70.7–75.5% were reached. The calorific value of the producer gas was 4.8 and 5.4 MJ kg^{-1}. The electric and CHP efficiency: 15% and almost 50%. Phases and main chemical reactions in a downdraft gasifier: Olive oil industry wastes, drying, pyrolysis, combustion, reduction, producer gas.	Operating temperature: 1050–1100 °C Outlet temperature: 400–500 °C Gas caloric value: > 4.5 MJ Nm^{-3}	-	Continuous	(Vera, Jurado, Margaritis, & Grammelis, 2014)
A two stage fluid bed plasma gasification plant	RDF-refused derived fuel from urban solid waste can be converted to clean syngas using conventional Fiber Bragg Grating system (FBG) tied with a plasma converter. Simultaneously converting ash-type components in the RDF into a stable vitrified product. The results show that the slag from the plasma converter unit can be assumed as fully recyclable. 90% of ash-type constituents in RDF are recuperated as a stable vitrified product.	Feed rate of the solids at rates of up to 50–60 kg/h plasma converter: 950–1150 °C FBG: 700–800 °C	-	Continuous	(Materazzi, Lettieri, Mazzei, Taylor, & Chapman, 2015)
Gasification of dried sewage sludge	Special rotary dryer produce particles, which differ significantly in size, geometry, porosity and weight. Three lines were planned to process the entire mass of 5.4 t/a ds6 with a water content of around 3–8%. Gas is blended with biogas from sludge fermentation and utilized in a gas engine or combustion chamber to produce heat.	Gasification temperature: 850–900 °C Installed power: 2.2 MW_{th} Type of dryer: Rotary dryer Electrical consumption: 75 kW Cold gas efficiency:70%	-	Continuous	(Judex, Gaiffi, & Burgbacher, 2012)

Table 1. Continued

Plant	Brief Description	Reaction Conditions	Presence of Catalyst	Process Type	
Japanese cedar wood (up-draft gasifier)	Gasification of cedar wood in a bench-scale externally heated updraft gasifier. Around 30-50 vol.% of H_2 can be produced from cedar wood gasification.	Feedstock: particle size of 1–2 mm Operating temperature: 650 °C – 950 °C Lower heating value of gas: 1–33.2 $mJNm^{-3}$	-	-	(Aljbour & Kawamoto, 2013)
Rice straw gasification (up-draft gasifier)	Rice straw gasification in an atmospheric fluidized-bed gasifier. A high quality syngas (10% H_2, 18% CO and 4% CH_4) with low tar content was produced.	Operating temperature: 700 °C – 850 °C higher heating value (HHV) of the produced gas: 5.1 $MJ(Nm)^{-3}$ cold gas efficiency: 52%	-	-	(Calvo, Gil, Otero, Morán, & García, 2012)
Willow and other agriculture residue-dry grains (up-draft gasifier)	The gasification has been performed using circulating fluidized bed (CFB) gasifier. The averaged concentration of H_2 obtained from willow and dry grains was around 28 vol. % and 20 vol. % respectively.	Feed rate: max. 20 kg/h Operating temperature: 800 °C–820 °C cold gas efficiency: 50 -70% power range: 60 kW	-	-	(Meng, de Jong, Fu, & Verkooijen, 2011)
gasification of pine woodchips (up-draft gasifier)	Gasification in bench-scale circulating fluidized-bed (CFB) gasifier. Steam was used as a fluidized and gasifying agent. Gas composition CO (27–40 vol.%), H_2 (22–27 vol.%), CH_4 (7–9 vol.%), CO_2 (39–42 vol.%)	Feed rate: 5 kg/h Operating temperature: 700-900 °C Power range: 15 kW higher heating value (HHV) of the produced gas: 17 $MJ(Nm)^{-3}$	-	-	(Ngo et al., 2011)
Bagasse gasification	Gasification was carried out in an intensified auto-thermal air-blown downdraft gasifier and at atmospheric pressure. The system consists of a gasifier, an air blower, a gas clean up system with two cyclones, a water scrubber and an ash collector. Very low tar content between 0.376–0.40 g Nm^{-3} in the gas.	Operating temperature: 1040 °C Power range: 50 kW	-	-	(Jordan & Akay, 2012)
Hazelnut shells gasification	Cracked hazelnut shells size between 5 and 10 mm. The gasifier consists of an ignition unit, a cyclone, a gas cleaning system, a measurement/control system and data recording units. Gas which is produced by the gasifier enters the cyclone and then it is divided into two streams. Gas composition: H_2(13 vol.%), CO (23 vol.%), CO_2 (11 vol.%), CH_4 (4 vol.%) with low tar content.	10 kg feeding capacity Operating temperature: 1000 °C Lower heating value of gas (LHV): 1 MJ/Nm^3 - 5 MJ/Nm^3 Power range: 45 kW	-	batch	(Olgun, Ozdogan, & Yinesor, 2011)
Biomass gasification	Pine wood blocks gasification unit consists of The gasification system consists of air intake equipment, a downdraft gasifier, ash chamber, gas cleaning system, roots blower, flow meters and off-gas burner. First the catalyst is uniformly distributed on the grate. Then the biomass is placed on charcoal. A specified (Lv et al., 2007) quantity of hot water is added into steam generating room. Afterwards feedstock in the gasifier is ignited. The gas contain around 70 vol.% of H_2 and CO. Biomass oxygen/steam gasification has its advantage for improving the hydrogen yield in less energy consumption.	Lower heating value (LHV) of fuel gas: 11.11 MJ/Nm^3 Hydrogen yield: 45.16 g H_2/kg	charcoal	batch	(Kirkels & Verbong, 2011)

Table 1. Continued

Plant	Brief Description	Reaction Conditions	Presence of Catalyst	Process Type	
Biomass gasification technology using integrated catalytic hot gas cleaning	A lab-scale pilot gasification facility of advanced gasification technology for production of high quality gas using innovative hot gas cleaning catalyst. In this process the tar content in the product gas could be reduced and the large amount of the aromatic ring systems in tar have been reformed and/or cracked. The increase contents of H_2 and CO and decrease of CH_4 and CO_2 was noticed. Gas composition: H_2 (54.2.%), CO (20 vol.%), CO_2 (6.7 vol.%), CH_4 (18.8 vol.%) with low tar content.	Feed rate: 4.4 kg/h gasifier reactor temperasture: 880 °C catalytic reactor temperature: 800°C tar content: below 83 $mgNm^{-3}$	Char-supported catalysts (woody chips soaked in 0.2 M $FeCl_3$ and dried)	batch	(Dong et al., 2013)
Plant of coal and supercritical water gasification system driven by concentrated solar energy	Gasification plant using concentrated solar energy system consists of: nitrogen bottle, feedstock tank, feeder, solar receiver/reactor, heat exchanger, cooler, filter; regulator, separator, pump, tanks, toroidal surface heliostat with the two axis spinning-elevation sun tracking, concentrator. Biomass glucose, corn meal and wheat stalk were gasified in the system for the production of hydrogen-rich gas.	Feedstock:1.03 t/h Maximal temperature and pressure:800 °C and 400 bar, respectively. Maximal concentrated solar power:163 kW. The maximal hydrogen production molar fraction: 55%	-	Continuous	(L. Guo, Jin, & Lu, 2015)
Solar receiver/reactor for hydrogen production	Hydrogen production with biomass gasification in supercritical water by using original solar hydrogen reactor. Gasification of glucose and corncob mixed with carboxymethyl cellulose mixture (CMC) was carried out to generate hydrogen-rich fuel gas. System consists of: feedstocks tank, pre-heater, high-pressure feeder, SCW reactor, heat exchanger, cooler, regulators, separators, pumps, valves, tanks, flow meter, multi-dishes concentrator.	The maximal throughput capacity was 16 kg/h. Feedstock temperature: 200–250 °C The maximal hydrogen production volume fraction: 55% Pressure: 240 bar Temperature: 543°C-676°C Feedstock: - Glucose concentration: 0.1 M, 0.2 M, 0.3 M, 0.4 M 2 wt% CMC + 1.5 wt% corncob, 2 wt% CMC + 3 wt% corncob, 2 wt% CMC + 3 wt% corncob + 0.5 wt% KOH, 2 wt% CMC + 5 wt% corncob	without or KOH	-	(Liao, Guo, Lu, & Zhang, 2013)
A transpiring-wall supercritical water oxidation reactor	SCWO pilot plant with a transpiring wall reactor including five streams (feed, oxygen, air, transpiring water and cooling water) are introduced into the reactor. Reactor is used to treat organic and recover energy. A total organic carbon (TOC) removal above 99% is reached even at a feed temperature of 369 °C.	Feed rate: 8–17 kg/h Reaction temperature: 476-725 °C	-	Continuous	(Zhang et al., 2012)
Hydrogen production from glycerol	Glycerol was used for hydrogen production using continuous flow tubular reactor which consists of: reactor, water tanks, pumps, cooler, preheater, mixer, reactor, regulators measuring equipment. The feedstock (glycerol solution) was first mixed with preheated water for avoiding side reactions. Hydrogen yield in relation to catalysts was in the following order: $NaOH > Na_2CO_3 > KOH > K_2CO_3$ Hydrogen-rich gas products - hydrogen molar fraction was 52.0–68.9%.	Reaction temperature: 445-600 °C Pressure: 250 bar residence time: 3.9-9.0 s.	alkali catalysts	Continuous	(Guo et al., 2012)

namic calculations were employed (Schmieder et al., 2000). Thermodynamic equilibrium calculations indicate that methane is preferably formed at lower temperatures, whereas at higher temperatures, hydrogen is the main product, besides CO_2 (Waldner & Vogel, 2005). Lower heating rates usually promote the formation of refractory compounds, resulting in more methane (rather than hydrogen) production. A possible solution to lower the high energy demand characteristic for the process could be the application of pressures exceeding conventional ones, up to 1000 bar. After exceeding the critical temperature (374 °C) at a pressure of 250 bar C_p of water decreases with further increase of temperature. The subsequent conclusion is that heating water at higher pressures to near critical conditions would result in a less energy intensive process.

Numerous non- conventional working fluids have been suggested for application in energy production processes due to their unique thermal and transport properties. The thermo-physical property change of the fluids is significant, in the high temperature and /or high pressure region (Yu, Chen, Zhao, Li, & Zhang, 2015). There are many advantages when using CO_2 supercritical cycles instead of classical systems: the compression ratio is low, so compressor efficiency is relatively high; volumetric refrigeration capacity is high, which helps reducing the size of the systems. Namely, in the proximity of critical point, the CO_2 fluid is very much expandable/compressible, the density and thermal conductivity change to be near one order of magnitude lower as temperature approaches the critical point. At the same time the Prandtl number and specific heat also form high peaks (Chen, Zhang, Okajima, Komiya, & Maruyama, 2016). When in a certain reaction system SCFs are applied as a reaction media, the particular thermodynamic

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

and transport data have to be considered. Investigations of basic thermodynamic and transport data like phase equilibria, density, viscosity, dielectric constant and diffusion coefficients are of fundamental importance to overcome many uncertainties associated with the parameters of the extreme supercritical systems, the methods for incorporating risk and uncertainty into process design and optimization.

In the frame of our past research, several gravimetric methods have been developed or modified to carry out the measurements at elevated pressures and temperatures:

- **Determination of Density of the Binary Systems:** Density of some gases increases significantly at certain conditions and thus the buoyancy effect when applying the magnetic suspension balance method can be well expected. Consequently, the sample is lifted and the measurement cannot be performed. For these systems, the external balance method presents an alternative to the Magnetic Suspension Balance (Figure 5).
- **Determination of the Viscosity of Binary Systems:** Experimental viscosity data at high pressure and high temperature was measured for multi-component mixtures. The measurements were conducted in a HPHT reactor (Figure 6).
- **Investigation of Interfacial Tension of Binary Systems:** A novel technique for predicting the interfacial tension based on the capillary rise phenomenon for the gas saturated compounds has been proposed for performing interfacial tension tests at high pressure and high temperature conditions (Figure 7).

To reduce hydrocarbon concentration and to increase the content of H2 and CO in the product, catalysts are introduced to the reaction mixture. If the aim of the reaction was the efficient gasification of biomass, alkali and metal catalysts were used. The alkali catalysts (NaOH, KOH, Na_2CO_3, $KHCO_3$, $K2CO_3$) (Cantero, Álvarez, Bermejo, & Cocero, 2015) significantly increased the H_2 and CO_2 yields and decreases CO yield by promoting the water-gas shift reaction (Guo et al., 2010). As heterogeneous catalysts, transition metals (Ru, Pd, Ni, Cu, Co) on different supports (TiO_2, Al_2O_3, ZrO_2, $CeZrO_2$, SiO_2) were used to increase biomass conversion and the yield of gas formation (Guan et al., 2014; Mehrani, Barati, Tavasoli, & Karimi, 2015). For the SCW reforming of biomass metals are much more attractive than alkalis. Their catalytic activity and stability of is influenced by the type of the support. Promoters such as Na, K, Mg or Cs may be also added to further improve catalyst activity and stability, and to favor the water-gas shift reaction. Activated carbon was also proposed as heterogeneous catalyst for enhancing biomass gasification in SCF (Ding, Azargohar, Dalai, & Kozinski, 2014). It was found that carbon gasification, the water-gas shift reaction and methanation reaction are favored by the presence of activated carbons. The main drawback is that activated carbon is prone to chemisorption of the intermediates which decreases the surface area, thus affecting its activity.

Corrosion is another issue that should be solved before considering construction materials. Unfortunately, it is almost impossible to prevent corrosion, however it is possible to control it. selection and the amount of corrosion inhibitor used depend on the acid type and its strength, the steel type, the desired protection time, and the expected temperature (Brondel et al., 1994). The main drawback considering corrosion inhibitors is that they are effective only for a particular metallic material in a certain environment (Finšgar & Merl, 2014). Already a very small change in the composition of a solution or alloy can significantly change the inhibition efficiency. Because the mechanism of how corrosion inhibitors work is usually not known and in spite of some proposed models for forecasting corrosion inhibition effectiveness, empirical experimental testing is still unavoidable (Brondel et al., 1994; Finšgar & Jackson, 2014). Inhibitors must be chosen after taking into account the nature and combinations of metals present, the nature of the corrosive environment, and the operating conditions: flow, temperature, and heat transfer. Recent studies have attempt to find a green (environmentally acceptable) corrosion inhibitor/inhibitor formulations such as plant extracts, essential oils and purified compounds (Znini et al., 2012).

FUTURE PERSPECTIVES

Applications of supercritical fluids certainly have a bright future. Particularly for the products for use in medicine, tissue engineering and nutrition from the point of the high value added products and treatment of excessive wastes generated by a wide range of processes, such as domestic and industrial wastewater treatment, wastes from oil and biodiesel industry, wastes from food, biomass processing and chemical industry. Combination of hydrolytic and bio-catalytic processes has proved to be a suitable method to convert very wet biomass and liquid streams to gases or other bio-based chemicals.

Integration of advanced processing concepts enable further application of residues from different industries with the principle goal to obtain value added products, avoiding the problems related to waste disposal. Limited supply of petroleum resources together with the ever-increasing demand for petroleum-based products has fueled the emergence of the bio economy. Global trends highlight the growth in fuel, energy, materials, chemicals and other products based on renewable feedstocks as economically viable alternatives to petroleum-based products. Therefore, there is no uncertainty that research needs and challenges that support the biorefinery concept, which is analogous to petroleum refinery, where instead of nonrenewable fossil fuels; renewable feedstocks are converted into chemicals, fuel, materials and other products. Thus, a biorefinery would integrate a variety of separation and conversion processes to produce multiple product streams from renewable feedstocks with little or no waste. Such developments in biorefinery approaches force us to consider integrated approaches to utilization of supercritical technology in biorefining where new approaches, such as energy recovery have key relevance. Namely, high temperatures involved in the process and the high energetic consumptions of these processes have been studied many times without an appropriate heat integration scheme. In design, knowledge of the reactions kinetics at different pressures and temperatures is of utmost importance and represents the fundamentals in the design of such process. The choice of biomass applied will dictate the operational conditions aiming to achieve a rapid conversion of polysaccharides with high saccharide production and low degradation products. The composition of biomass available varies considerably. Some natural materials contain relatively high amounts of complex substances that increase the resistance of the material to hydrolysis processes and require that conditions that are more aggressive. Lignocellulosic materials such as corn stover and sugar cane bagasse are some of them. Lignin is present in a complex structure with cellulose and hemicellulose that require high pressures and temperatures to carry out the complete hydrolysis. Thus the composition of the raw material is of fundamental importance in SubWH and SupWH processes, since it will determine (Brunner, 2015).

To overcome the obstacles between the research and application of the sustainable processing concepts in practice, more research is needed in order to understand the reaction mechanisms. Beside biomass treatment, hydrothermal technology has a great perspective for industrial scale production of materials, as they are part of the green chemistry. Particularly supercritical CO_2 and H_2O will have an important role in production of nano-particles and of nano-material owing to the multi-faceted advantages. The obtained products may be used as insulating materials or as catalysts. In such a process, initial material is dissolved in supercritical water in the first step. Then it is mixed with cold solutions to reduce the solvent power of the supercritical water and to achieve precipitation of the nano-materials. These are swept out with another flow of cold water and then separated from the water. Operation cost of such processes are relatively low due to the lower energy consumption and above all, the approach is less time consuming than the traditional processing methods (Brunner, 2015). Besides, the properties of the obtained products such as structure of electronic energy levels and transitions, electron affinity,

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

conductivity, phase transition temperature, magnetic properties, melting points, etc. may be "tailored" since they depend on the nanoparticle size and shape, which is relatively easily controlled by varying the process conditions (Byrappa, 1991).

CONCLUSION

The chapter discussed hydrothermal processing of biomass to obtain bio-oil, bio-gases and bio-carbon with a highlight on current research trends that tend towards growth and implementation of new technologies which enable transition to "green" chemistry without further use of environmentally and health hazardous organic solvents as a basic step towards sustainable development. Such processing concepts comprise reuse of residues according to a basic concept of biorefineries. After extraction of source material, further conversion of residues (biomass) to a wide range of useful products, including second-generation biofuels, base chemicals, biospecial chemicals and bioefficient materials, is suggested. The main impetus for this conversion is on one way driven by a concern to the environment to reduce the usage of conventional solvents and energy. By the assessment of sustainable biomass potential and the evaluation of benefits of different bioenergy options, favorable conditions to set up a second-generation biofuel industry will be established. Several benefits are derived from the economic point of view; countries that are currently not able to produce second-generation biofuels could profit from new technology and market opportunities once the technology is commercially available.

"Process intensification" as a part of necessary sustainable development and "green" revolution uses also high pressure as a processing tool which enables production of goods with completely new specifications. Since higher pressures allow economically feasible processing, the future research will most probably lead towards investigation of the fundamental thermodynamic data pertaining to the conditions such processes.

Hydrothermal technique offers a great perspective of the future as an excellent possibility for processing of various product options from biomass degradation in hot compressed water. Hydrothermal processes are also a promising basis for the production of a variety of different intermediates to be used for energy and chemical purposes. As a reaction media water opens new perspectives compared to "dry processes", needing lower reaction temperatures. The polar character of water and the high reactivity of biomass with its many polar bonds in water offers an opportunity of processing at lower temperatures. Selectivity of water can be easily fine-tuned by slight changes in operating conditions – therefore different products with special properties can be obtained and by variation of pressure and temperature, production yields may be increased considerably. The advantages of hydrothermal technology are several and the waste biomass conversion for production of energy carriers are performed by applying supercritical water and supercritical water by the introduction of supercritical CO_2 to the binary systems supercritical water/biomass or supercritical water/biomass. The benefit of such processing reflects in lower energy consumption and production of specific products of a benefit. Current trends in hydrothermal materials processing are presented in relation to the concept of soft solution processing and above all, low energy consuming fabrication technique. Dissemination of the new approaches to the industrial scale processes, with the emphasis on waste biomass conversion for production of biofuels and bio-chemicals by applying supercritical fluids to improve the economic, environmental and energy efficiencies will play a significant role in the upstream and downstream processing in the oilfield industry. The challenge is not in the conversion of the feed to the product, but to achieve the product efficiently by understanding process

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

backgrounds in terms of mass transfer, thermodynamic system characteristics, process optimization and scale up, which is still the main obstacle for a wider application of these technologies.

It is thus about the development of advanced technologies involving sub- and supercritical fluids which can provide efficient products, have low or even zero impact to the environment and do not require much energy.

Undoubtedly, much research is still needed and a close collaboration between scientists, industry and governmental agencies is required to make the large-scale application of such advances technologies for production of energy possible.

KEY TERMS AND DEFINITIONS

Bio Based Chemicals: Sustainable, cost-advantaged, drop-in replacements and substitutes for petroleum-based chemicals that are used in variety of industrial applications.

Bio Oils: Dark brown organic liquids, which are chemically complex mixtures and/or emulsions of water and degradation products of lignin.

Biofuel: A fuel, such as biogas or biodiesel that is produced from renewable resources, especially plant biomass, vegetable oils, or treated municipal and industrial wastes.

High Pressure Phase Equilibrium: Equilibrium relations between phases at high pressure.

High Pressure View Cell: A reactor that allows both, observation through the windows and quick and precise thermodynamic measurements during experiments, carried out at elevated pressures by a precise volume control with measurement of the piston position in the cell. Pressure and temperature are maintained constant during entire measurement.

Hydrothermal Carbonization: Thermochemical conversion process, which usually takes place at moderate conditions (523 K and 2 MPa) where carbonaceous bio solid product named "hydro char" is obtained.

Hydrothermal Gasification: A process in which biomass waste without pre-drying reacts with water that acts not only as a solvent, but also as a reactant under subcritical and supercritical conditions to produce gaseous products, mainly CH_4, H_2, CO_2 and C_1-C_4 carbon gases.

Hydrothermal Liquefaction: A process for converting waste biomass into chemicals and biofuels, where the reaction is performed under medium temperature and high pressure (553-643 K, 10-25 MPa), sufficient to keep the water in a liquid state.

This research was previously published in Advanced Applications of Supercritical Fluids in Energy Systems edited by Yuhiro Iwamoto and Lin Chen; pages 554-587, copyright year 2017 by Engineering Science Reference (an imprint of IGI Global).

Chapter 51
Life Cycle Costing for Sustainability

Mustafa Üç
Epoka University, Albania

Cemal Elitaş
Yalova University, Turkey

ABSTRACT

Life cycle costing supports sustainability by stressing the costs not only in the production and selling phases but also considering the costs which are incurred after the sale of the products. This chapter reveals main characteristics of life cycle costing as follows: Life cycle costing also includes production costs which are; (a) research and development costs, (b) marketing, selling, distribution and design costs, (c) and also user costs. User costs have three dimensions: transaction costs, maintenance costs, and disposal costs. Therefore one can simply assert that life cycle costing has a broader approach in the calculation of the costs compared to other conventional costing systems. After introducing the main characteristics and basic definitions of life cycle costing, this chapter will discuss the implementation of life cycle costing in comparison with other conventional costing systems. Following this, we will analyze the link between life cycle costing, waste management and sustainability. Overall review will be done in the conclusion.

INTRODUCTION

The businesses are the catalyst in the development of globalization and some problematic impacts of their operations on the environment become an international issue. The largest corporate initiative in the world, the United Nations Global Compact determined ten principles for the companies that setting core values in the four different basic areas affect the human life. These principles ask the companies to substantially respect human rights, labor standards, the environment and anti- corruption. The principles 7-9 are related to environment area and call the companies; to be precautionary against the environmental challenges, undertaking initiatives to promote greater environmental responsibility and to be supportive

in the development and diffusion of environment friendly technologies (Rasche & Kell, 2010). Existence of the Global Compact acknowledges that environmental problems arose from the businesses' operations have rising importance and cannot be left local regulations and regulators or initiatives in the solution of the problems which affect the humanity. The businesses are the economic units to produce and sell their products to meet the needs of the society and to survive in future by earning profit. While the environmental problems, particularly pollution, may occur in the production phases, inefficient use of products by consumers or dispose of products may cause some other environmental problems too.

Especially to prevent side effects in product disposals, some businesses have begun to undertake more responsibility within the corporate sustainability and/or corporate social responsibility approaches. Besides estimating the cost of production, they started considering the cost of disposal before the sale of the products. This contemporary costing system, which is named life cycle costing (LLC) is used to achieve this objective. There, LCC includes disposal cost in the determination of total product costs. Life cycle costing considers both production costs and user costs. User costs are also known as transaction, maintenance, and disposal costs which they are closely involve in sustainability and waste management. Therefore, one can simply assert that LCC has a broader approach providing full cost in the calculation of the costs, compared to other conventional costing systems.

This study primarily focuses on revealing the fundamentals of the LCC and its relations with waste management, considering the sustainability perspective. In order to fulfill these objectives, the organization of the paper is as follows. The main characteristics and basic definitions relating to life cycle costing are presented in the background. After the background of LCC, the implementation of life cycle costing and the comparison of LCC with other conventional costing systems are discussed. In following, the links among life cycle costing, waste management, and sustainability will be analyzed. An overall review will be done in the conclusion.

BACKGROUND

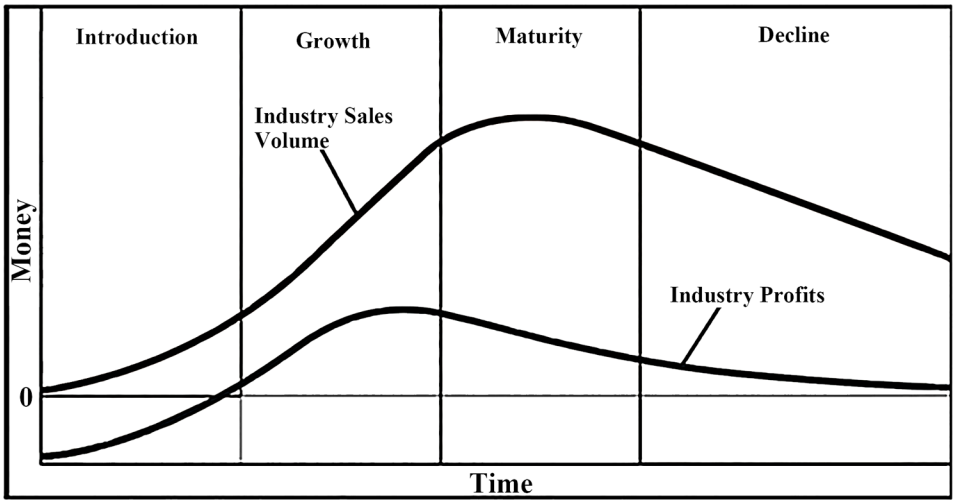
The Basics of Life Cycle Costing

LCC varies from other traditional costing systems by considering the total cost of products throughout the life cycle of products. To enhance a clear comprehension of the LCC, explanation on the term of 'product life cycle' is vital. The graph below demonstrates the stages of the product life cycle. A product moves four major stages through its life cycle; introduction, growth, maturity, and decline.

Introduction is the first stage of the life cycle of product. Launching a new product incurs development costs, in addition to some other important period expenses, which incur during promotion and distribution. This situation results with low revenue and zero profit in the earliest phase of introduction stage. As time passes, sales start to increase and earn profit. Second stage is 'growth' and during the growth stage sales rise rapidly, and profits reach a peak. This stage is the most significant stage for the battle with competitors in order to gain consumers' acceptance and create loyal customers. Therefore, companies increase their promotion expenses. The third stage is 'maturity'. As it is seen on the figure above, sales curve peaks and it starts to decline parallel with profit curve. There is still a severe competition with the competitors and improvements and differences are required to promote the products. The last stage is 'decline'. During the decline stage, sales fall rapidly due to launch of the new products developed or updated with new technologies. As one product is declining, other products of a company

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 1. The four stages of the product life cycle
Source: Pride, Hughes, & Kapoor, 2014



are in the introduction, growth or maturity stages. Thus, when companies understand and ensure that the product has completed full life cycle, they deal with new products and do not promote the existing product anymore. Moreover, sales volume and profitability are very low though costs are high in the decline stage of a product life cycle (Pride, Hughes, & Kapoor, 2014).

The use of LCC was the first in US Department of Defense, in order to provide an effective cost management on the procurement of weapon systems dating from1960s. It took a notable place in construction management literature owing building industry that needed a more holistic approach (considering the environmental costs such as; demolition of buildings at the end) in the calculation of full cost. For example, the initial costs start in the designing project, then surveying, construction of the buildings, after finishing the construction, other operational costs incur such as maintenance of the buildings. In some cases, demolition of the buildings completes the life cycle in this industry. Especially, calculation of the full cycle's cost at the beginning, starting from the cost of project design phase to the demolition of the building in the end; this process requires advanced technical skills.

In this context, one of the main advantages of LCC over the traditional cost systems is that, it estimates future costs, which were not addressed very well (Emblemsvag, 2003; Gluch & Baumann, 2004). Jan Emblemsvag who is one of the prominent scholar studies on LCC, reviews on the comparison of the traditional systems' past oriented and LCC's future oriented (estimated) time perspectives by reminding with the concept of 'cost management' with following sentences: *"Even worse, we try to control costs after they are incurred instead of eliminating them before they are committed. The result is a massively wasteful economy"*(Emblemsvag, 2003). The cost is sacrifice, measured by the money and there are many cost classifications according to different criteria in the cost and managerial accounting theory. A cost classification refers the 'according to calculation of the costs as full or partial (direct) cost will be taken' full cost is the most appropriate cost insight for the LCC(Davidson, Maher, Clyde, & Weil, 1981; Altug, 1996). In other words -and in a more practical sense- the full cost is referencing to LCC.

There are many LCC definitions found in the extant literature. Here, some of the basic definitions are presented:

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

The life cycle cost of an item is the sum of all funds expended in support of the item from its conception and fabrication through its operation to the end of its useful life. Thus, the LCC of a physical asset begins when its acquisition is first considered, and ends when it is finally taken out of service for disposal. (Woodward, 1997)

The total costs that are incurred, or may be incurred, in all the stages of the product life cycle. (Emblemsvag, 2003)

LCC is a system that tracks and accumulates business function costs of the value chain attributable to each product from initial R&D to final customer service and support. (Horngren, Datar, Foster, Rajan, & Ittner, 2009)

As it was mentioned above; first implementations of LCC were in public procurements. In this context, another LCC definition from public administration point view, which defines the LCC with regard to public purchase process, is following:

LCC is purchasing process which considers the total cost of ownership of a commodity. In contrast to the traditional purchasing approach which relies on the initial acquisition cost, LCC also takes into account the cost of the using and disposing of particular commodities. (Coe, 1981)

As the definitions given above, LCC includes production costs which are; (a) research and development costs, (b) marketing, selling, distribution, and design costs, (c) and user costs. User costs have three dimensions: transaction costs, maintenance costs, and disposal costs respectively and they are much related to sustainability and waste management. Thus three dimensions of the user costs will be explained elaborately. Production costs, which mentioned here, are also considered by the conventional costing systems and they are very well known cost types in existing literature.

Transaction Costs

"Transactions costs are those costs associated with consummating a trade, over and above the trade itself. A simple example is the commission paid to an agent to sell a house" (Kolstad, 2000). In addition to the commissions payments, the property tax payments and expenses incurring when someone buys a house such as notary and registration for transferring of title deed can be assessed in transaction cost terms. This cost is the first cost component appears in user costs because when a person starts to buy something, transaction costs incur before acquiring it fully. Thus, transaction costs can be pointed as a prerequisite for having ownership of the goods.

Maintenance Costs

This cost is necessary to keep the product ready for useable and/or using it in an efficient way. Maintenance costs include direct labor, materials, fuel power, and equipment and purchased services. Maintenance costs can normally be broken down into smaller classifications such as:

- Regular planned maintenance;

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

- Unplanned maintenance (responding to faults);
- Intermittent maintenance (for major life refurbishment).

A regular, planned, preventive maintenance policy reduces the downtime costs but resources are used in the form of maintenance expenditure. The 'run it until it breaks' approach, on the other hand, reduces the maintenance expenditures but increases the downtime loss (Woodward, 1997).

Disposal Costs

This cost type is incurred at the end of an asset's working life in disposing of asset/product. The disposal cost may occur in following forms: demolition, scrapping or selling the asset/product. This user cost component has crucial importance on protecting environment and sustainability.

Lastly, it should be also specified that user costs are subject to effects of changing economical conditions and technical developments, for example a technological development may require making some updates in a product which it incurs maintenance cost (Ross, 1960). Though acquisition cost term includes and recognizes the transaction costs in external financial reporting, it is evident that, the other two user costs have never been taking place in the external financial reporting or traditional costing approaches.

THE COMPARISON OF LIFE CYCLE COSTING WITH TRADITIONAL COSTING METHODS

While traditional costing systems emphasizes the calculation of costs that incurring during the production, however, the LCC has a broader perspective. Firstly, it takes into account the costs incurred after the production and secondly it does not only take into account the production costs but also sales, marketing, administrative, and user costs in terms of variety. The main differences between traditional costing systems and LCC are evaluated in Table 1.

As it is seen from the table there are significant differences between traditional costing methods and LCC. These differences may affect the unit product cost computations. Although, recognition of product development costs as period expenses does not bring serious difference from the point view of external financial reporting, it is important for a more precise determination in the matching of the product's total income and cost throughout its entire life.

Table 1. The comparison of life cycle costing with traditional costing methods. Source: Acar, 2005.

Traditional Costing Methods	Life Cycle Costing
The development costs of the product are recognized as period expenses.	The development costs of the product are recognized as component of product costs and capitalized.
In the computation of the unit product cost only production costs are considered.	In the computation of the unit product cost all the costs items linking to product are considered.
Time perspective of reporting is in periodical basis.	Time perspective of reporting is theentire life of product (life cycle).

THE INTERRELATIONS OF LCC WITH WASTE MANAGEMENT AND SUSTAINABILITY

The sustainable development means business activity that produces the goods and services needed in the present without limiting the ability of future generations to meet their needs (Hilton, 2009). The green accounting, environmental and societal accounting, accounting for carbon emissions and LCC are the concepts that very related to sustainability and they can be merged in a broader term 'accounting for sustainability'.

The accounting for sustainability or sustainable development has emerged as a new accounting area concerning with environmental accounting and social accounting concepts, which sometimes this three terms are used interchangeable. In other words, the environmental and social accounting can be pointed out as initial attempts or movements towards the rising of broader term 'accounting for sustainable development'. The emerging of environmental accounting as an identifiable research area in the accounting discipline occurred in 1980s (Bebbington & Larrinaga, 2014).

In this section, the relationships of LCC among waste management and sustainability will be reviewed with the major previous studies in the literature. Reich (2005) examined the economic assessment of municipal waste management system using the combination of LCA and LCC through a case study. The study's results showed that economic methods (LCC financial and LCC environmental approaches) can provide useful tools to an evaluation of waste management systems.

Gluch & Baumann, (2004) assessed the usefulness of LCC oriented tools for environmental decision-making in building industry. They conclude the study with pros and cons of usefulness of LCC in environmental decision making as folow.

Kumaran, Ong, Tan, & Nee, (2001) studied the environmental life cycle cost analysis of products. They included the eco-costs into the total cost of the products. Eco-costs are defined as both the direct and indirect costs of the environmental impacts caused by the product in its entire life cycle and these

Table 2. Pros and Cons of LCC of Usefulness of LCC in Environmental decision making in building industry. Source: Gluch & Baumann, 2004.

Pros of LCC	Cons of LCC
Uses a familiar unit, money	Fails to handle decisions under uncertainty
Gives an indication on which aspects to consider	Fails to handle irreversible decisions
Limits the information flow by simplifying multi-attributed alternatives.	Neglects items without owner, such as the environment
May entail learning by participating in the calculation process	Over-simplifies environmental problems into a monetary dimension
Has a life cycleperspective	Underrates future environmental costs
	Suffers from poor availability and reliability of data
	Relies on many estimated variables due to the complexity of the building and building process
	Results are biased towards the decisionmaker's personal values
	May restrain learning if too mechanically used
	Is beset with conceptual confusion due to many similar LCC-oriented tools and inconsistent life cycles.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

costs can be also accepted in user cost definition. The aim of the research to design a hypothetical conceptual model including to a new category of costs which named eco-costs in addition to traditional product costs. They determined elements of eco-costs as follow:

- Cost of effluent control;
- Cost of effluent/waste treatment;
- Cost of waste disposal;
- Cost of implementation of EMS;
- Costs of eco-taxes;
- Costs of rehabilitation (in case of environmental accidents);
- Costs of energy; and
- Cost savings of recycling and reuse strategies.

LCC is costing system developed to compute product cost, and it was found very useful decision-making tool for the companies stressing the sustainability and environmental issues. The academic studies on sustainability and environment are interested in LCC as a useful tool. On the other hand, a pure or traditional LCC approach has been also criticized by some academics, because of taking mostly economical aspects into account and paying less attention to environmental aspects. Therefore, a differentiation appears about the LCC approach in the environmental context (Ristimaki, Saynajoki, Heinonen, & Junnila, 2013).There are three types of LCC implementations taking place in the existing waste management and sustainability literature in the environmental context, which uses the LCC together with Life Cycle Assessment (LAC). The types of LCC may vary from each other in terms of convergence and appropriateness of life cycle assessment. The first LCC is "conventional" and its relation with LAC only recognizes internal costs. The second LCC is "environmental" and its relation with LCA is very parallel besides internal costs, including external costs as well. The third LCC is "societal". It internalized the LAC thus, it can be asserted as the most appropriate LCC with LAC (Sanchez, Kromann, & Astrup, 2015).

This section ends with showing a theoretical design of product life cycle proposed by Emblemsvag (2003). In figure 2, each activity is in the manufacture and demanufacture process, considered precisely in the cost calculation LCC approach.

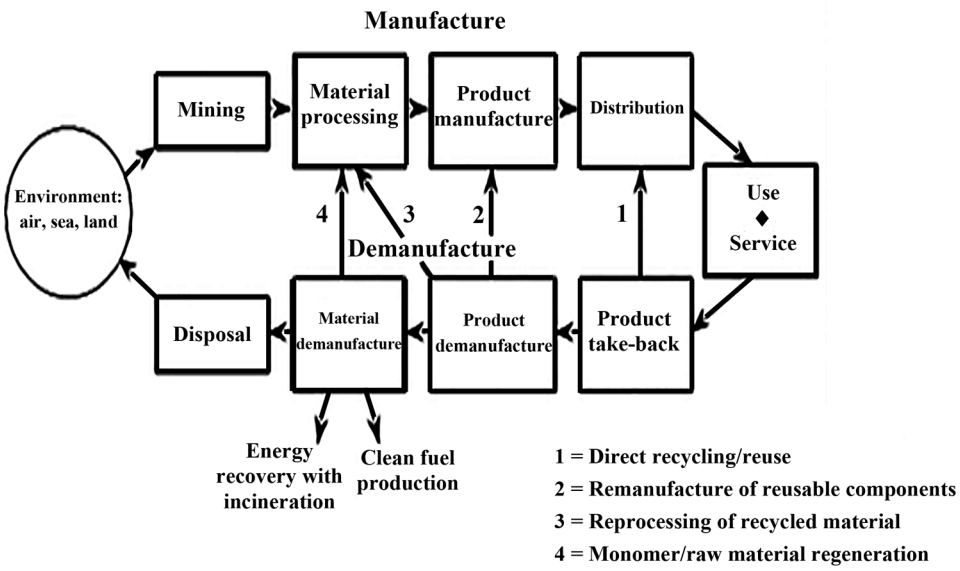
As it is seen from the figure, reuse or recycling starts from product take back at early stage to the material demanufacture stage. First factor of production is land and raw materials are taken from it. After they were processed, they are finally disposed again to land. But the figure elaborately shows that, before the products dispose, there are four opportunities to recycle or reuse them. By the way the resources will be consumed efficiently in terms of the needs of the humanity. LCC considers the every type of cost item incurring in this figure to calculate product cost in its lifespan.

CONCLUSION

This chapter aimed to reveal the foundations of life cycle costing and its relationship with sustainability. The future oriented time perspective of LCC prevents using more resources to fulfill the organizational objectives and provides efficiency and sustainability. Traditional costing systems are past or present oriented and they try to control the costs after committed. Eventually, this situation can result in waste

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 2. Product life cycle with activities
Source: Emblesvag, 2003



of the resources. LCC considers not only manufacturing costs but also user costs which incur after the sale of product. The aspect of LCC which considers the user costs is linked to sustainability, and among the user costs; maintenance and disposal costs have particular importance on sustainability. Current paradigm in businesses is not taking into account disposal costs unless a regulation requires. Therefore, they do not involve and take responsibility for negative impacts of the disposal of products on the environment. LCC recognizes the disposal costs within the total production cost and this aspect makes the LCC a very environmental costing system. With regard to using LCC by more businesses, we can draw a conclusion that widespread adoption and use of LCC will increase the awareness of the businesses about the disposal costs and potential impacts of the disposal of products on the environment.

Coe (1981) defines the rationale behind LCC as follows. While the initial acquisition cost of a product may be greater than a *competing product*, the total cost of ownership may be less because over its useful life it is less expensive to operate. With respect to Coe's definition on the rationale behind LCC, we can revise it by adding the sustainability perspective with replacing 'competing product' with 'ability and opportunity of the future generations to acquire and benefit from the similar products' in his definition. Because in his times, LCC was understood as a only superior cost management technique to compare two different products, therefore the definition of rationale emphasizing competing product. But when we adapt it into the conditions of the present time, we are altering the term of 'competing product' with 'sustainability'. In terms of the sustainability, both in purchases of products and in the manufacturing, the companies take maintenance and disposal costs into considerations. If a product's maintenance cost is very high and its dispose causes some environmental problems though it has very low acquisition cost and has benefit for its present users, that product must not be produced for providing the sustainability. The use of LCC in the product purchase processes and in the manufacturing will be helpful to protect the environment for future generations.

KEY TERMS AND DEFINITIONS

Life Cycle Assessment (LCA): Life cycle assessment (LCA) is an established way of measuring total environmental effects of products and services. It considers the impact of a product or service on the environment.

Life Cycle Costing (LCC): The total costs incurred or may be incurred in the all the stages of product life cycle. The main difference between LCC and traditional cost systems is LCC also considers user costs in the cost calculations.

Production Costs: It is also known as manufacturing costs. They are direct material cost, direct labor cost, indirect material and indirect labor costs which the combination of these two indirect costs is called as overhead cost.

Sustainability: Business activity that produces the goods and services needed in the present without limiting the ability of future generations to meet their needs.

Traditional Costing: It is also referred as conventional costing and basically consists of two main systems, which they are job-order costing and process costing. In job-order costing; costs are collected for each unit produced and in process costing system; costs are accumulated in a department or production process. Both systems' ultimate objective is to find out total and unit production cost and they do not consider user costs.

User Costs: The term 'user costs' is used for the costs which are incurred after sale such as; transaction, maintenance and disposal costs. Life cycle costing considers the user costs in the cost calculations and especially disposal cost is much related to sustainability.

Waste Management: A set of activities that include collection, treatment and disposal of waste. It provides sustainability in environment and economy.

This research was previously published in the Handbook of Research on Waste Management Techniques for Sustainability edited by Ulas Akkucuk; pages 96-107, copyright year 2016 by Information Science Reference (an imprint of IGI Global).

Chapter 52
Advancement in Bioremediation of Pharmaceutical and Personal Care Products

Vasudha Agnihotri
G. B. Pant National Institute of Himalayan Environment and Sustainable Development, India

ABSTRACT

Pharmaceutical and personal care products (PPCPs) are regularly used by human being for their day to day life. These products contains various chemical compounds which are regularly added in our surface and ground water sources either through untreated or partially treated domestic and industrial wastes or through agricultural runoffs etc. These are present at the concentration of µg liter-1, and at such low concentration also these have shown harmful affect to living being. A lot of studies have been carried out for studying their effects on animal biodiversity, which can directly or indirectly affect human being also. So their removal from waste water is essential. Various technologies are being tested for removing these compounds from polluted water; bioremediation is also one of them. Present chapter will briefly give the description of various PPCPs present in waste water, their impact and removal technologies available for their removal with special emphasis on bio remediation.

INTRODUCTION

Water is one of the prime element and necessary for every living being on earth. Two third of the earth is covered by water and major fraction of our body is also made up of water. Further in the body, it regulates the activities of fluids, tissues, cells, lymph, blood and glandular secretions. So its contamination can easily affect our metabolism as well as that of all the living creatures. Fresh water present in the earth's surface is put to multifarious uses. It is used for drinking, domestic and municipal uses, agricultural irrigation, industries, navigation, recreation, etc. The used water becomes contaminated and is called waste water. Water passing through industries, agricultural lands and the urban settlements gets spoiled up and is rendered harmful to plants, animals and human being. This water gets loaded

with organic and inorganic chemicals, pathogenic and non- pathogenic organisms including viruses and cysts. Usually these waters do not remain fit for human consumption and for life of plants and animals as well. There are different types of pollutants polluting the water e.g. Sewage and fertilizers, chlorinated hydrocarbons and pesticides, heavy metals, oil and petroleum products, radioactive substances, plastics, pharmaceutical and personal care products (PPCPs) etc. Role of PPCPs as environmental pollutant is recent in comparison to other pollutants.

Now the question is what are pharmaceutical and personal care products? Different types of medications both for human as well as for livestock, cosmetic products, and antibiotics for agriculture etc are being used. Excess of these flush out through domestic effluents and become a part of water or sediments/ soil if not treated properly, known as PPCPs. Places where the waste water from hospitals, residential areas and industries are directly released into surface water without pretreatment, chances of presence of PPCPs becomes more prominent. As these group of compounds are still emerging therefore also known as a subgroup of "contaminants of emerging concern," as well as "emerging contaminants" or "trace organic compounds" (Sedlak et. al., 2000). Contaminants of emerging concern as a whole are compounds that are not commonly monitored due to their "emerging" nature. A wide range of PPCPs may be present in wastewater and the environment receiving it (Daughton & Ternes, 1999; Kolpin et. al., 2002). These compounds are mostly less biodegradable, high persistent in the environment, poorly removed in wastewater treatment plants (WWTPs), and often detected in the micro to nano grams per liter concentrations. Leaching of these compounds in groundwater is the potential risk as due to its usage for drinking purposes in most o the areas. The present chapter is providing different aspects of PPCPs such as type of PPCPs present in environment, their impacts on environment and available removal technologies for PPCPs from waste water with the emphasis on bioremediation.

BACKGROUND

Bioremediation was first used by the Romans, at around 600 BC, to clean their waste water. This process was officially invented in the 1960's by George Robinson. He had experimented with microbes inside of polluted glass jars. In the 1970s, Ananda Chakrabarty and his colleagues at General Electric discovered a strain of bacteria that is able to degrade some components in crude oil. He obtained this strain by isolating a Pseudomonas from a soil filled with. First commercial in situ bioremediation system was installed in 1972 to cleanup a Sun Oil pipeline spill in Ambler, Pennsylvania. The Exxon Valdez oil spill in 1989 in Prince William Sound, Alaska, was the genesis of global attention to this process. Importance of bioremediation is that it can completely destroy contaminants, converting them to carbon dioxide, water, and new cell mass. So this can be a good technique for removal of PPCPs from waste water.

Now days many PPCPs are detected at wide concentration ranges in a variety of environmental samples (Halling-Sørensen et al., 1998, Snyder et al., 2003) and in animal tissues, human blood, and breast milk samples (Rimkus et al., 1999; Adolfsson-Erici et al., 2002). Study was conducted by researchers at the U.S. Geological Survey in 1999 and 2000 to provide baseline information on the occurrences of pharmaceuticals, hormones and other wastewater contaminants in water resources. Researchers found organic wastewater contaminants (OWCs) in 80% of the streams e.g. coprostanol (a fecal steroid), cholesterol (a plant and animal steroid), tridosan (an antimicrobial disinfectant), 4-nonylphenol (a non-ionic detergent metabolite) and caffeine as the most frequently detected compounds (Nakada, 2007). The highest concentration reported was 40 ng/l for meprobamate (Benotti et al., 2009). Several pharmaceuticals were

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

found in tap water at different concentrations ranging from nanograms to low micrograms per litre in several countries in Europe, including Germany, the Netherlands and Italy (Huerta-Fontela et al, 2011). 20 different drugs were found in rivers and streams of Germany having water coming out of sewage treatment plants (STP). Some of them were lipid regulator bezafibrate, antiphlogistics diclofenac, ibuprofen, naproxen, metabolites like clofibric acid, salicylic acid, betablocker metroprolol, propranolol, antiepileptic carbamazepine etc (Ternes, 1998). Two separate studies in Germany (Reddersen et al., 2002; Zühlke et al., 2004) found phenazone and propylphenazone (an analgesic and an antipyretic drug, respectively) in Berlin drinking-water, with the highest concentration being 400 ng/l for phenazone. This high value was largely attributed to groundwater, used as a drinking-water source, contaminated with sewage (Jones et al., 2005).

In the Netherlands, traces of antibiotics, antiepileptic and beta blockers were detected in the drinking-water supply at concentrations below 100 ng/l, with most concentrations below 50 ng/l (Mons et al., 2003). Pain reliever ibuprofen was detected in the influents of several Switzerland WWTPs at concentration levels of 1 to 3.3 μg L^{-1} (Buser et al., 1999). As medical substances are developed with the intention of performing some sort of biological function, they have a tendency to bioaccumulate and induce effects in aquatic and terrestrial ecosystems (Halling-Sorensen et al., 1998). These compounds can easily come out from water treatment plants in original or modified forms, so their removal techniques from waste or drinking water need to be modified.

PPCP: SOURCES IN WASTE WATER, IMPACT ON ENVIRONMENT AND APPROACHES FOR REMOVAL

Sources of PPCPs in Waste Water

Millions of dollars are spent each year on PPCPs, many of these products are never used or only partially used and end up thrown out in the trash or dumped down the drain (Daughton & Ternes, 1999; Meador et al., 2016). The pervasive use of biocides in consumer products to improve hygiene and destroy bacteria creates another set of chemical contaminants that pass readily into water supplies as they are usually associated with cleaning and are dumped directly into household or industrial drains. These can affect human health due to their potential biomagnifications through the food chain in aquatic organisms (Crane et al., 2006). Generally the water is examined in terms of conventional physico-chemical parameters i.e., major nutrients, bulk organic matter in terms of BOD, COD, TOC etc. But with development, problems related to PPCPs have increased as these are harmful even at ng/L levels. The tendency for these compounds to persist or be only partially degraded during treatment or to bypass treatment altogether via sewage overflows will, therefore, contribute to their load in receiving waters, many of which serve as recreational and drinking water sources. These include PAHs, PCBs, pesticides, detergent residues (alkylphenols), plasticisers (DEHP), linear alkylbenzene sulfonates (LASs), natural and synthetic estrogens, poly brominated diphenyl ethers (PBDEs), disinfection by-products and others (Figure 1, Figure 2, and Figure 3). High percentages of many pharmaceuticals can be excreted from the body unmetabolized and enter wastewater as biologically active substances (Buhner, 2002) e.g. 90% of the drug, propofol found in anesthesia, is excreted un-metabolized (Kummerer, 2001). Aquaculture wastes are also the source of antibiotics in the waste water as it contains fish feed, dead fish, faecal matter, egg shells and chemicals used for treatment of fishes (Antibiotic overflow. Down to Earth, 1-15 August, 2016).

Impact of PPCPs on Environment

PPCPs potentially impact both the ecology and environment as these compounds may be active at very low concentrations. These are wide spread and released in large quantities in water bodies through waste water. In an aquatic system, the residence time of a pollutant and its distribution between water, sediments, and biota depends on its capacity to bound to suspended particles and accumulate in sediments. Thus, the affinity of hydrophobic organic compounds for biotic and abiotic phases is an important determinant of both the rate of a detoxification of water system and its response time to changing loadings. Polarity of these compounds determines their fate in potential matrices of environment. Non polar compounds generally more attracted towards soil colloids and sediments as also accumulate in biota (Heberer, 2002), while the polar PPCPs are more labile in the environment.

These compounds can affect human health due to their potential biomagnifications through the food chain in aquatic organisms (Crane et al, 2006). These are found to be associated with various health hazards as presence of PPCPs in water can potentially leads to carcinogenic, reproductive developmental effects by interfering with various hormonal pathways, disruption in general metabolism, producing acute toxicity, immune system effects (Kotz et al., 2012). These compounds often exert their effects at relatively low concentrations and through specific mode of action. Reduction of vulture population by consuming declofenac contaminated carcasses (Oaks et al., 2004), feminization of fish due to ethinylestradiol contaminated water obtained after sewage treatment are the examples of effect of PPCPs on living creatures (Shanmugam et al., 2014, Desbrow et al., 1998, Larsson et al., 1999, Thorpe et al., 2003, Kidd et al., 2007). Most pharmaceuticals are non-bioaccumulative and eliminated from human or animal body after administration. After passing through body metabolism, hydrophilic functions generally added in the molecule for their successful excretion with urine/ feces (Katzung, 2001). These compounds often exert their effects at relatively low concentrations and through specific mode of action.

PPCPs are used as antibacterial agents, these when released in waterways and sediments allowed bacterial flora to develop antibacterial resistance to those particular agents. The development of resistance to antimicrobial agents makes treatment of infections very difficult to cure; therefore this issue is an important consideration for the treatment of wastewater, especially that which is discharged from hospitals, veterinary clinics, or other locations where large amounts of antibiotics are used. Interplay of bacteria with antibiotics present in waste water make them resistant and increases their populations in waste water. Quaternary ammonium compounds (QACs) are cationic microbial compounds that are important ingredients in disinfectants, which are used in hospitals as well as households. They are known to inhibit the proper functioning of aquatic microorganisms, and they have a low biodegradability. Inhibitory effects have also been found against denitrifying bacteria in very low concentrations of QACs. In India, high resistance is observed in treatment of prevalent infectious diseases like pneumonia, tuberculosis, urinary tract infection, and infection of bloodstream and gut ('Hatching Superbugs', Down to earth, 1-15 August 2014).

The tendency for these compounds to persist or be only partially degraded during treatment or to bypass treatment altogether via sewage overflows will, therefore, contribute to their load in receiving waters, many of which serve as recreational and drinking water sources.

Some Advanced PPCP Removal Technologies

PPCPs include a wide range of compounds with different chemical and physical proprieties that affect their removal. Due to the low PPCP concentrations reported in wastewaters (ppb or ppt) and their complex chemical structure, common technologies used in sewage and drinking water treatment plants may not be efficient enough to accomplish their complete removal. Various bench- scale studies have been conducted for removal of PPCPs from polluted water. Coagulation, lime softening, activated carbon adsorption, biofiltration, chlorination, membrane bioreactor, photocatalytic treatment, ultraviolet photodegradation, ozonationation and advanced oxidation (AOP) are some of the methods tried in batch scale studies for removal of PPCPs from waste water. Information about physico-chemical characteristics such as acidity, lipophilicity, volatility and sorption potential is a useful tool to understand the different removal patterns observed. In the removal efficiency of biological treatment processes for PPCPs is related to hydrophobicity and to consequent adsorption in activated sludge, whereas more polar compounds are

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

released in the effluent (Heidler & Halden, 2008). In the conventional physical-chemical processes, surface water conventional treatments (i.e. coagulation, sand filtration, softening) frequently used as tertiary wastewater treatments, and are not efficient for the complete removal of organic micropollutants. Particularly, the use of aluminium sulphate, ferric chloride or lime removes less than 20% of many EDCs and PPCPs (Westerhoff et al., 2005).

Advanced treatments with high removal efficiencies of emerging contaminants are adsorption on activated carbon, nanofiltration (NF) and reverse osmosis (RO) (Snyder et al., 2007). However, the NF/RO processes produce a large amount of concentrate whose treatment and disposal is very expensive, therefore, their application is less suitable in inland areas. The typical doses used in disinfection by UV irradiation (< 40 mJ/cm^2) are unable to remove EDCs and PPCPs (removal efficiencies are often less of 20%) (Rosario-Ortiz et al., 2010). Ozone and chlorine oxidation are selective for the chemical structure and functional groups of PPCPs and EDCs, whose removal range between 90% with a prominent efficiency of ozonation (Westerhoff et al., 2005). However, chlorination and ozonation are known to lead to the formation of by-products that account for largely unidentified compounds to date. This issue raises concerns regarding their potential impact on the environment and human health. The AOPs, including ozonation which produces OH radicals in wastewater application, are able to degrade a wide range of emerging contaminants. Membrane processes are an effective mean to reduce the concentrations of several EDCs and PPCPs from drinking water and wastewater. The removal rate is related to membrane characteristics and to molecular properties of particular contaminant.

The performance of activated carbon depends on the properties of the activated carbon sorbent (surface area, pore size distribution, surface charge, oxygen content) and on the properties of the solute (shape, size, charge and hydrophobicity). Hydrophobic interactions are the dominant mechanisms of removal for most organic compounds in activated carbon adsorption systems. However, ion exchange interactions can result in removal of polar solutes (Crittenden et al., 1999; Matsumura et al., 1985; Youssef et al., 1982). As a result of the hydrophobic interactions, activated carbon efficiently removes most non-polar organic compounds. The ability of activated carbon to remove most polar compounds will depend upon the strength of the polar interactions. Tanghe & Verstraete (2001) showed that the sorption capacity of crushed granular activated carbon for nonyl phenol (NP) was at least 100 mg/g. Based on the results of their static adsorption tests, they concluded that a full-scale GAC filter unit would be adequate to remove environmentally relevant NP concentrations of 10 µg/L. Many other studies have been carried out for removing organic pollutants from contaminated water (Knappe et al, 1999; Rodriguez et al, 2016).

Biological activated carbon (BAC) consists of a pre-ozonation followed by a GAC filter which supports the growth of bacteria. This technology has been used for drinking water treatment and has proven to be able to significantly remove natural organic matter, ozonation by-products, disinfection by-products precursors as well as odour and taste compounds. Recently, it has been reported that BAC systems are very effective to remove EDCs and PPCPs (Gerrity et al., 2011; Reungoat et al., 2011). However, more studies are needed for a better evaluation of BAC removal efficiencies taking into account several operating conditions through full-scale applications. During IBAC treatment, the process of microorganisms immobilizing is of great complexity, which is not only related to various acting forces, but also involves microorganism growth as well as the ability for producing extracellular and external appendages (Collins et al., 2003). Although there is a relatively high repulsive force during the process when the bacteria approaching to the activated carbon, the bacteria will ultimately contact with the activated carbon under the bridging effect of EPSs (Takeuchi et al., 1996). There are various ways to immobilize microorgan-

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

isms, and any method with a limitation for free flowing of microorganisms can be used to produce and immobilize microorganisms, an ideal and universal application way for immobilizing microorganisms is still not available (Jin et al., 2013).

MICROBIAL POTENTIAL IN PPCP BIOREMEDIATION

Bioremediation is the technology of using biological agents particularly microorganisms, to remove toxic pollutants from the environment, particularly from soil and water. In case of bacteria, it can grow in both the aerobic as well as anaerobic conditions. Under aerobic conditions, bacteria use molecular oxygen as their terminal electron acceptor and in anaerobic conditions other compounds such as carbon dioxide is used (Figure 4).

This is a continuous method as it cannot be turned on or off because it is a living system, so constant source of nutrients are required for microbes. Aerobic bacteria is suitable for degrading organic compounds for the range of 50 to 4000 mg/l with some exception up to lower range while anaerobic bacteria can work in the range of 4000 to 50000 mg/l concentration (Nyer, 1992). It was also found that organic contaminants are mineralized and recycled more efficiently when a diverse microbial population is present (Torsvik & Øvreås, 2002). However the relationship between microbial diversity and biodegradation is not linear as many metabolic processes are carried out by a consortium rather than individual microbial species (Jjemba, 2004). Mixed microbial communities have the most powerful biodegradable potential because the genetic information of more than one organism is necessary to degrade the complex mixture of organic compounds present in contaminated sites.

Pollutants are decomposed to non-toxic substances through microbial metabolism (Pelczar, et al., 1993). In-general biodegradation process is based on two processes: growth and co-metabolism (Figure 5).

Microbes use naturally occurring as well as synthetic chemicals for growth by using these molecules as source of carbon, nitrogen, phosphorus, sulfur, energy and any other elements needed by the cells (Riser-Roberts, 1998). For all these processes, optimum conditions of pH, temperature, nutrient concentrations and target organic concentration below toxic limit for microbes should be maintained (Figure 6). The target organic pollutant should be compatible with microbes. Initial intracellular attack of PPCPs is an enzymatic reaction. These are oxidation reactions catalyzed by oxygenases and peroxidases. Oxygen

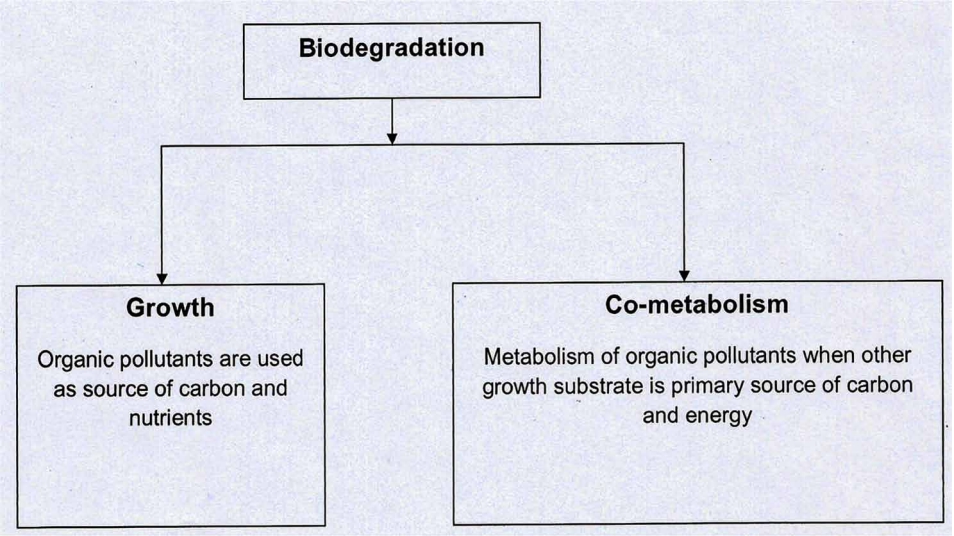
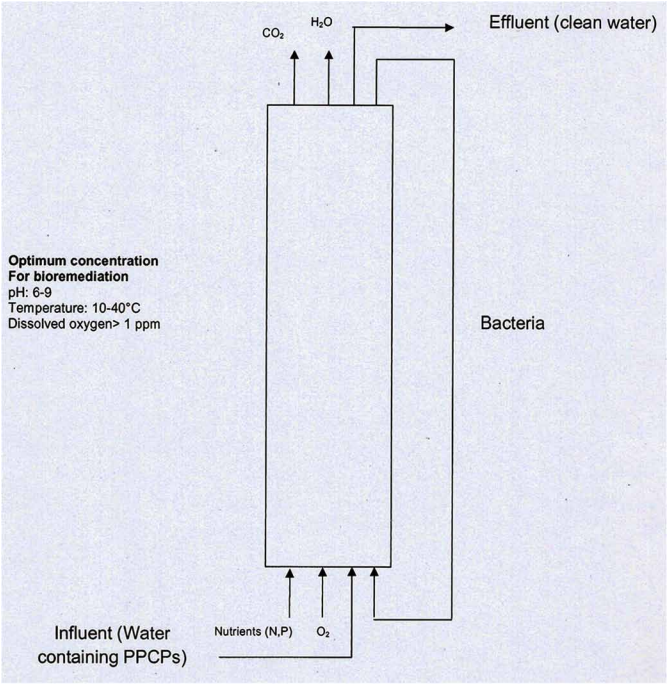
Figure 5. Biodegradation process in case of microbes



molecule is also required for respiration process. Peripheral degradation process converts organic pollutants into the intermediates of converts' organic pollutants into intermediates of tri-carboxylic acid (TCA) cycle, then biosynthesis of cell biomass takes place. In case of cometabolism, organic pollutants are transformed or degraded by microbes but they are unable to use the substrate as a source of energy or of one of its constituent elements.

Figure 6. Bioremediation of PPCPs contaminated water



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

In an aquatic system, the residence time of a pollutant and its distribution between water, sediments, and biota depends on its capacity to bound to suspended particles and accumulate in sediments. Thus, the affinity of hydrophobic organic compounds for biotic and abiotic phases is an important determinant of both the rate of a detoxification of water system and its response time to changing loadings. Polarity of these compounds determines their fate in potential matrices of environment. Non polar compounds generally more attracted towards soil colloids and sediments as also accumulate in biota (Heberer, 2002), while the polar PPCPs are more labile in the environment. Microbial degradation of any compound starts with low molecular weight compounds and proceeds to higher molecular weight compounds. Degradation of molecules proceeds through introduction of molecular oxygen into the structure of target molecule. Normal paraffin proceeds via terminal oxidation and subsequently β oxidation to yield C-3 units and carboxylic acid. In case of aromatic hydrocarbons, ring cleavage required de-hydroxylation reaction, introduction of both the oxygen atoms of the molecule in the aromatic ring and subsequent formation of cis- diol. Small molecules generate CO_2 and water after degradation but aromatic hydrocarbon yields phenolics and benzoic acid intermediates, which are then readily metabolized by β-oxidation and incorporated in TCA cycle with the uptake of some ATP (Figure 7) (Fritsche & Holrichter, 2005).

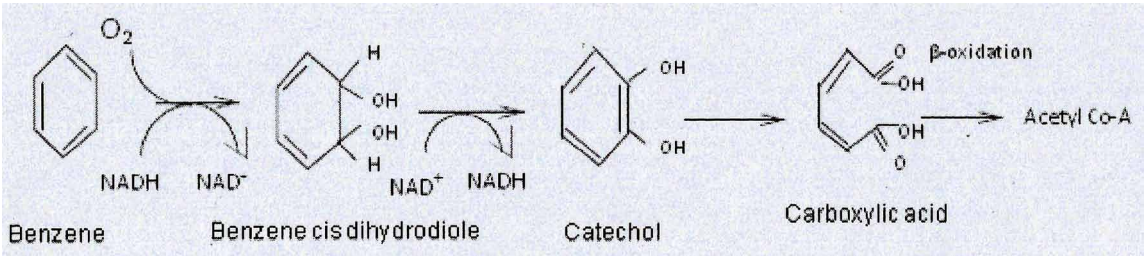
The distribution of non-polar organic compounds between water and natural solids (e.g., soils, sediments and suspended particles) or organisms, can be viewed in many cases as a partitioning process between the aqueous phase and the bulk organic matter present in natural solids or in biota (Schwarzenbach et al., 2004). Fate of their attachment to different environmental matrices can be determined through analyzing log of K_{ow} value of PPCPs. The octanol/water partition coefficient (K_{ow}) is defined as the ratio of a chemical's concentration in the octanol phase (C_o) to its concentration in the aqueous phase (C_{aq}) of a two-phase octanol/water system (Equation 1).

$$K_{aw} = \frac{C_O}{C_{aq}} \tag{1}$$

Values of K_{ow} represent the tendency of the chemical to partition itself between an organic phase (e.g., a fish, a soil) and an aqueous phase. Biological activity of selected organic pollutant can be correlated with log K_{ow} through the equation (2)

$$BR = a + b\log K_{ow} \tag{2}$$

Figure 7. Biodegradation of benzene to carboxylic acid



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

BR may be one of the large numbers of reactions of organisms after introduction of organic pollutants, a and b are the constants for particular system. When organic pollutants come in contact with the cell, then partitioning of the compound takes place from aqueous like phase to organic like phase, which is controlled by the partition coefficient of that compound. Hydrophobic compounds tend to accumulate in organisms because they are metabolized slowly and are effectively stores in tissues (Sangster J., 1997).

Compounds which are resistant to microbial attack can be rendered biodegradable by chemical treatment to yield low molecular weight carboxylic acid (Garg et al., 1994). Mode of degradation of compounds by microorganisms depends upon the nature of chain length of hydrocarbons along with its stereochemistry as well as species of microorganisms. Aliphatic organic compounds are more readily attacked than aromatic compounds by microbes. These are potential carbon and energy source for microbes so these are biodegradable (Bartha & Atlas, 1977). *Pseudomonads* (aerobic gram negative rods) were found to have immense potential of degrading organic compounds due to their catabolic enzymes along with their capability of metabolic regulations (Haughtan & Shanley, 1994). *Rhodococci* and *Corynaform* bacteria have also shown degradation capacity of organic compounds. Some bacteria under this group generate mycolic acid at the external surface of the cells which are long chain alcoholic and fatty acids, esterified to peptidoglycans of the cell wall. So these can work against the lipophilic/ hydrophobic organic compounds. Pharmaceutical and Personal care products also occur either as aliphatic or aromatic moieties with either polar or nonpolar nature. But major differences with other general organic compounds are that PPCPs are mainly designed to harm microorganisms responsible for infections. So selections of microbes from nature, which are not harmful, are essential.

Adsorption processes using activated carbons are widely used to remove pollutants from wastewaters and occurrence of large numbers of bacteria on GAC filters is well documented (American Water Works Association. 1981, Eberhardt, 1976). The microorganisms attached to the GAC then convert the biodegradable portion to biomass, carbon dioxide, and waste products before that material can occupy adsorption sites on the GAC. Biological Activated Carbon (BAC) process is developed on the basis of activated carbon technology, which uses the synergistic effect of adsorption on activated carbon and biodegradation to purify raw water. Activated carbon has a high specific surface area and a highly developed pore structure, so it is characterized by its great effect on absorbing dissolved oxygen and organics in raw water. For BAC technology, activated carbon is used as a carrier, by accumulating or artificially immobilizing microorganisms under proper temperature and nutrition conditions. The microorganisms will reproduce on the surface of the activated carbon and finally form BAC, which can exert the adsorption and biodegradable roles simultaneously (Qing & Jihua, 2006). Activated carbon is suited as supporting material by its large adsorptive surface (Andrew & Tien, 1981; Shimp & Pfaender, 1982). Microbes can take part in the degradation of harmful aromatic compounds as these are the growth substrate for microorganisms. The crucial step in their degradation is overcoming the resonance energy that stabilizes the ring structure (Fuchs et al., 2011). Inoculation and maintenance of bacteria with special degradation capabilities resulted in a lower consumption of GAC and thus to extended shelf life (Stucki & Thuer, 1994). Microorganisms which can carry out biodegradation in different environments are identified as active members of microbial consortiums. These microorganisms include: *Acinethobacter, Actinobacter, Acaligenes, Arthrobacter, Bacillins, Berijerinckia, Flavobacterium, Methylosinus, Mycrobacterium, Mycococcus, Nitrosomonas, Nocardia, Penicillium, Phanerochaete, Pseudomonas, Rhizoctomia, Serratio, Trametes* and *Xanthofacter* (Singh et al., 2014). Species of *Candida* and *Pseudomonas* have been used for their immobilization on activated carbon. Phenol adsorbed on carbon surface was 90% degraded by microbes (Ehrhardt & Rehm, 1985).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

The relationship between the activated carbon and contaminants is simply the effect of adsorption on activated carbon, and the reaction depends on the properties of the activated carbon and contaminants. Meanwhile, the activated carbon can absorb dissolved oxygen (DO) and microorganisms which were adsorbed on the surface of activated carbon, feed on DO will biodegrade contaminants. The activated carbon used in BAC process, should be highly developed in the pore structure, especially for the filter pores. The basic principle of immobilization biological activated carbon (IBAC) is screening and acclimation dominant bio-community from nature, followed by immobilizing the community on activated carbon, to enhance the efficiency and rate of degradation. Meanwhile, dominant biocommunity should be nonpathogenic and has strong antioxidant capacity and enzyme activity which enable the growing and reproducing under poor nutrition environment. Therefore, the effect of biodegradation after activated carbon adsorption saturation is highly improved by Immobilization BAC (Scholz & Martin, 1997; Wang & Luo, 2003). Due to large surface area available for degradation of pollutants by microbe (Bancroft et al., 1983), biological activated carbon can be a better approach in combination with other conventional or advanced methods to solve the problem of PPCPs present in different matrices of environment.

FUTURE RESEARCH DIRECTIONS

PPCPs are a group of diverse chemicals consumed as drugs, cosmetics, as well as in agriculture etc. These compounds can easily become a part of fresh water resources either through agricultural runoff or through the addition of untreated or partially treated sewage water containing the waste water of household and industries. Various technologies are available for the treatment of waste water, and a lot of work on removal of PPCPs from waste water is also going on. Still in many areas of the world, even the preliminary screening of PPCPs in water resources is lacking, so the first requirement is to assess the concentration of these compounds in water resources (both the surface and ground water) used for the purpose of drinking. After getting the exact concentration of these compounds, the removal technologies should be used accordingly.

So, future area of research on PPCPs removal may be classified in two parts. First will be their assessment and quantification in existing water resources and their possible point sources and then the development of suitable removal technology for PPCPs based on their concentration in the area. As these compounds are harmful at very low concentration and varies in their physico-chemical properties, so no single removal technologies will be able to solve the problem. Combination of existing removal technologies with bioremediation process will be helpful for removal of these harmful compounds from water. In Bioremediation, microbes use these compounds as source of energy or as secondary substrate. So selection of suitable microbes for biodegradation of PPCP compounds present in waste water will be required. This will be helpful for utilization of microbes for bioremediation directly in the sludge or in the form of biological activated carbon.

CONCLUSION

Chemicals used as PPCPs are being released into the environment in extremely large quantities on a regular basis. Exact effect of these compounds on human system is not yet completely known, still based on some studies their harmful effects cannot be ignored. These compounds are tremendously harmful in

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

respect to environmental and human health at very low concentration even at microgram level, therefore, effective and efficient removal technologies need to be developed to treat the contaminated effluents in order solve this dreaded problems. As bioremediation using microbes is based on biodegradation of pollutants and these living cells of microorganisms are able to degrade organic compounds at very low concentration, this could be play important role in this respect as an ecofriendly efficient technology for removing PPCPs from waste water.

KEY TERMS AND DEFINITIONS

Activated Carbon: It is a highly porous carbonaceous substances composed by carbon atoms having potential adsorption properties.

Biodegradation: Degradation of materials using biological systems e.g. enzymes generated by microbes etc.

Bio-Magnification: Accumulation of any toxic substance in living cells.

Bioremediation: Removal of pollutants using biological materials e.g. microbes, plants etc.

Hydrophilic: Material which attract water.

Hydrophobic: Material which repel water.

Partition Coefficient: Ratio of distribution of any compound between two immiscible mediums.

Water Partition Coefficient: It refers to ratio of concentrations of a compound in a mixture of two immiscible phases at equilibrium.

This research was previously published in the Handbook of Research on Inventive Bioremediation Techniques edited by Jatindra Nath Bhakta; pages 451-469, copyright year 2017 by Engineering Science Reference (an imprint of IGI Global).

Chapter 53
Treatment of Landfill Leachate by Anammox Process

Grzegorz Cema
Silesian University of Technology, Poland

Adam Sochacki
Silesian University of Technology, Poland & Czech University of Life Sciences, Czech Republic

ABSTRACT

In most cases, the anammox process is used for nitrogen removal from reject water coming from dewatering of digested sludge. However, there are more industrial streams suitable for treatment by partial nitritation/anammox process. The landfill leachate may be a good example of such wastewater. Generally, landfilling is the most used solution for treatment of urban solid wastes. The problem with landfill leachate production and management is one of the most important issues associated with the sanitary landfills. These streams are highly contaminated wastewater with a complex mixture of organic and inorganic compounds and characterized by a high ammonia content and low biodegradable organic fraction matter. The objective of this chapter is the short characteristic of landfill leachate and a short review of its treatment methods with special focus on nitrogen removal by partial nitritation/anammox process.

INTRODUCTION

In Europe, the total amount of landfilled municipal waste has been diminishing, due to European Commission Council Directive (Council Directive 1999/31/EC). Nevertheless, landfilling of the municipal waste is still a common practice in the waste management system in some European countries and the rest of the world because it is the simplest and cheapest method of waste disposal. Even discontinuation of landfilling in the EU will not instantaneously eliminate the problem related to landfill leachates because even closed and capped landfills will produce these wastewater streams. Such waste management option has several negative impacts on the environment. The major potential environmental impact related to landfill leachate generation is pollution of groundwater and surface water (Kjeldsen et al., 2002). The problem with landfill leachate production and management is one of the most important issues associated

with the sanitary landfills. These streams are highly contaminated wastewater with a complex mixture of organic and inorganic compounds and are characterized by high ammonia concentrations and low biodegradable organic fraction matter content. High loads of refractory compounds, the low value of BOD_5 (five days Biochemical Oxygen Demand) to COD (Chemical Oxygen Demand) ratio and high concentration of nitrogen cause that this kind of wastewater is complicated and expensive for treatment, as well as requires various processes to be effective (Kaczorek & Ledakowicz, 2006). The changes in waste management caused by the EU directives resulted in reduced volume of leachate produced per tonne of waste landfilled and thus increased leachate strength (Brennan et al., 2015).

Both physical/chemical methods and the biological process can be used to treat landfill leachates. In spite of stable treatment effects, and preferable adaptability to the changes of wastewater quantity and quality, physical/chemical methods have several shortcomings: odors, air pollution, high chemical costs and high energy consumption. The main reason for the selection of a biological process for nitrogen removal is the lower cost compared to the physicochemical methods. Conventional biological nitrogen removal with the use of nitrification/denitrification is probably the most efficient process to eliminate nitrogen from leachate; however, the biodegradable carbon to nitrogen ratio necessitates the use of external carbon source for complete denitrification. Additionally, the nitrification process requires high energy input for aeration. For these reasons, it was important to obtain technology that facilitates enhanced nitrogen removal under the conditions of low carbon availability and with low energy requirements for nitrification. During the last two decades, the possibility of treatment of highly loaded streams with low C to N ratio by partial nitritation and the anammox process has been tested and demonstrated. However, up to now, there are still very few studies reporting the use of anammox process to treat landfill leachate.

CHARACTERISTICS OF LANDFILL LEACHATE

Landfill leachate is generated by the rainwater infiltrating through the landfill site, the surface and groundwaters flowing into the site as well as water present in the wastes and generated as a result of organic matter degradation. The quality and the quantity of leachate is mainly related to: chemical and physical properties of waste, volumes of infiltrating water, environmental conditions, the landfill age and also storage and reclamation techniques (Christensen et al., 2001; Kulikowska & Klimiuk 2008; Müller et al., 2015).

Generally, the discharge from landfill depends on rainfall, evaporation losses and redistribution in time of infiltrating water in the soil cover and in the waste deposited. The water infiltrating into the site may be transpired to the atmosphere, evaporated from the surface soil, stored in cover soil or percolate downwards through the cover (Peyton & Schroeder 1993; Bengtsson et al., 1994). The water balance on the landfill site can be summarized as follows (Blakey, 1992):

$$L = P - R - \Delta U_s - ET - \Delta U_W \quad (1)$$

where: L – leachate production, P – precipitation, R – surface run-off, ΔUs – change in soil moisture storage, ET – actual evaporative losses from the bare-soil/evapotranspiration losses from a vegetated surface, ΔUw – change in moisture content of the refuse components.

Leachate is known as wastewater whose treatment is very complicated and expensive as its composition is variable from different landfills and, moreover, its composition is changing with the landfill age.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

For this reason, the treatment methods have not been unified so far (Kaczorek & Ledakowicz 2006; Kulinowska & Klimiuk 2008). The components present in the leachate usually have different origins. However, four main groups of compounds may be distinguished (Alkalay et al., 1998; Christensen et al., 2001; Kjeldsen et al., 2002): dissolved organic matter, inorganic macro-components, heavy metals and xenobiotic organic compounds. Generally, it is stated that low BOD_5/COD ratio, the presence of heavy metals and high concentration of nitrogen compounds are the most important problems associated with landfill leachate treatment (Kaczorek & Ledakowicz 2006; Renou et al., 2008).

As landfill leachate contains numerous categories of contaminants, like organic compounds, ammonia, refractory macro and micropollutants and heavy metals, it may be toxic to the aquatic environment. Additionally, the leachate composition is unstable, and furthermore the toxicity of leachate is a consequence of its composition as well as their synergistic or antagonistic effect and different physical-chemical properties (Alkalay et al., 1998; Bloor & Banks, 2005; Kalka, 2012; Marttinen et al., 2002; Słomczyńska & Słomczynski, 2004; Ribé et al., 2012). Thus, the physicochemical methods of leachate characterization should be accompanied with the toxicity tests to get more specific information about the potential environmental impact (Kalka, 2012; Oliveira et al., 2014). Research conducted by Ribé et al. (2012) showed that even treated landfill leachate may still have an acute toxic effect on aquatic organisms. Kalka (2012) studied the change of toxicity of landfill leachate in the function of landfill age in combined treatment with municipal wastewater. The leachate was mixed with the municipal wastewater in different ratios (1 and 10%) and then treated in a lab-scale A2O system (Anaerobic-Anoxic-Oxic activated sludge system). The toxicity of raw and treated wastewater was determined using toxicity tests with *Daphnia magna, Thamnocephalus platyurus, Vibrio fischeri* and *Raphidocelis subcapitata*. The toxicity of this wastewater declined during treatment, however still it was harmful to all tested organisms. It was stated, that the concentration of landfill should be only 0.05% not to be harmful to aquatic organisms (Kalka, 2012).

It is also very important that the composition of landfill leachate is not stable and undergoes changes with time. These changes in time are related to the seasonal changes and what is even more important with the age of landfill. Generally, the leachate may be characterized with its biodegradability which is decreasing with landfill age (Kulikowska & Klimiuk, 2008, Lo, 1996, Renou et al., 2008, Yao, in press). In young landfills (usually up to 5 years) there is an acidogenic phase and as a consequence, the leachate contains large amounts of readily biodegradable carbon with volatile fatty acids (VFA) as the main product (Renou et al., 2008; Słomczyńska & Słomczyński, 2004; Welander et al., 1997). Generally, young landfills are characterized by the pH in the range of 3.7 – 6.5 (as a result of presents carboxylic acid and bicarbonate) and high biodegradability as the BOD_5/COD ratio ranges from 0.2 to 0.7. The BOD_5/COD ratio of leachates decreases from 0.7 to 0.1 and even less with the aging of landfills, thus becoming less biodegradable. Additionally, the pH for old landfills rises to 8.0-8.5 (Kulikowska & Klimiuk, 2008, Renou et al., 2008; Słomczyńska & Słomczyński, 2004). The landfill leachate may be characterized by the basic standard parameters: COD, BOD, BOD/COD, suspended solids, pH, ammonium nitrogen, total Kjeldahl nitrogen (TKN) and heavy metals (Renou et al., 2008). Table 1 summarizes the composition of landfill leachate in terms of standard wastewater parameters based on different studies.

The landfill leachate contains a high concentration of ammonium nitrogen which can vary from less than 100 mg/l in low-strength leachate to over 5000 mg/l and more for high-strength leachate. The ammonium nitrogen, especially in the form of free ammonia is toxic to the aquatic environment and can also disturb the biological treatment of landfills leachate, so it should be removed from this wastewater stream. However, the BOD_5/N-NH_4 ratio for young leachate is usually larger than 1, conversely, for older

leachate this ratio is very often lower than 1 (Słomczyńska & Słomczyński, 2004). As a result of high nitrogen concentration and, additionally, unfavorable nitrogen to biodegradable organic carbon ratio the nitrogen removal from landfill leachate is complicated and there is no standard method.

LANDFILL LEACHATE TREATMENT METHODS REVIEW

The landfill leachate treatment technologies can be based on biological, physical-chemical or integrated methods (Wiszniowski et al., 2006a). The treatability of landfill leachate depends on its composition and characteristics (Kurniawan et al. 2006). The application of biological processes for the treatment of landfill leachates is a challenging task due to their complex matrix and high toxicity. Consequently, some physical-chemical methods are needed either as a pretreatment step or a polishing step (Wiszniowski et al., 2006a). Renou et al. (2008) proposed that the treatment methods for landfill leachate can be classified into three groups:

1. Leachate transfer including recycling and combined treatment with municipal wastewater,
2. Biodegradation: aerobic and anaerobic processes,
3. Chemical and physical methods:

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

a. Chemical oxidation,
b. Adsorption,
c. Chemical precipitation,
d. Coagulation/flocculation,
e. Sedimentation/flotation,
f. Air stripping,
g. Struvite precipitation, and
h. Membrane processes.

Combined Treatment with Municipal Wastewater

Both co-treatment and recycling of landfill leachate were common methods used for the indirect treatment of this waste stream (Renou et al., 2008). The application of these methods was detrimental to the treatment efficiency at the municipal wastewater treatment plants and was found to inhibit methanogenesis in the mound (Renou et al., 2008). Quant et al. (2009) investigated the co-treatment of municipal wastewater with increasing, from 1 to 5% (vol.), quantity of landfill leachate in the A2O system. It was possible to achieve high BOD_5 and COD removal exceeding 90%. However, there was also a significant increase in nitrogen concentration in the effluent. Additionally, the addition of leachate caused a significant drop in phosphorus removal. Çeçen & Çakiroğlu (2001) studied the influence of landfill leachate added to domestic wastewater in a volumetric ratio from 5 to 20%. They observed extensive nitrification, however the nitrite accumulation was also observed. It was as a result of an increase in the initial NH_4-N concentration and the same the increase of free ammonia concentration what caused the nitrite build-up. Ferraz et al. (2014) used pilot-scale submerged aerobic biofilter for co-treatment of leachate (pretreated by air stripping) with domestic wastewater and observed high efficiency of this treatment method with an optimum volumetric ration of the leachate of 2%. However, in other study, Kalka (2012) showed that even 1% (vol.) of leachate addition to municipal wastewater can cause acute toxicity to aquatic organisms. Noteworthy, the accepted maximum volume of leachate to be co-treated at a municipal wastewater treatment plant is based on the annual influent hydraulic loading and is regulated by the respective authorities (e.g. 4% in Ireland) (Brennan et al., 2015). In a recent article, Brennan et al. (2015) pointed out that increasingly stringent wastewater treatment plant discharge limits may disrupt sustainability of co-treatment of landfill leachate with municipal wastewater. This is also because high leachate production coincides with high maximum hydraulic loading at municipal treatment plants as suggested by Brennan et al. (2015).

Biological Treatment

Biological methods for landfill leachate treatment are commonly used for the treatment of leachate containing a high concentration of BOD. This is a reasonable treatment especially for the young leachate (high biodegradable carbon to nitrogen content). In the case of stabilized leachate, problems with achieving permitted COD levels due to recalcitrant characteristics of organic carbon in the leachate may be encountered. Another problem is related to the toxicity of high concentration of ammonia nitrogen. Generally, the biological nitrification and denitrification are probably the most common methods for elimination of nitrogen from leachate mainly because they are well-known processes. Problems associated with nitrification and denitrification of landfill leachate are associated with ammonia toxicity,

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

low temperature during the winter time and lack of biodegradable organic carbon, especially in mature leachate. Hoilijoki et al. (1999) studied the nitrification process of landfill leachate at low temperature. They tested three different temperatures: 10, 7 and 5°C in two kinds of activated sludge reactors. One was with the addition of plastic carrier material (ASC) and the second one without (AS). In both reactors complete nitrification was achieved at temperature 10°C, at 7°C the nitrification efficiency was decreased to 93% and finally at 5°C in the ASC reactor the complete nitrification was achieved after reducing the nitrogen load from 0.023 g NH_4-N/g MLVSS to 0.01 g NH_4-N/g MLVSS. At the same time, in the AS reactor the nitrification efficiency was only 61%. Also, Isaka et al. (2007) conducted nitrification at 10°C using nitrifying bacteria immobilized in a polyethylene glycol gel carrier material. The stable ammonium oxidation was maintained for more than one year. However, due to the low affinity of immobilized nitrifying bacteria for ammonium, in the effluent from the reactor, the ammonium nitrogen at low concentration was detected. Moreover, the nitrite oxidizing bacteria were inhibited by the free ammonia present in the reactor. Welander et al. (1997) investigated nitrification and denitrification of landfill leachate at temperature varied from 10 to 26°C. They proved that in such condition it is possible to sustain complete nitrification and denitrification using suspended carrier biofilm reactor. In the case of the denitrification process the carbon to nitrogen ratio is one of the most important issues. Generally, in landfill leachate there is a deficiency of biodegradable carbon, thus the artificial carbon source should be added. Usually acetic acid (Welander et al., 1997), sodium acetate (Kaczorek & Ledakowicz, 2006) or methanol (Kulikowska & Klimiuk, 2004) are used as a carbon source for denitrification.

An interesting and low-cost technology for leachate treatment is the use of constructed wetlands (CWs) (Białowiec et al., 2012; Kadlec & Zmarthie, 2010; Nivala et al., 2007; Yalcuk & Urgulu, 2009; Miksch et al., 2015). CWs have been shown to be very effective in the treatment of landfill leachate and additionally they have low operational and maintenance requirements (Yalcuk & Urgulu, 2009). The main types of CWs that could be used for the on-site treatment of landfill leachate are free water surface systems, and subsurface flow systems with either vertical or horizontal flow (Kadlec &Zmarthie, 2010). Ammonia can be efficiently removed in vertical flow CW due to their elevated oxygen transfer rate. Horizontal flow CWs and free water surface CWs are more effective for denitrification and may follow vertical flow CWs in order to remove nitrates and some poorly biodegradable organic compounds and residual metals via multiple-mechanism pathway including biotic and abiotic processes (Kadlec & Zmarthie, 2010). Due to the carbon deficiency of the wastewater treated in vertical flow CWs it may be necessary to add external carbon source for denitrification in the subsequent treatment steps unless the carbon generated in the CWs is sufficient (Kadlec & Wallace, 2009; Rustige & Nolde, 2007). The combination of several low-energy treatment steps offered a very high mass reduction of ammonia (99.5%) and several other contaminants (including metals and trace organics) in a well-documented system in Saginaw Township, MI, USA (Kadlec & Zmarthie, 2010). This system consists of a sedimentation basin (preceded with cascade aeration), vertical gravel beds and free water surface CWs. Białowiec et al. (2012a) showed that horizontal flow CW with reed and willow can effectively remove ammonium nitrogen. In the research performed by Nivala et al. (2007) it was shown that in spite of seasonal variation in leachate composition, and additionally in temperature, the ammonium nitrogen removal may be stable with very high efficiency exceeding 90% when horizontal flow system with forced aeration is used. Sawaittayothin and Polprasert (2007) showed that using subsurface-flow CW it is possible to remove even over 90% of total nitrogen. Kadlec and Wallace (2009) suggest, however, that multiple cells or multiple units should be used to provide very high removal efficiency. This is because of the constraint of hydraulic efficiency. Leachate quality may be detrimental to some wetland plant species, therefore species that can tolerate

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

elevated concentrations of ammonia should be used and additionally recirculation of treated effluent may be needed to protect the plants (Kadlec & Wallace, 2009). The elevated concentrations of Fe and Mn in landfill leachate may reduce hydraulic conductivity of bed medium of subsurface flow CWs and cause clogging. According to Urbanc-Berčič (1996) the application of aerated lagoon and a sedimentation lagoon as a pretreatment step prior to subsurface flow CWs could efficiently reduce the risk of clogging. Interestingly, Sun and Austin (2006) demonstrated through mass-balance analysis that the CANON (Completely Autotrophic Nitrogen Removal Over Nitrite) process took place in a subsurface vertical flow experimental columns treating landfill leachate containing high ammonia concentration but low BOD. The overall removal of total nitrogen in one of the columns was 52% and was partly associated with CANON process. Indeed, Zhi et al. (2015) found that anammox was one of the primary processes responsible for efficient performance (76% removal of ammonia nitrogen and >81% removal of TN) of experimental tidal flow (fill-and-drain operation) CWs treating artificial wastewater (not a landfill leachate). Zhu et al. (2011) presented an integrated approach to sustain high anammox bacteria activity and biodiversity in the microcosm CW. Further studies are needed to evaluate the feasibility of using CW with enriched anammox for long-term treatment of various types of wastewater including landfill leachate.

Physical-Chemical Treatment

The physical-chemical methods for the treatment of landfill leachate are used as a pre-treatment step, polishing step or as a main process for the removal of major contaminant (e.g. air stripping of ammonium) (Renou et al., 2016).

Air stripping is the most common method for the elimination of ammonium from various types of wastewater (Anfruns et al., 2013; Kurniawan et al., 2006; Marttinen et al., 2002; Renou et al. 2008). For this method high pH is required. Ozturk et al. (2003) studied the ammonia stripping from landfill leachate. After 2 hours of aeration at pH equal to 12 the ammonium removal efficiency was 72%, while it was only 20% at pH equal to 10 and 11. Also, Hasar et al. (2009) investigated ammonia air stripping as a pretreatment step before biological treatment. They tested four different pH values 9.0, 10.0, 11.0 and 12.0 at different air flow rates and contact time. The best results were obtained for pH 11.0 and 12.0 and were equal to 91.7% and 93.3% respectively. Guo et al. (2010) showed that at pH 11 and 16 hour contact time it is possible to remove over 96% of the ammonia. However, the drawback of this method is the necessity of pH adjustment and that the contaminated gas phase must be treated (Renou et al., 2008).

The struvite precipitation is another method used for ammonia removal from landfill leachate. Li et al. (1999) showed that ammonium may be effectively reduced as magnesium ammonium phosphate (MAP) within 15 minutes, when $MgCl_2 \bullet 6H_20$ and $Na_2HPO_4 \bullet 12H_2O$ were applied with Mg_2^+:NH_4^+:PO_4^{3-} molar ratio of 1:1:1. As usually there is a lack of the Mg_2^+ and PO_4^{3-} in the landfill leachate, and there is demand for large amounts of these compounds, Huang et al. (2014) proposed the waste phosphoric acid as phosphorus source and low cost of MgO obtained from calcinations of magnesite. The obtained ammonia nitrogen removal was 83% with Mg:N:P ratio of 3:1:1. Using low-cost of phosphate and magnesium source enabled to reduce chemical cost by 68%.

Adsorption can be used to reduce the concentrations of COD and ammonium nitrogen. Activated carbon (granular or powder) is the most commonly used adsorbent and it allows for 50-70% removal of both COD and ammonia nitrogen (Wiszniowski et al., 2006a). The aim of using activated carbon is to:

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

1. Remove residual heavy metals and recalcitrant organic pollutants in the final treatment steps, and
2. To provide growth support for microorganism and thus enhance biodegradation.

Other absorbents provided elimination efficiencies comparable with those achieved with activated carbon. These adsorbents are: zeolite, vermiculite, illite, keolinite, activated alumina, municipal waste incinerator bottom ash (Abbas et al., 2009) and clinoptilolite (Wang et al., 2006).

Coagulation-flocculation has been successfully used for the treatment of landfill leachate both as pre- and post-treatment step (Abbas et al., 2009). The coagulation processes served as a pre-treatment step prior to membrane bioreactor and reverse osmosis and it allowed for 36% and 46% removal of COD and suspended solids, respectively (Hasar et al., 2009). The coagulants commonly used in the treatment of landfill leachate are: aluminium sulphate (alum), ferrous sulphate, ferric chloride and ferric chlorosulphate (Wiszniowski et al., 2006a). One of the main drawbacks of coagulation is the production of large volumes of sludge and increased concentration of aluminium or iron (Abbas et al., 2009), and when coagulation is used as a pre-treatment prior to membrane processes, membrane fouling (scaling) may occur mainly due to application of lime or sodium hydroxide to control the pH (Wiszniowski et al., 2006a).

The main membrane processes applied in landfill leachate treatment are: microfiltration, ultrafiltration, nanofiltration and reverse osmosis (Renou et al., 2008). Hasar et al. (2009) stated that reverse osmosis and nanofiltration have been used alone to treat the water, whereas microfiltration and ultrafiltration have been coupled with other processes namely biological treatment and as pre-treatment for other membrane processes (Renou et al., 2008). For nanofiltration, nearly 60-70% removal of COD and 50% removal of ammonia nitrogen were widely reported, whereas reverse osmosis provided at least 98% removal of COD and 99% of heavy metals (Abbas et al., 2009). Wiszniowski et al. (2006a) identified fouling and the need to treat the retentate as the main drawbacks of the membrane processes. Also the combination of membrane processes with activated sludge technology in membrane bioreactors seems a viable technology for the treatment of wastewaters with high organic and nutrient loadings and offered removal of COD and total nitrogen as high as 90% in a single bioreactor at SRT of 30 d (Hasar et al., 2009).

Chemical oxidation (including advanced oxidation processes, which are based on the generation of highly reactive hydroxyl radicals) is widely studied and applied to remove recalcitrant organics from various types of wastewater including landfill leachate and offers high removal efficiencies for a wide range of organic pollutants (Renou et al., 2008; Miksch et al., 2015). Chemical oxidation methods can be used to fully mineralize (as a final treatment step) the target pollutants or to increase biodegradability of contaminants prior to biological treatment. Advanced oxidation processes are recommended for the treatment of industrial wastewater with relatively low COD (<5 g/L), which is due to high energy and reagents consumption (Miksch et al., 2015). Chemical oxidation techniques have been regarded as expensive, but the operation cost can be decreased when hybrid processes are used (e.g. with biological methods) and when sunlight-induced photodegradation (preferably with a catalyst) is used. Indeed, a combination of CWs with sunlight-induced photodegradation is a promising low-cost solution for treating various types of wastewater (Liu et al., 2015). Photocatalytic post-treatment (UVC with TiO_2 catalyst) of biologically treated leachate caused further removal of more than 80% refractory organics remaining in the leachate (Wiszniowski et al., 2006b). In a recent study, a combination of persulfate and hydrogen peroxide was applied to treat landfill leachate and 81% removal of COD and 83% removal of ammonia nitrogen was observed (Hilles et al., 2016). The treatment of landfill leachate in an O_3/H_2O_2-based advanced oxidation system resulted in 48% reduction of COD, enhanced biodegradability of 0.7 (from 0.1) and color removal of 94% (Tizaoui et al., 2007). Deng & Englehardt (2006) reviewed various

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

studies related to the application of conventional Fenton process, photo-Fenton, electro-Fenton process to the treatment of landfill leachate to observe that the range of COD removal was 45-85% and that the biodegradability was enhanced up to 0.60 (as BOD_5/COD ratio). Despite high removal efficiency and low operating cost (in comparison to other chemical oxidation methods), Fenton treatment of landfill leachate may be limited as:

1. Some organic compounds are recalcitrant to this method,
2. Significant amount of acid needed to adjust the pH of typical leachate,
3. Slow initial kinetics at temperature less than 18.3°C (Deng & Englehardt, 2006).

Also electrochemical oxidation was proposed as an efficient method for the treatment of landfill leachate as it offered maximum removal efficiencies as high as 90% for COD, almost 100% for ammonia nitrogen and 86% for color (Deng & Englehardt, 2007). The drawbacks of this process that may somewhat limit its application are high energy consumption and potential chlorinated organics formation may limit its application (Deng & Englehardt, 2007).

LEACHATE TREATMENT USING ANAMMOX PROCESSES

Because of requirements for high oxygen input and external carbon source addition, treating nitrogen-rich streams with nitrification/denitrification would become expensive and unsustainable. The least resources consuming pathway for the conversion of ammonium to nitrogen gas is a combination of partial nitritation and anammox processes. The main advantages of this combined processes compared to the conventional nitrification/denitrification are: low sludge production, decrease in the aeration costs by almost 60% (only half of the ammonia is oxidized to nitrite in the nitritation process without further oxidation to nitrate), and no need for external organic carbon source addition (anammox process) (De Clippeleir et al., 2011; Mulder, 2003). Furthermore, anammox bacteria oxidize ammonium under anoxic conditions with nitrite as the electron acceptor, and converse energy for CO_2 fixation, which resulted in 90% reduction of CO_2 emission in comparison to nitrification-denitrification. Additionally, the biomass yield of the anammox process is very low (0.08 kg VSS kg NH_4-N^{-1} in comparison to 1 kg VSS kg NH_4-N^{-1} in conventional nitrification/denitrification process) consequently, little sludge is produced. The low sludge production is another factor that contributes to the substantially lower operation costs compared to conventional denitrification systems. However, the low biomass yield also demands efficient sludge retention (Strous et al., 1997).

Partial Nitritation

As the anammox process requires nitrite nitrogen as electron acceptor, the partial nitritation is needed as a preceding step and for its application in wastewater treatment, different set-ups are used to provide nitrite: in the single reactor systems (Van der Star et al., 2007; Cema, 2009) or in the two-reactor systems (Kartal, 2008; Vázquez-Padín et al., 2009; Cema, 2009). In the two-step process part of the ammonium nitrogen is converted to nitrite in the first reactor which is followed by an anoxic reactor where the anammox process occurs. Separation of nitritation and anammox processes in space allows flexibility and more stable process performance since both steps can be controlled separately (van Hulle et al.,

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

2010).The partial nitritation may be achieved in several ways like using high temperature to promote ammonium oxidizing bacteria (AOB) growth over nitrite oxidizing bacteria (NOB) or by changing other parameters like pH or dissolved oxygen. Kulikowska (2012) investigated partial nitritation followed by denitrification in a two-stage SBR system treating mature landfill leachate. The operational temperature of the system was equal to 20±2°C. It was shown that for oxygen concentration between 1.2 and 1.3 mg O_2/l the nitrite accumulation ratio was between 32 and 37%, whereas with the decrease in the oxygen concentration to 0.8 – 0.9 mg O_2/l the nitrite accumulation ratio increased to 96%. Fudala-Książek et al. (2014) showed that during the co-treatment of landfill leachate with municipal landfill leachate, the volumetric addition of leachate up to 10% promoted the partial nitritation if the oxygen concentration was in the range from 0.5 to 1.5 mg O_2/l and free ammonia ranged from 2.01 to 35.86 mg N/l. Li et al. (2013, 2014) achieved stable partial nitritation using endpoint pH control which was necessary to get nitrite-to-ammonium ratio suitable for the anammox process. The high free ammonia and low dissolved oxygen were also necessary to inhibit the nitrite oxidation. The other possibility to achieve partial nitritation was to operate the process at high temperature (over 30°C) and with low sludge retention time to wash out nitrite oxidizers from the system (Akgul et al., 2013; Ganigué et al., 2007; Sri Shalin & Joseph, 2012). Gabarró et al. (2012) showed that for leachate with very high concentration of ammonium nitrogen (around 6000 mg N/l) it was also possible to get stable partial nitritation. At temperature 25°C the free nitrous acid was responsible for inhibition of NOB whereas at temperature equal to 35°C the combination of free ammonia and free nitrous acid was responsible for suppression of NOB.

Anammox

The anammox process is considered as a technology specifically used for nitrogen rich wastewater with deficiency of organic carbon. This process, in combination with partial nitritation, was successfully used for the treatment of landfill leachate. The single-reactor process of partial nitritation/anammox was first observed in a rotating biological contactor (RBC) for the treatment of landfill leachate in Mechernich, Germany (Hippen and Rosenwinkel, 1997), Kölliken, Switzerland (Siegrist et al., 1998) and Pitsea, Great Britain (Schmid et al., 2003). Up to now, there is over 100 full scale applications of the anammox process (Lackner et al., 2014). Most of these installations are used for reject water treatment, however, there has been very intensive research on the application of the anammox process to landfill leachate treatment (Akgul et al. 2012; Cema et al., 2007; Miao et al., 2012; Scaglione et al., 2012; Sri Shalini & Joseph, 2012; Wang et al., 2014). Zhang & Zhou (2006) showed the possibility of nitrogen removal from landfill leachate by the anammox process performed in the Upflow Anaerobic Sludge Blanket Reactor (UASB). The leachate treated in UASB was the leachate mixture blended with leachate and effluent of SBR system. The average removal efficiency of total nitrogen was 79.6%. Cema et al. (2007) used RBC for landfill leachate treatment by the anammox process. They demonstrated that nitrogen removal by anammox process is possible at a temperature below 20°C. Scaglione et al. (2012) demonstrated the use of single-stage partial nitritation/anammox SBR with granular anammox biomass for the treatment of landfill leachate. Akgul et al. (2012) demonstrated the nitrogen removal using anammox process from young landfill. In order to remove high organic content, which can inhibit the anammox bacteria, the biodegradable carbon was removed in UASB reactor and a membrane bioreactor in sequence, and the effluent was given to the SHARON (Single reactor system for high activity Ammonium Removal Over Nitrite) reactor were partial nitrification takes place and then to the anammox reactor. In such system

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

the COD and nitrogen removal efficiency exceeded 90%. Miao et al, (2014) demonstrated a three stage SBR comprising: pretreatment of organic matter, nitritation and anammox for nitrogen removal from mature leachate. The nitrogen removal efficiency reached 90%.

Heavy Metals Inhibition

Landfill leachate is characterized by high concentration of COD and ammonium nitrogen and especially in the case of old landfills by low COD to nitrogen ratio. This causes that, generally, landfill leachates are difficult to be treated by biological methods. Additionally, they can contain several heavy metals and high salinity which may lead to process inhibition. In Table 2 heavy metals concentration in landfill leachate and the IC_{50} for the anammox are presented.

Kimura and Isaka (2014) studied the effect of heavy metals (Ni, Cu, Co, Zn and Mo) on anammox bacteria. Molybdenum was the most influential on the anammox activity, and the concentration higher than 0.2 mg/l strongly influences the anammox reaction. Additionally, the inhibition caused by Mo is irreversible. The 50% inhibition concentration (IC_{50}) of Ni, Cu, Co and Zn were 7.9, 6.5, 9.7, and 12.5 mg/l, respectively. Li et al. (2015) studied the inhibitory effect of six metals commonly present in landfill leachate (Cu, Cd, Ni, Zn, Pb and Mo). In short-term studies, Cu, Zn, Cd, and Ni were the most toxic metals with 50% inhibiting soluble concentrations of 4.2, 7.6, 11.2, and 48.6mg/l, respectively. Lead caused only 32% inhibition at the highest tested concentration (6 mg/l of soluble Pb). The IC_{50} values of Cu and Zn were comparable with the results obtained by Kimura and Isaka (2014). In the research performed by Li et al (2015), Mo was not inhibitory at a soluble concentration up to 22.7 mg/l, however in contrast to studies of Kimura and Isaka (2014) this was performed in the batch test without any earlier biomass exposure to the heavy metals. Lotti et al. (2012) investigated the Co and Zn influence on the anammox sludge, and they found the 50% inhibition concentration after 24 hours exposure equal to 1.9 and 3.9 for copper and zinc, respectively. Zhang et al. (2015) studied the short and long-term effect of Zn(II) on the anammox process. The Zn concentration to 5 mg/l was tolerated by the anammox bacteria, and they were suppressed at 8 mg/l. The 50% inhibitory concentration of Zn(II) was 25 mg/l. The inhibitory effect was reversible and after short term of recovery period, the sludge characteristics were remitted to the normal. Zhang et al. (2016) evaluated the long-term effect of Cu and Zn on the anammox activity. Cu and Zn at a concentration of 1 mg/l both, and with a joint loading rate of 0.4 kg/m^{3}d did not affect the process,

Table 2. Heavy metals concentration in landfill leachate and the IC_{50} for the anammox

Heavy Metal	Concentration in Landfill Leachate		IC_{50} for Anammox	
	Value [mg/l]	Reference	Value [mg/l]	Reference
Co	0.005-1.5	Kjeldsen et al., 2002	9.7	Kimura and Isaka 2014
Cu	0.005-10	Kjeldsen et al., 2002	6.5	Kimura and Isaka 2014
Ni	0.015-13	Christensen et al. 2001	7.9	Kimura and Isaka 2014
Pb	0.001-5	Kjeldsen et al., 2002	6*	Li et al. 2015
Zn	0.03-1000	Christensen et al. 2001	12.5	Kimura and Isaka 2014

*32% inhibition at the highest tested concentration

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

while the joint loading rate of 0.12 kg/m^{3}d caused it rapid collapse. Generally, the IC_{50} concentrations for anammox process are quite high, however in the case of Cu, Ni, Zn their concentration in landfill leachates may be much higher than IC_{50} concentration. Also, the composite inhibition research is needed.

Influence of Organic Matter

Also, the presence of the organic matter in the landfill leachate could cause some problems as a result of the development of heterotrophic denitrifiers. Generally, partial nitritation/anammox process was mainly applied for wastewater with low COD to N ratio (even below 0.5). The COD requirement for nitrate denitrification is 2.9 g COD/g N-NO_3^-, but for nitrite denitrification COD to N ratio is decreasing to 1.71 g COD/g N-NO_2-. Chamchoi et al. (2008) demonstrated the reduction of anammox activity with an increase in COD to N ratio from 0.9 to 2.0, which was caused by the concurrent denitrification. The reactors were continuously fed with synthetic wastewater and the operational temperature was 35°C. They found that the COD concentration of 300 mg/l could inactivate or even eradicate anammox biomass when the reactor is operated under low nitrogen loading rates (below 0.1 kg/m^{3}d). Similar observations were performed by Molinuevo et al. (2009) using a semi-continuous UASB reactor at 37°C, fed with synthetic wastewater and then with pig manure effluents (after UASB post digestion and after partial oxidation). By contrast, Tang et al. (2010) showed that with a high nitrogen loading rate of 13.92 kg/m^{3}d heterotrophic denitrification prevailed in the UASB (upflow anaerobic sludge blanket) reactor fed with synthetic wastewater in which high influent COD/NO_2 ratio of 2.92 was applied. Generally, the anammox bacteria growth is suppressed due to weaker competition for nitrite and much lower specific growth rate in comparison to heterotrophs. Recently, Janni et al. (2014) showed the application of partial nitritation/anammox with the step wise increasing COD to N ratio to 1.4. They noticed a decrease in sludge retention time (SRT) to the critical value for the anammox bacteria with increased COD loading. However, reduction of biomass loss caused the rise of anammox bacteria activity. What was interesting, the anammox population changed from mixed community to *Candidattus Brocadia fulgida* as the dominant type which is known to oxidize acetate. However, to avoid the heterotrophic bacteria growth in the anammox reactor, the two step process is recommended (Nhat et al., 2014). In such configuration, the organic carbon is oxidized in the first aerobic reactor so the second anammox reactor is protected from high organic influent and the same anammox bacteria overgrowing by heterotrophic bacteria. Nhat et al. (2014) showed the successful combination of partial nitritation in SBR reactor followed by anammox process in anammox hybrid reactor (HAR) treating old landfill leachate. The same principle of operation is in Panammox® technology which consists of two step partial nitritation-anammox process operated in two SBR reactors treating real landfill leachate. The first partial nitritation SBR reactor is operated under high temperature (35°C) with free ammonia (FA) and free nitrous acid (FNA) as key parameters for NOB suppression. The following SBR reactor was operated as anammox reactor with working temperature at 36°C. The obtained results showed that the anammox process is not inactivated by denitrification and moreover nitrates produced by anammox were removed by heterotrophic denitrification. An 85.1% of the nitrogen removal was due to the anammox process whereas the denitrification was responsible for 14.9% of nitrogen removal (Ruscalleda et al. 2008). Further study showed that the suitable influent nitrite-to-ammonium molar ratio is a crucial factor for process stability, and the lower nitrite supply may result in loss of anammox activity due to nitrite competition with denitrifiers

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

(Ruscalleda et al., 2010). Miao et al. (2014) demonstrated nitrogen removal from landfill leachate using three stage SBR system, comprising pretreating SBR (SBR_{pre}), nitritation SBR and anammox SBR. The SBR_{pre} was used for pretreating the biodegradable organic substances and at the same time for reducing the adverse effect of organic substances on anammox process. In this system, the overall nitrogen removal efficiency reached 90% with nitrogen loading rate at 0.81 kg/m^3d (Miao et al., 2014 and 2015). Lu et al. (2016) demonstrated the coupling of upflow anaerobic sludge blanked with ANITA™Mox process. The pilot study demonstrated that the combined process was capable of treating high strength leachate with high COD and nitrogen removal. The total nitrogen removal efficiency was about 70%. The system was designed and patented for young landfill leachate treatment with high organic carbon content. The high COD concentration about 45000 mg/l was first removed in UASB reactor with an efficiency about 93% and then before the anammox reactor, there was the C-stage MBBR (Moving Bed Biofilm Reactor) to treat additional 500 to 1000 mg/l of COD to protect the anammox step from high organic carbon inflow.

Salt Inhibition

Another problem associated with the landfill leachate is high salinity considered as an inhibitory factor for biological nitrogen removal processes (Dapena-Mora et al., 2010; Liu et al., 2014). The high concentration of salt in the leachate mostly is chloride (250 – 4500 mg/l), Sodium (70-7700 mg/l) and Potassium (50-3700 mg/l) (Kjeldsen et al., 2002). Kartal et al. (2006) operated two SBRs for one year using seeding sludge consisting of equal amounts of marine and freshwater species. One reactor was operated with the salinity up to 30 g/l. It was shown that *Kuenenia stuttgartiensis* can adapt to high salt concentration. The same observation was later made by Liu et al. (2009). Also, Dapena-Mora et al. (2010) demonstrated that the anammox bacteria can adapt to high salinity and consequently can be used to remove nitrogen from effluents with high salinity.

Physical-chemical treatments have been found to be suitable not only for the removal of refractory substances from stabilized leachate, but also as a refining step for biologically treated leachate. Anfruns et al. (2013) studied the combination of partial nitritation anammox process with two AOP-based technologies (coagulation-flocculation + ozonation and photo-Fenton) in terms of nitrogen removal and carbon. Biological treatment prior to advanced oxidation processes allowed to reduce the amount of reagents. It was possible to achieve total nitrogen removal efficiency in the range from 87 to 89%.

Recently, the full scale application of partial nitritation and anammox treating landfill leachate was reported (Wang et al., 2010). Wang et al. (2010) demonstrated the occurrence of simultaneous partial nitrification, anammox and denitrification process (SNAD) in a single partially aerated full-scale bioreactor. The process was performed in two aeration tanks with 384 m^3 of working volume and 1.26 d of hydraulic resident time, which was located in Taiwan. The DO concentration in the reactor was maintained at 0.3 mg/l which promoted coexistence of anammox microorganism and denitrifiers. The reactor was operated at a temperature ranging from 30°C to 33°C.The removal efficiencies of COD and $N\text{-}NH_4$ were 28% and 80%, respectively, with the total nitrogen removal by partial nitritation/anammox as high as 68% and contribution of heterotrophic denitrification to 5% and 23% of total nitrogen and COD removal, respectively.

CONCLUSION

The landfill leachate is very difficult to be treated due to its complex composition. So far, there has not been a standard treatment method for this type of wastewater. In last years there has been an increasing interest in using partial nitritation in combination with the anammox process for nitrogen removal from landfill leachate. Due to complex composition of landfill leachate and the presence of inhibitory substances like heavy metals, organic carbon or salts, there is a tendency to use combined treatment methods with some pretreatment – especially for organic carbon removal, and also with some post-treatment methods like constructed wetlands or with AOP-based technologies. The use of partial nitritation with combination of the anammox process gives a cost effective alternative for biological removal of nitrogen from landfill leachate. Although, some full scale applications are single stage technology (first installations used rotating biological contactors), there is rather tendency to use two-step partial nitritation/anammox technology instead of a one-step process, for example the Panammox® technology. It is mainly because the first partial nitritation reactor protects the following anammox reactor from organic carbon and some potentially toxic substances. However, further research is needed to determine the influence of very low temperatures especially with combination of some toxic substances which may be present in leachate. Also, further research is required on combined methods coupling partial nitritation/anammox process with other techniques.

KEY TERMS AND DEFINITIONS

Ammonia Air Stripping: The process in which the ammonia in high concentration is stripped by aeration or air flow.

Anammox: Anaerobic Ammonium Oxidation is a microbial process performed by Anammox bacteria belonging to planctomycetes group. In this process the ammonium nitrogen is anaerobicallu oxidized to dinitrogen with nitrites as electron acceptor.

Denitrification: The reduction of nitrate nitrogen to nitrogen gas performed by heterotrophic bacteria.

Landfill Leachate: A liquid that passing the waste deposited in a landfill. Once in contact with solid wastes, the perocating water becomes polluted.

Nitrification: The microbial process performed by chemolitotrophic bacteria in which the ammonium nitrogen is oxidized to nitrate nitrogen.

Nitritation: In this process the nitrification process is limited to its first step – ammonium oxidation to nitrite nitrogen.

Struvite: Magnesium ammonium phosphate is a white crystalline substance with formula $NH_4Mg-PO_46H_2O$.

ABSTRACT

Upgradation and advancement in every field related to mankind leads to the origin of a contaminated environment. Development in science and technology enabled humans to combat the rate of contaminants by using biological agents, commonly known as bioremediation. The chapter deals with the different species of bioremediation agents viz. bacteria, fungi, algae, plants, animals and organic wastes to treat diverse environmental pollution. The extent of environmental bioremediation encompasses inorganic viz. arsenic, chromium, mercury, cyanide etc. and organics viz. Hydrocarbons, petroleum, pesticides etc. Thus, the reasons for the control of water and soil by considering bioremediation are concern on public health, protection of environment, and cost reduction of decontamination. Different case studies have been demonstrated herein to understand the enigmatic process and evaluate practical efficacy of the environment to decontaminate itself by the presence of various biological organisms.

INTRODUCTION

Expeditious growth of population and their anthropogenic activities in industry, agriculture and domestic sectors leads to the generation of huge hazardous toxic materials. These toxic elements can persist in the environment for a long time. Thus, continuous generation along with long persistence make a favorable condition for pollutants to accumulate in different matrices (air, water and soil). This filthy condition is gradually capturing our world with its adverse effect on the human health. Hence there is an utmost requirement to combat with the pollution load for our better health and environment. There are several processes to deal with the contaminants, among them biological process is recently gaining popularity for its eco-friendly nature. Nature teaches us different remedies to manage any type of condition. Development in scientific research, scientists are able to develop efficient and economic processes for remediation of contaminants (Elekwachi et al., 2014). Use of biological agents like plants, animals, algae, fungi, microbes, etc. in pollution abatement is commonly known as bioremediation. Some species of plants, animals, algae, fungi, microbes, etc. also increases in certain places so as to make them highlighted by being polluted.

The principle of bioremediation involves the biological organisms to wipe out the contaminants or convert them into less harmful variety by formation of porous fence, intra and extracellular confiscation, active transport, enzyme mediated detoxification, chelation of metals, precipitation through the production of organic harmless substances and biotransformation reactions (methylation, oxidation, reduction and volatilization). They multiply themselves by generating energy and nutrients from the atmosphere. In very few cases, the nature provides all the essential materials for cleaning up the contaminated sites, known as intrinsic bioremediation. But in most of the cases, essential materials are regularly supplied from an outer source to the organisms, this process is known as engineered bioremediation. These two types can further be classified under different techniques viz. biostimulation i.e., by stimulating viable native microbial population; bioaugmentation i.e., artificially introducing viable population; bioaccumulation i.e., applying live cells; biosorption i.e., using dead microbial biomass; phytoremediation i.e., by using various species of plants and rhizoremediation i.e., by using plant and microbes at the same time (Chowdhury et al, 2012). Different species of these agents are used to identify pollution as well as treat diverse environmental pollution. Inorganic, organic as well as air pollutants can be treated through bioremediation. Aquatic plants also act as biosensor and help in the remediation of polluted water. It is an interesting fact that besides plants and microbes, soil animals like protozoans, nematodes, earthworms, mites, insect larvae, arachnids, millipedes and centipedes are also involved in bioremediation. They usually play a very regulative role in the decomposition rate of the contaminants. The process of bioremediation is very simple and very cost effective usually driven by the solar energy (Prasad, 2011). The only part for effective bioremediation includes the proper selection of biological species for a definite problem of contamination in polluted sites may it be land or water. Progress in various paths for the destruction and degradation of pollutants and contaminants has been developed for ensuring a sustainable bioremediation strategy. Following proper techniques of bioremediation can result in productive and non-deleterious quality of the environment. Till now several researches are going on to find the best agent for providing best green remediation. This chapter explains the causes, processes and mechanisms used in bioremediation emphasizing efficiency of different living organisms (tools) and case studies to cleanup the environmental contaminants.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

A BRIEF HISTORICAL OVERVIEW

In bioremediation, different microorganisms, fungi, algae and plant species has been extensively used to decrease, degrade, transform and detoxify the pollutants from the contaminated sites. Potential living organisms present in the contaminated sites spontaneously may involve in the remediation process, mimicking this natural process, researchers are trying to make the process more efficient.

The concept of bioremediation is not new; Romanian in 600 B.C established a sewer system for biological wastewater treatment. Before the 1940s, scientists hypothesized the degradation of petroleum hydrocarbons by microbes but their mechanism and limitation was unknown. However, in 1960 George M Robinson has invented a bioremediation process during experiments with polluted containers. His pioneer concept for commercial utilization of dried microbes gained acceptance throughout the 1960s (Sonawdekar, 2012). In 1970 Dr. Ananda Mohan Chakrabarty discovered crude oil degrading bacterial strain. First commercially, bioremediation techniques were used in 1972 to clean up the Sun oil pipeline spill in Ambler, Pennsylvania. In this meantime, research had progressed in the field of genetic modification of microbes to enhance its stability, substrate specificity and efficiency and therefore, in 1975 Dr. Chakrabarty once again brought revolution by discovering oil-eating superbug (*Pseudomonas putida*) using genetic cross linking. Burning, mechanical cleanup and chemical dispersants methods were used to remediate the contaminated shoreline after Exxon Valdez oil spills in 1989. By 1990s, bioremediation got its significance through the commercial application of this process for the treatment of contaminated soils and groundwater. According to the Environment Protection Agency (EPA) survey report in 1992, 240 bioremediation cases were identified. In the year of 2005, UK researchers identified uranium degrading bacteria from a decomposed state in an insoluble forms (Evan, 2005). In 2014, Norwegian researchers in Trondheim have gotten remarkable results of nature's ability in oil spills clean up (Doan, & Domingo, 2015; Pal et al., 2010).

MECHANISM OF BIOREMEDIATION

For the bioremediation purpose environmental factors and the properties of the biological agent involved in this process plays a crucial role. A proper uniform contact of agents with pollutants is also an important factor. Activity and growth of microorganism, degradation mechanism of contaminants and efficiency of the process are broadly depended on various factors like moisture, pH, temperature, types of matrix, redox potential, availability of oxygen, mass transfer characteristics etc (Uqab et al., 2016). Mechanism of bioremediation basically depend on the unique property/tricks of living organisms involve in this process by the means of absorption, adsorption, uptake, conversion to simple no/less toxic materials, degradation and decomposition (Figure 1).

Adsorption

Adsorption is carried out by the binding of pollutants in the binding sites of microbial cellular structure. Extracellular polymeric substances (EPS) which is a reactive compound have a significant effect on acid-base properties and metal adsorption through the mechanism of proton exchange and micro-precipitation of metals (Dixit et al., 2015).

For the plant species surface of the roots binds many pollutants. Interaction of the plant root and microbes resulted into secretion of proton, organic acids, enzymes and phytochelatins increase the metal dissolution in rhizosphere zone (Revathi et al., 2013).

Biosorption

By the biosorption process positively charged heavy metal ions get absorbed by the negatively charged microbial cell membranes and polysachharides. In this process contaminants first entered in to the cell cytoplasm through cell membrane by the help of transporter proteins. From the surface, the metals are transported into the cell cytoplasm through the cell membrane with help of transporter proteins. Specific binding sites present in the transporter proteins binds and transports ions from outer side to inside of the cell (Sinha et al., 2013).

Precipitation

Precipitation of metals occurs by compartmentalizing and/or converting to more innocuous form. Micro-organism precipitate metals in different forms like metal sulphides, metal oxides, metal protein aggregates or elemental metal crystals. These forms of metals form particulates which are closely associated with cytoplasmic membrane (Bhakta, 2016).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Detoxification

Possible mechanisms of the detoxification of contaminants by microorganisms are 'valence transformation', by 'extracellular chemical precipitation' or by 'volatilization'. In general by redox conversion of inorganic pollutants or conversion of inorganic pollutants to organic forms, detoxification occurs by microbial population. Aerobic bacteria produce harmless CO_2 and water by the degradation of natural and synthetic hazardous organic substance on the other hand anaerobic bacteria are responsible for the degradation of halogen and nitrosamine, reduction of epoxides to olefins, reduction of nitro groups. Microbial methylation of metals is another aspect of detoxification. Living organisms are used for biomethylation of arsenic to gaseous arsines, selenium to volatile dimethyle selenide and lead to dimethyl lead (Sinha et al., 2013).

Enzymatic Bioconversion

Microbial enzymes act as a biocatalysis which facilitate the bio-conversion of substrates into products. Different types of enzymes like monooxygenase, dioxygenase, laccase, lignin peroxidase, manganese peroxidase, versatile peroxidase, lipase, cellulase and protease are involved in oxidoreductase and hydrolysis of toxic materials (Karigar and Rao, 2011).

Degradation/Decomposition

Several microbes has been identified which are involved in the breakdown of toxic organic substances and xenobiotics in the environment. Heterotrophic microbes which cannot produce their own food are involved in the decomposition process to gain their growth nutrients. These microbes utilize Oxygen (O_2), ammonia (NH_3), and phosphate (PO_4^{3-}) from the organic material as a nutrient source and produce harmless materials. Degradation process may be carried out in the absence (Anaerobic process) or presence (Aerobic process) of oxygen. Anaerobic process produces carbon dioxide (CO_2) to methane (CH_4) in the presence of the available hydrogen (H_2).

Hydrocarbons of waste organics (*Acetogens*) → Acetate + Organic Acids + CO_2 + H_2O

Organic Acids + CO_2 + H_2 (*Methanogens)* →Byproducts + Energy

On the other hand aerobic process produces CO_2 and water.

Organics + Molecular Oxygen (Aerobes) → CO_2 + H_2O + Other products + Energy (Sinha et al., 2013).

LIVING MACHINE (TOOL) OF BIOREMEDIATION

A vast array of biological components in ecosystem play important role in self-cleaning process of ecosystem as living machines or tools. Several studies determine and demonstrated their services and efficacy in remediation of polluted/contaminated environment. Therefore, it is well established that

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

biological agents have potent capacity in bioremediation by removing and/or transforming from higher to lower toxic forms. Biological components act a very important role in biotransformation and biodegradation of contaminants to less toxic substances. Biotransformation deals with the amendment of the structure of a substrate by microorganisms, where biodegradation deals with the breakdown of organic and biotransformation of inorganic compounds into non-toxic compounds. Bioremediation utilize different types of biological agents like bacteria, fungi, algae, plant, etc. to clean up the contaminated sites. This technology promotes the growth of the microorganism in contaminated sites and can be enhanced by adding nutrients, adding terminal electron acceptor; maintaining temperature and moisture content (Singh et al., 2014).

Bacteria

Microbes have been widely used for environmental clean-up. Microbial degradation process involved in metal reduction, methylation, demethylation, enzymatic reduction, metal organic complexion, metal ligand degradation (Okeke et al., 2014). Different types of species of which are extensively utilized for the management of contaminated sites like *Streptomyces*, *Pseudomonas* and *Bacillus* for metal biosorptions. Few others commonly use microorganisms are the species of *Achromobacter, Citrobacter, Escherichia, Cinetobacter, Flavobacterium, Micrococcus, Mycobacterium, Norcardia, Pseudomonas* and *Rhodococcus* etc. (Bhatnagar, & Kumari, 2013; Kumar et al., 2011). Versatile properties of these microorganisms can change in metal mobility, speciation, toxicity and mineralization and thus helps in the degradation and transformation of the huge variety of compounds viz., metals, hydrocarbons, chlorinated solvents, chlorinated phenol, BITEX, polychlorinated biphenyls (PCBs), polyaromatic hydrocarbons (PAHs), pesticides, radionuclide (Joutey et al., 2013). Bioremediation can be classified into 3 phases i) by natural attenuation ii) by supplying nutrients and iii) by adding microbes to the system (Seo et al., 2009). Many factors like pH, temperature, moisture, and availability of nitrogen, phosphorous, carbon, production of toxic metabolites, solubility of contamination and concentration of pollutants influence the existence of microorganism population and the capability of degradation (Naik and Duraphe, 2012). Hence, there is an urge for the preparation of high potential microorganism to work a wide range of environmental condition and thus genetically engineered microorganisms (GEM) came into the scenario. Four principle approaches for the development of GEMs for bioremediation application are i) identification of the microorganism which are suitable for modification ii) pathway construction and regulation iii) adaptation of enzyme specificity and affinity and iv) bioaffinity, bioreporter sensor applications in chemical sensing, toxicity reduction and end point analysis (Kulshreshtha, 2013). Some examples of GEMs are *Alcaligenes eutrophus* 2050, *A. eutrophus* H850Lr, *Burkholderia. cepacia* BRI6001, Comamonas testosteroni VP44, *E. coli* FM5/pKY287, *Pseudomonas* sp. B13, *P. putida* KT2442, *Pseudomonas* sp. FR1, *Pseudomonas* sp. LB400, *P. pseudoalcaligenes* KF707-D2, *P. putida* TVA8, *P. fluorescens* HK44, *P. fluorescens* 10586s/pUCD607 and *P. fluorescens* 10586s/pUCD607. These microorganisms are used in the process monitoring, end point analysis, stress response and toxicity assessment (Menn et al., 2008).

Fungi

Morphological, physiological and genetic features of fungi are important to make them unique in bioremediation process. They can easily persist and colonize in all matrices in the environment and thus play an important role in the reduction, elimination and transformation of contaminants. Air is the main

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

vehicle for fungal propagules, though aquatic environment is steadily colonized by fungi but the major habitat is soil. Fungi can be found in different ecological niche extended from arctic tundra to the desert sand dunes. All fungi are heterotrophic in nature and utilize organic substance in their growth by three ways: saprophytism, parasitism and mutualistic symbiosis. One or more fungal species can degrade almost all natural organic compounds by producing a variety of enzymes viz., amylases, lipases, and proteases. They degrade natural polymers like keratin, chitin, and lignin, which are mainly complex and resistant to microbial attack. Wood fungi can degrade numerous aromatic and aliphatic, xenobiotic compounds, different pollutants like polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), pesticides, and herbicides. White-Rot Fungi, Brown-Rot Fungi, Litter Fungi, Soil Fungi and Mycorrhizal Fungi are some examples which are extensively used in the bioremediation process (Anastasi et al., 2013). Some examples of fungi and their application in pollution remediation are listed in Table 1.

Yeasts show the capability to resist under adverse environmental condition. The major application of yeast is dye decolourization of food industry effluents. Different types of yeast species like *Clavispora, Candida, Rhodosporidium, Pichia* and *Rhodotorula* etc. are used in the bioremediation process (Bhatnagar, & Kumari, 2013).

Algae

Algae are important bioremediation agents, used in pollutant abatement in waste water. The major advantage of algae as a bioremediation agent is its high biomass yield capability which leads to high absorption and accumulation of metals, tolerance to heavy metals, capability to grow both autotrophically and heterotrophically, large surface area/volume ratios and potential for genetic manipulation (Chekroun, & Mourad, 2013). Algal species are used broadly for the bioremediation of heavy metal, oil, pesticides, toxins, radioactive and several organic compounds (Prabha et al., 2016). A list of some algal species and their bioremediation of specific pollutants has been enlisted in Table 2.

Table 1. List of some potential fungi used in bioremediation

Fungi	Application
Phanerochaete chrysosporium	Degrade lignin macro molecules, organopollutants (PAH's, PCBs) dioxins, synthetic dyes, pesticides, nitrocranditics, chlorolignins, chlorophenols
Phanerochaete flavido-alba	Decolorize olive oil mill wastewater
Trametes versicolor	Degrade lignin, PAHs, polychlorinated biphenyl mixture and synthetic dyes. Delignify, dechlorinate and decolorize bleach kraft pulp
Pleurotus ostreatus	Degradation of PAHs
Pleurotus tuber-regium	Ameliorate crude oil polluted soil
Lentinus squarrosulus	Mineralization of soil tainted with crude oil and thus at the end nutrient contents increased in the soil
Pleurotus pulmonarius	Management of cement and battery polluted soils

Adenipekun, & Lawal, 2012.

Plants

Use of plants is a low cost and eco-friendly tool for effective and efficient remediation process of pollutants. It plays a significant role in the removal of toxic materials from contaminated soil and water. Plant species provide advantages by its unique and selective uptake capabilities of root, accumulation and degradation of pollutants by whole plant. Pollutants accumulation capacity varies from plant to plant and thus high accumulator plants known as 'hyperaccumulator' which can take up toxic materials up to the levels of thousand ppm (Tangahu et al., 2011). Examples of some hyper accumulator plants are *Armeria maritima* (Seapink thrift), *Ambrosia artemisiifolia* (Ragweed), *Brassica juncea* (Indian

	Chlorella vulgaris, Spirulina platensis and *Dunaliella* saline	COD and Phenolic Compounds
	Chlorella vulgaris and *Scenedesmus quadricauda*	PO_4^{3-}, NO_3^-, COD and BOD
	Chlorella minutissima	P and NO_3^-
	Oscillatoria, Synechococcus, Nodularia, Nostoc and *Cyanothece*	BOD, COD, Dissolved Oxygen, NH_3, NO_3^-, Mg, Organic and Inorganic Phosphates
	Isochrysis zhanjiangenesis	P, NH_3, N, NO_3^- and NO_2^-
	Spirogyra sps. and *Oscillatoria* sps.	Cd^{2+} and Ni^{2+}
	Aphanocapsa sps., *Chlorella autotrophica, Coccochloris elabens, Dunaliella tertiolecta, Oscillatoria* sps., *Scenedesmus obliques, Synechococcus elongates* and *Volvox*	Crude Oil
	Chlorella vulgaris	Textile waste effluents (Color and COD)
Bioremediation of oil	Cyanobacteria (Blue-green algae)	Benzene, toluene, naphthalene, phenanthrene, pyrene
	Mycobacterium sp.	n-Undecane
	Strains of *Pseudomonas putida*	Phenol cresols
	Trichosporon pullulans	Paraffins
	Acinetobacter calcoaceticus	Petroleum derivatives
	Microcystis aeruginosa	Acrylonitrile
	Aeromonium sp.	Total petroleum hydrocarbons
Pesticides	*Chlamydomonas* sp.	Mirex, Lindane, naphthalene, phenol,
	Selenastrum capricornutum	Benzene, toluene, chlorobenzene, 1,2-dichlorobenz ene,nitrobenzene naphthalene, 2,6- dinitrotoluene, phenanthrene, di-nbutylphthalate, pyrene
	Cylindrotheca sp	Dichlorodiphenyltrichloroethane (DDT)
	Euglena gracilis	DDT, parathion
	Scenedesmus obliquus	DDT, parathion, Naphthalene sulfonic acid
	Chlorella sp.	Toxaphene, methoxychlor, Lindane, chlordimeform
	Chlorococcum sp.	Mirex
	Dunaliella sp.	Mirex, DDT, naphthalene

Prabha et al., 2016; Chekroun, & Mourad, 2013; Priyadarshani et al., 2011.

mustard), *Brassica napus* (Rape, Rutabaga, Turnip), *Brassica oleracea* (Flowering/ornamental kale and cabbage, Broccoli), *Festucaovina* (Blue/sheep fescue), *Helianthus annuus* (Sunflower), *Thalspi rotundifolium* (Pennycress), *Triticum aestivum* (Wheat), *Zea mays* (Corn) (Paz-Alberto and Sigua, 2013). Plants have a very efficient mechanism and highly specific to attain essential micronutrients when present in low concentration. Plant root produces chelating agent and thus make pH change and redox reaction which helps to solubilize and uptake the nutrients. Not only for uptaking, but these same mechanisms are involved in the translocation of storage of pollutants in different parts of the plant. There are several

Bhatnagar, & Kumari, 2013; Pandey, & Bagga, 2013; Paz-Alberto, & Sigua, 2013.

mechanisms of pollutant uptake by plants, these are phytoremediation phytoextraction, phytostabilisation, rhizofiltration, and phytovolatilization (Tangahu et al., 2011). A list of some plants involved in phytoremediation process presented in Table 3.

Not only for water and soil, plant species are extensively used to remediate pollutants from the air. These types of plants should have certain properties like evergreen, big leaved, coarse bark, native, low water requisite, high absorption of pollutants, agro-climatic suitability, pollution tolerance and dust scavenging capacity etc. *Tamarindus indicus, Mangifera indica, Derris indica, Thespepsia populnea, Polyalthea longifolia, Azadirchta indica, Bombax ceiba, Delonix regia, Ficus religiosa, Jacaranda mimosifolia, Lagerstroemia indica, Plumeria rubra, Syzygium cumini* are suitable for pollutants elimination from air (Kumar et al., 2013).

Animals

Animal induced bioremediation capacities are not widely known and are rarely used for bioremediation for its ethical concern. Animal mediated bioremediation can be achieved by the introduction, culture, and harvest of animals from the contaminated sites. Some examples of animal involved in aquatic system bioremediation are oysters, mussels, clams, fish, polychaetes and sponges. This process is termed as 'zooremediation' (Gifford et al., 2006). The mechanisms employed are zooextraction, zoostabilisation, zootansformation and animal metal-hyperaccumulation. This remediation process occurs in two ways i)

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

by taking part in the process, increasing in number and soil metabolic activity. ii) as a good indicator of contaminated soil, to evaluate the toxicity and risk of the end product (Haimi, 2000). Aquatic animals accumulate contaminants in several orders of magnitude higher than the surrounding water. Accumulation is depend on several factors like temperature, pH and salinity of the matrix and biological factors like age, sex, sexual maturity stage of premeditators (Gupta and Singh, 2010). Earthworms also found as a potential species for the removal of contaminants. It involves in the remediation of pesticides, heavy metals and lipophilic organic micropollutants like the polycyclic aromatic hydrocarbons (PAH) from the soil. In the soil the area of earthworm and pollutants interactions is known as "drilosphere system" and the process of remediation called as "Vermiremediation" (Sinha et al., 2009). Some names of decomposer animal are listed in Table 4.

Organic Wastes

Organic manures/wastes have been extensively used throughout the world for the improvement of soil fertility by adding organic matter and nutrients (Anyanwu, & Okorie, 2013; Umar et al., 2013). Like other agents application of organic waste is a promising tool in bioremediation process (Bahadure et al., 2013). Basically addition or amendment of the soil by organic waste increases the microbial population and activity by providing nutrients (Chijioke-Osuji et al., 2014).

Table 4. Name and groups of some animals involved in bioremediation process

Animal Group	Species
Earthworms	*Eisenia fetida/Andrei* *Aporrectodea caliginosa* *Lumbricus terrestris*
Enchytraeids	*Enchytraeus albidus*, also other species
Collembola	*Folsomia candida* several species, e.g. *Folsomia fimetaria* and *Orchesella cincta*
Mites	*Platynothrus peltifer*
Isopods	*Porcellio scaber* *Trichoniscus pusillus*
Nematodes	*Plectus parietinus*
Protozoans	*Colpoda cucullus*
Animal-Hyperacculators	*Crassostrea virginaca* *Mytilus edulis* *Pinetada albino albina* *Crassotrea rhizophorea*
Molluscs	*Pera viridis.* *Chione fluctifraga* *Mytilus edulis*
Sponges	*Chondrilla nucula* *Hymeniacidon perleve* *Halichondria panicea* *Spongia officinalis*
Arthropods	Carabid beetle *Poecilus cupreus* *Pterostchus oblogopunctatus*

Haimi, 2000; Okeke et al., 2014.

SOME CASE STUDIES

Bacterial Bioremediation

Case 1

Singh and Fulekar in 2010 isolated *Pseudomonas putida* strain MHF 7109 for biodegradation of benzene, toluene and o-xylene (BTX). By this process, they successfully degrade BTX (50mg/L) within a time period of 48, 96, and 168 h, respectively, but higher concentration of BTX (250 and 500mg/L) repressed the action of microorganisms. 100 mg/L benzene and toluene was completely degraded within 120 and 168 h respectively where same concentration of o-xylene was degraded within 168 h by 62%.

Case 2

A pilot scale study was conducted by Mukherjee, & Bordoloi (2011) for the reclamation of petroleum oil hydrocarbons contaminated soil. Bacterial consortium (20% v/w) consisting three strains (*Bacillus subtilis* DM-04 and *Pseudomonas aeruginosa* M and NM) were used for these remediation processes for a period of 180 days. After the experimental period, results showed a significant degradation of contaminants in polluted soil by 76%. An ecotoxicity study by observing seed growth of Bengal gram (*Cicer aretinum*) and green gram (*Phaseolus mungo*) in contaminated and remediated soil was carried out where 72–74% seeds were germinated in the remediated soil (after 180 days experiment) which is very much similar to uncontaminated soil.

Case 3

In the year of 2013, Ahluwalia, & Goyal reported 100% removal of chromium (VI) from the metal processing industry effluent. In this study a non living biomass (*Aspergillus terreus*) was used as a biosorbent to remove chromium. Removal efficiency up to 10 cycles and 100% removal of metal up to 5 weeks made this process more cost-effective and commercially viable.

Case 4

Pilot scale studies were carried out at different oil refineries in India for the purpose of the removal of petroleum hydrocarbon. Four species of bacterial consortium were used for remediation of 48,914 tons of different types of oily waste. Initially, total petroleum hydrocarbon (TPH) content varied 83.50 to 531.30 gm/kg of oily waste in 44 contaminated sites. This process successfully degraded 10 gm/kg of oily waste within the time period of 2-12 months (Mandal et al., 2012).

Case 5

A new metal resistance lactic acid bacterial (LAB) strain was isolated (*E. faecium* Pb12) for the purpose of the removal of metal contaminants. This strain shows minimum inhibitory concentration of 120 mg/L for cadmium and 800 mg/L for lead. The researchers successfully removed cadmium and lead by

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

0.0377 mg/h/g and 0.0460 mg/h/g of cells (wet weight) respectively. Thus, a potential metal resistant probiotic strain has been discovered which can be used for heavy metal removal from fish intestinal milieu (Bhakta et al., 2012).

Case 6

A mixture of 6 microbial consortiums was used for the remediation of oil contaminated area in upper Assam, India. From 2009 to 2010, they were able to remediate about 1210 metric ton (MT) and 5045 m^3 of contaminated soil and water respectively. After 7-13 months 74-90% degradation was occurred in soil and in case of water, 90% contaminants were degraded within 4-6 months (Agrawal et al., 2010).

Case 7

Mandal et al. (2012) utilized a four species of bacterial consortium for the degradation of TPH of the oily waste. After the period of 2-12 months of successful application of the microbial consortium, 95% degradation of TPH was occurred.

Case 8

Jové et al. (2016) studied on the degradation potentiality of anthracene in cork by three ligninolytic white-rot fungi and three non-ligninolytic fungi. *Aspergillus niger, Penicillium simplicissimum and Mucor racemosus* were selected as ligninolytic white-rot fungi and *Phanerochaete chrysosporium, Irpe lacteus and Pleurotus ostreatus* were selected as non-ligninolytic fungi. After 61 days of experimental period, *P. simplicissimum* was capable to degrade the highest amount of contaminant (86%) followed by *P. chrysosporium* (40%) and *I. lacteus* (38%) in cork.

Case 9

Mouhamadou et al. (2013) studied bioremediation of polychlorinated biphenyl (PCB) using different autochthonous filamentous fungal strains. From this research *Myceliophthora thermophila, Thermoascus crustaceus, Aspergillus fumigates, Doratomyces nanus, Phoma eupyrena, Doratomyces purpureofuscus, Doratomyces verrucisporus* strains showed >70% degradation ability of PCBs. Among all these strains *Aspergillus fumigatus* S2-9 has degraded 84.99% of PCB.

Case 10

Lee et al. (2015) carried out the bioremediation of Polycyclic Aromatic Hydrocarbons (PAHs) in Creosote contaminated Soil by *Peniophora incarnata* KUC8836 strain. After 2 weeks, concentration of phenanthrene, fluoranthene, and pyrene were degraded by 86.5%, 77.4%, and 82.6% respectively. Total initial PAHs concentration (229.49 mg/kg) was reduced by 85.7% after 4 weeks of incubation period.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Algal Bioremediation

Case 1

El-Sheekh et al. (2016) treated a mixture of wastewater (sewage, sea and well) by fresh water (*Chlorella vulgaris*) and marine (*Chlorella salina*) algae. Both alga species were successfully reduced total dissolved solids (TDS), biological oxygen demand (BOD), chemical oxygen demand (COD), nutrients concentration (nitrate, ammonia, phosphate, sulphate, calcium, magnesium, sodium, potassium) and heavy metals concentration (Zn, Cu, Mn, Ni, Co, Fe and Cr) after 10 days of experiment. Overall *C. vulgaris* was more efficient in pollutants removal than *C. salina*.

Case 2

Alcohol distillery wastewater treatment has been done by using a new strain of *Chlorella sorokiniana* using a high-density photobioreactor. 92.5% removal of COD, 95%, 77%, 35% removal of nitrate, phosphate and sulfate, respectively were achieved by this process (Solovchenko et al., 2014).

Case 3

Degradation of Triclosan, a widely used antimicrobial agent, was carried out by *Chlorella pyrenoidosa,* a ubiquitous green alga. After 96 h of experiment, 77.2% degradation was achieved. Degradation of Triclosan leads to the disruption of the chloroplast and the release of organic material into the aquatic body and thus affects the membrane metabolism.

Case 4

Spirulina platensis was successfully used as a biosorbent for the removal of azo dye, C.I. Basic Red 46 (C.I. BR 46). After 1 h of wastewater treatment, for the particular algal species maximum dye biosorption was accomplished as 25.46 mg/g (Deniza, & Kepekcib, 2015).

Case 5

An experiment on the bioremediation rate of deepwater horizon crude oil was carried out using *Aphanocapsa* sp., *Chlorella autotrophica*, *Coccochloris elabens*, *Dunaliella tertiolecta*, *Oscillatoria* sp., *Scenedesmus obliquus, Synechococcus elongatus* and *Volvox aureus*. Maximum 34.99% crude oil degradation was observed by *Coccochloris elabens*. Hence it can be concluded that algae is potential degrader of crude oil and can be flourish in the high crude oil environment (Cao et al., 2013).

Case 6

A pilot scale study was conducted for the treatment of chrome-sludge generated from electroplating industry. *Desmococcus olivaceus* (Persoon et Acharius) J.R. Laundon VIAT029 was utilized for the treatment process. In this open pond system TDS, total suspended solid (TSS), ammonia, nitrate, phosphate and chromium were successfully removed by the algal species (Sivasubramanian et al., 2010). Another

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

pilot scale study as well as World's first phytoremediation plant has been established at Ranipet, India. From 2006 this pond is in operation. About 30-40 kiloliters of effluent has been generated from alginate industry every day and 100% sludge has been achieved by this process. A blue green alga *Chroococcus turgidus* has been used for this treatment process (Sivasubramanian, 2011).

Chlorella vulgaris was used for the treatment of raw effluent of a Confectionery industry in Tamil Nadu, India, which generates 50-70 kiloliters of effluent per day. Algal pretreatment has been employed at the flow rate of 3500 L/h before anaerobic digestion, because this pretreatment process helps to maintain pH, reduce BOD, COD and sugar level (Sivasubramanian, 2011).

Plant Mediated Bioremediation

Case 1

Reclamation of a 1600000 m^2 (approx.) metal-contaminated site known as Ahangaran lead and zinc mine of Malayer city, southwest of Hamedan, was successfully done by 12 plant species (*Euphorbia macroclada Boiss, Centaurea virgata Lam, Reseda lutea* L, *Echinophora platyloba DC, Cichorium intybus* L, *Tamarix ramosissima Ledeb, Cirsium congestum Fisch and C. A. Scrophularia scoparia Pennell, Chaerophyllum macropodum Boiss, Cardaria draba* (L.) *Desv, Scariola orientalis (Boiss.) Sojak, Reseda alba* L.). Mainly from the top 20 cm of the soil was contaminated with heavy metals such as Zn, Mn, Cu, Pb and Fe. These hyper accumulator plants showed suitable remediation efficiency for the reclamation of this contaminated site (Cheraghi et al., 2011).

Case 2

Phytoremediation of heavy metals was successfully done by *Typha latifolia, Eichhornia crassipes, Salvinia molesta and Pistia stratiotes* through constructed wetland. The source of effluent was a rare earth separating industry, Kerala, India, which contain high concentration of lead, arsenic, cadmium and copper. 100 x 45 x 45 (cm) plastic tubs were constructed for the remediation purpose. Lead, copper, arsenic and cadmium were significantly removed by *Typha latifolia, Eichhornia crassipes, Salvinia molesta and Pistia stratiotes* from the effluents of Travancore Titanium Products (TTP). Initial concentration of lead, arsenic, copper and cadmium in TTP effluent were 2.984 ± 0.021 ppm, 0.016 ± 0.004 ppm, 0.096 ± 0.012 ppm and 0.253 ± 0.019 ppm, respectively. (Sukumaran, 2013). Maximum lead was removed by *Eichhornia* sp. (1.012 ± 0.11 ppm residual), arsenic, copper and cadmium by *Typha* sp. (0.002 ± 0.0003, 0.024 ± 0.002 and 0.102 ± 0.015 ppm residual).

Case 3

A highly sulfonated textile dye Remazol Red (RR) was completely degraded by a macrophyte (*Alternanthera philoxeroides Griseb*). Initial concentration of dye was 70 mg/L which was completely degraded within 72 h. Several enzyme activities like azoreductase and riboflavin reductase was found in the root and stem tissues respectively. On the other hand, lignin peroxidase, laccase and dichlorophenolindophenol (DCIP) reductase activity were present in leaf tissues (Rane, 2015).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Case 4

Amaranthus dubus which is leafy high biomass content vegetable crop, effectively applied for decontamination of metallic elements such as Fe, Cd, Co, Pb, and Cr in Patancheru, Hyderabad, India. Its rapid growth and huge biomass content make it suitable for phytoremediation. *Amaranthus tricolor*, *Amaranthus dubius* wild I and *Amaranthus dubius* wild II were used in combination with Phosphate Solubilising Bacteria (PSB) and solely for the remediation purpose. *Amaranthus dubius* wild II accumulate 2.54 fold and 3.56 fold elevated Cr and Cd concentrations, respectively than control one. In the case of Co *Amaranthus dubius* wild I show highest accumulation than other treatment (2.70 fold than control). *Amaranthus tricolor* with the combination of PSB shows the highest removal of Pb (26.8 mg/kg) (Shankar, 2011).

Case 5

A heavy metal (Zn, Cu, Cr, Ni, Pb, Cd) contaminated area (6,667 m^2) in Chang-Hwa City, Taiwan, was selected for the decontamination of pollutants through plant species. *Jatropha curcas* was used for the remediation purpose. About 800 plants were planted with the density of 0.12 plant/m^2. From 0-30 cm depth, soil sample was collected. After 2 years of plantation, plant species were successfully removed Cd, Cr, Cu, Ni, Pb and Zn by 51.16, 12.80, 38.88, 14.10, 17.61, 17.88%, respectively (Chang, et al., 2014).

Animal Assisted Bioremediation

Case 1

Kaur & Hundal (2015) successfully established the metal accumulation potentiality of earth worm (*Eisenia fetida*). Organism was able to removal of 42.3%, 24.5% and 8.5% for lead, chromium and nickel respectively from contaminated soil. This experiment was carried out in the contaminated soil collected from the vicinity of Buddha Nullah at Ludhiana.

Case 2

Cadmium was removed by the *Anodonta woodiana* from cadmium contaminated synthetic water. Cd was accumulated in different tissues of the mussels. Maximum Cd accumulation was found in the digestive gland (0.142 mg/g) followed by gills and mantle of the mussels. Though it is an experiment but make a print of evidence of pollutants accumulation by animal species (Bhakta & Munekage, 2008).

Case 3

Kundu et al. (2016) observed the accumulation of lead (Pb) in East Kolkata Wetland (22°27' N 88°27' E), India through fish (*Oreochromis niloticus)*. Lead concentration in fish *was* highest in intestine (0.0182 µg/mg) and lowest in fin (0.0004 µg/mg) with an order as intestine > liver > skin > muscle > scale > bone > fin.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Case 4

Removal of phenol was successfully carried out by Mohan Krishna et al, 2011 using *Eisenia foetida*. Different concentration of phenol contaminated (20 to 100 ppm) were taken for the experiment. As a result *Eisenia foetida* established as a potential tolerant species for phenol removal than other two earthworm species (*Eudrillus eugenia* and *Anantapur* speciesand can uptake upto 100 ppm phenol completely with in 72hours.

Case 5

Eisenia fetida and green waste compost (GWC) were to desalinate a coastal saline soil (38° 46' N, 117°13' E) in Tianjin, North China. Mean annual temperature of this area is 14°C, where the mean monthly temperature ranges from -2 °C in January to 28 °C in July. Maximum soil salinization occurs during March-May moths in the topsoil. 60 number of *E. fetida* were used in per m^2 area and municipal waste was used as green waste compost which moisture content was 60% (w/w) and the C/N ratio of 25-30. Results revealed increased contents of humic acid, available N, and available P in the GWC-amended soil in reclaimed soil. Modeling from this study predict that total salt content of the saline soil would decrease by > 2 g/kg when 29-90 individuals per m^2 of *E. fetida* (Zhang et al., 2015).

Case 6

A successful bioremediation of polluted water was carried out in off the coastline of the urban center of Zanzibar-Stone Town by the implementation of sponge and pearl oyster mariculture. The experiment reveals the strong pollution filtration abilities of both species. Sponges and oysters help to decrease the phosphate concentration of polluted water from 3.93 ug/L to 1.33 and 1.73 ug/L, respectively. Marine sponges also reduce the turbidity level within 36 h (Oakland, 2013).

Waste Based Bioremediation

Case 1

Hara et al. (2013) used food waste compost in order to remediate oil contaminated site in Japan. Bioremediation was carried out in an oil factory site in Japan from the month of August to November, 2006. Climatic condition such as temperature was recorded as 9.5 to 31.5 °C and precipitation was 0 to 50.5 mm per day during the experiment time. The experiments were carried out taking 2,000 kg of contaminated soil in 4 sections in such as control section, compost section (3.8% [w/w] compost), chemical nutrient section (0.5% [w/w] ammonium sulphate and 0.1% [w/w] phosphorus fertilizer), mushroom section (3% [w/w] *Merulius tremellosus*) and biofertilizer section (0.2% [w/w] bionutrients and TerraXyme). In the food waste compost treatment maximum degradation was occurred from the concentration 4,700 ppm to 2,300 ppm of TPH after 74 days followed by other treatments.

Case 2

In the Southeast of Mexico, drilling mud-polluted site (contaminated with petroleum hydrocarbons) was reclaimed by composting in biopiles with addition of urea and K_2HPO_4 were added as nitrogen and phosphorous sources to achieve optimum C/N/P ratio. Biopiles were amended with the addition of nutrients to get a C/N/P ratio of 100/3/0.5 and straw as a bulking agent (30 kg of bulking agent per each ton of soil). A polluted mudpit site near an oil well drilled in the early 1970s, at the Mexican State of Tabasco was chosen for the remediation purpose. The average atmospheric temperature was in the range of 26 °C to 35 °C during the experimentation period. Soil was clay loam and slightly alkaline (pH 7.9) in nature with the water content of 25% and an existing C/N/P ratio of 6089/76/1. Average TPH concentration of contaminated soil was 99300 ± 23000 mg per kg soil. After 180 days TPH concentration was reduced by 77% (22900 ± 7800 mg per kg soil as residue) in the soil (Rojas-Avelizapa et al, 2007).

Case 3

Three types of organic wastes such as goat manure, poultry droppings and cow dung, were used for the treatment of oil contaminated soil due to pipeline vandalization and local refinery activity, collected from Isaka Mangrove, in Okirika Local Government Area of Rivers State, Nigeria. Organic wastes were mixed with the soil in the ratio of 10/1 (soil/organic waste). Total count of heterotrophic bacteria, hydrocarbon utilizing bacteria and heterotrophic fungi were increased gradually during the experimental tenure while TPH concentration were decreased by 87.1%, 76.6%, 70.7%, and 32.1% after treated with goat manure, poultry droppings and cow dung, respectively after the 28 days experiment (Obiakalaije et al., 2015).

CONCLUSION AND FUTURE PROSPECTS

Bioremediation is a natural way to clean the environment without having any adverse effect on the society. As the process involves all the biological organisms, such as bacteria, fungi, algae, plant and animals, it is considered as a safe technology, environmental friendly and aesthetically pleasant and also of low cost as compared to other physical or chemical treatment methods. These agents effectively remediate pollutants from contaminated matrix by the diverse mechanism of absorption, adsorption, precipitation, enzymatic hydrolysis, detoxification and degradation. Each and every agent has particular niche and unique mechanism to deals with the contaminants. It is very easy to implement and maintain and also can be done on-site or off-site. Though there several benefits but the process is not without its drawbacks, long time taking, limitation in contaminants degradation, difficult to extrapolate from bench and pilot scale study, lack of potential biological agents, lack of proper knowledge are the main setback of bioremediation process.

Prior to go for bioremediation, meticulous knowledge of the environment must be taken and proper selection and characterization of the bioremediation agents should be done. Time taking nature of the process can be overcome by the development of modified versions of the species by the help of biotechnological techniques which may serve very effective, less time consuming process. It will also enhance the capacity of the agents for biotransformation of most toxic contaminants present in the environment. Recently, application of potential biological tools in designing the engineered ecosystem for the benefit

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

of both human and environment is an emerging field. On the basis of decontamination efficacy of various useful biological tools/component, the ecosystem can be designed following the ecological engineering technology, which would be an important environmental friendly solution for cleaning up the contaminated domain of the environment.

Future research in the area of protocol evaluation, innovative site characterization techniques, model improvement and the capabilities of bioremediation to deep will open the new frontiers in bioremediation. Special focus on understanding the biological agent's communities, their responses towards natural environment and pollutants, technology development for the degradation of complex mixture of contaminants may open the new door in bioremediation history. On the other hand a wide variety of potential bioremediation agents are waiting to be explored. However with the existing laboratory scale process development, field trials of the technology for the remediation of organic compounds, metals, metalloids, radionuclides and complex polycyclic hydrocarbons should be employed immensely. Improvement of the microbial genomics studies will be providing several robust technologies for the bioremediation of contaminated waters and land contaminated with metals. Though, the concept of potential biological tool based-engineered ecosystem is in very infancy stage, it has significant future prospect in sustainable development of pollutants free environment.

KEY TERMS AND DEFINITIONS

Biological Tools: It refers to organisms or biological substances used in any systems.

Bioremediation: It is an eco-friendly biological process employed in remediation of environmental problems (such as, pollution, contamination, etc.) using biological system or organisms.

Contaminants: Presence of unwanted substances in any matrix which cause several physicochemical changes and made the substrate polluted, toxic, unsafe, harmful to environment as well as causes health hazards.

Decontamination: The process involved in the elimination or neutralization of contaminants.

Eco-Friendly: It refers to method or product or system having no negative impacts on environment.

Ecological Engineering: It refers to an emerging technology for designing the sustainable ecosystem by integrating human society with its natural environment for the benefit of both or the fusion of engineering and ecology for the development of human and environment by the design, construction and management of ecosystems which are beneficial for both human and environment.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Ecosystem Services: Services provided by the ecosystem by the means of provisioning, regulating, cultural and supporting services. This is a self-regulating mechanism driven by the ecosystem components which fulfill the basic needs of human beings.

Living Machine: Biotic system or organisms used in bioremediation process to protection environment from degradation/destruction.

Phytoremediation: Use of different types of plants in the bioremediation, such as purification of wastewater, air and reclamation of contaminated soil are known as phytoremediation.

Zooremediation: It is a kind of bioremediation process driven by the animal systems using the mechanism of uptake, accumulation, and transformation of contaminants.

Chapter 55
Effective Management of Agro-Industrial Residues as Composting in Mushroom Industry and Utilization of Spent Mushroom Substrate for Bioremediation

Rajender Singh
Directorate of Mushroom Research (ICAR) Solan, India

Mamta Chauhan
Jaypee University of Information and Technology, India

ABSTRACT

Different types of edible mushrooms like Agaricus, bisporus, A. bitoriqus, Pleurotus spp., Volvariella volvacea, Lentinula edodes, Calocybe indica, Flamullina, Ganoderma lucidum etc. are cultivated in industrial scale. Majority of edible fungi secretes extracellular Ligninocellulolytic enzymes like Laccase, lignin peroxidase, manganese peroxidase, cellulase etc. for effective conversion of ligninocellulolytic substrate to compositing form which led to fruiting of mushrooms. Consequently, an adequate disposal method is needed for the high quantities of spent mushroom substrate (SMS) generated in this agro-food industrial activity. On the other side, textile industry among the largest water consuming industries in the world and approximately, 10,000 different dyes and pigments are used at industrial scale. It is estimated that nearly 40% of the total dyes used in the dyeing process may find their way in wastewater. So, there is an attempt to utilize the ligninolytic enzymes rich SMS of different mushroom for efficiently biodegradation of textile wastewater & polyaromatic pollutants.

1. INTRODUCTION

Mushroom cultivation is a common practice all over the world and is a major income source in China and other developing countries which also suffer from serious pollution. Total edible species of mushrooms are approximately 2000 and total edible species under cultivation are nearly 20 at commercial level. World mushrooms production annually is greater than 25 million ton (Li, 2012). Total annual mushroom production in India is 1, 20, 000 tons (DMR, 2014). Annually, world production of major lignocellulolytic biomass waste is around 1088.258 million tons (FAO). Mushroom cultivation offers a highly efficient method capable of not only biodegradation and bioremediation of agro-industrial waste but also biotransformation into proteinaceous food that can sustain food security in the developing countries (Ingale & Ramteke 2010; Narain et al. 2011; Philippoussis & Diamantopoulou 2011; Kulshreshtha et al. 2010). Many basidiomycetes fungi are edible mushrooms whose industrial production generates significant amount of spent mushroom substrate (SMS) with residual high levels of lignin-degrading extracellular enzymatic activities. Annual spent mushroom substrate required to be disposed of in India is around 6,00,000 tons (Table 1) . Spent mushroom substrate (SMS), has recently gained importance because of its unique physical, chemical and biological properties. Spent mushroom substrate (SMS) is a biomass waste generated from mushroom production. About 5 kg of SMS is generated for every kg of mushroom produced (Williams et al., 2001). Spent mushroom substrate (SMS) is the substrate left over after mushroom harvesting. The rapid growth in mushroom production worldwide has resulted in large quantities of SMS (about 13.6 million tons per year) (Williams et al., 2001; Uzun, 2004). These massive amounts of waste can cause environmental problems, which has led to increased research to develop technologies for treating these type of waste substrate. SMS mainly contains lignocellulosic materials, such as sawdust, wheat straw, paddy straw, wheat bran, chicken manure and cotton seed hulls, which have been decomposed and permeated by mycelium.

The composting of spent mushroom substrate yields a product that is valuable for agricultural utilization and soil reclamation. Mushroom produces don't reuse this spent mushroom substrate (SMS), because disease incidence, nutrient depletion and growth factor depletion. SMS has rich heterogeneous microbial populations with remains of mushrooms mycelia, actinomycetes and bacteria. It has a high organic content and low concentration of essential plant nutrient contents.

Activities in mushroom industry is steadily growing, the quantity of mushroom waste (SMS) generated annually is increasing. In recent years, the mushroom industry has faced challenges in storing and disposing these waste substrates. The obvious solution is to explore new applications and development of new technologies for the management and effective utilization of SMS. In last decades, there has been considerable discussion recently about the potential of using SMS for bioremediation of environmental pollutants.

The increasing industrialization has specially put pressure on natural resources like water bodies, agricultural land and the physical area by adding unwanted chemicals in the environment. The manufacturing and use of dyes and pigments is a multibillion-dollar industry. The use of these chemicals is an integral part of almost all manufacturing processes. Dyes are synthetic chemical compounds having complex aromatic structures, which are extensively used in the textile, cosmetics, plastic, food, paper printing, colour photography and pharmaceuticals industries. Approximately 10,000 different dyes and pigments are used at industrial scale and over 0.7 million tonnes of synthetic dyes are produced annually, worldwide (see Figure 1 and Table 1).

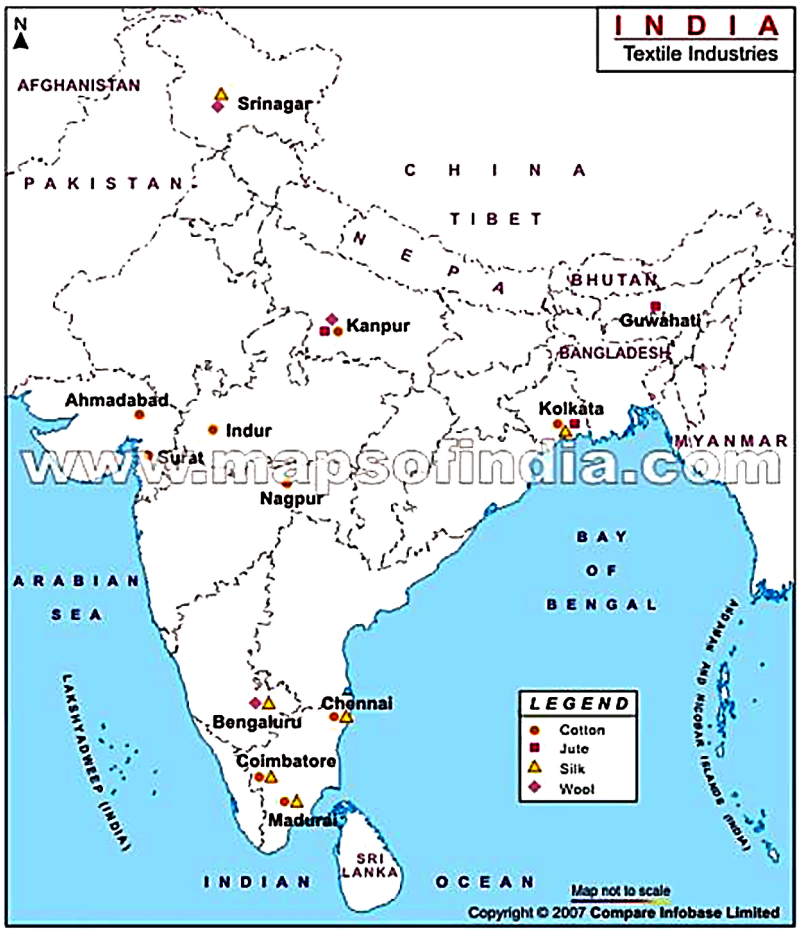
Figure 1. Location of major textile industries in different parts of India



When such wastewater effluent is discharged onto the land adjoining the agriculture crops, it causes the gradual deterioration of land quality and ultimate reduction in crop yields. Colour is the first recognised contaminant in textile wastewater and has to be removed before discharging it into receiving water body. Among various industrial effluents involved in an increase of chemical load (COD) of water systems, effluents from textile dyeing industries are the major source, resulting discharge of coloured water causing toxicities to aquatic life. The presence of a variety of dyes in the wastewater emanating from textile dyeing industries is a serious concern because of their resistance to environmental conditions like light, temperature and pH, resulting in low biodegradability. The presence of high level of heavy metals viz., copper, zinc, cadmium, chromium in wastewater further aggravates the problem. Available physical and chemical methods used for wastewater treatment have limitation due to high cost, low efficiency and in-applicability to a wide variety of dyes. Hence feasible and environmental friendly approach that is Bioremediationis used. The use of microorganisms to detoxify environmental pollutants is generally referred as bioremediation. Environmental issues are now of increasing concern and biological methods are being more directed towards technologies to minimize pollution or to remediate it if it occurs. Mushroom species like, *Pleurotus*, *Agaricus*, *Volvariella, Lentinula, Ganoderma* spp. along with white rot fungi and their ligninolytic enzymes appear to have wide industrial applications (Figure 2).

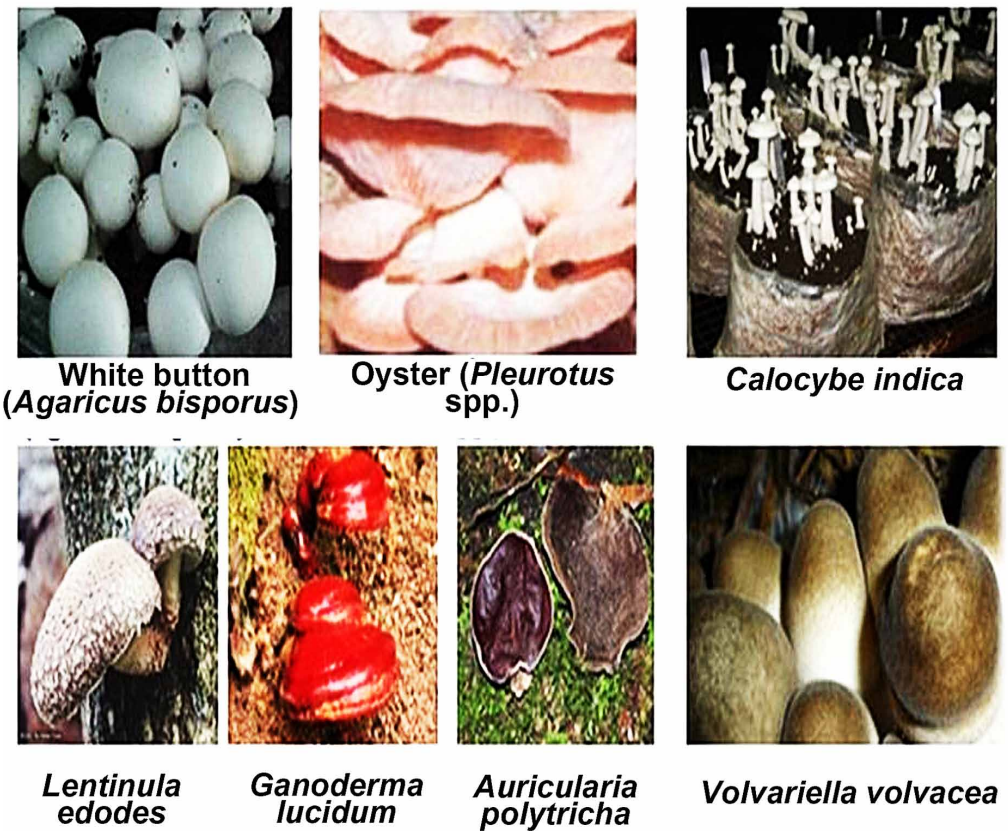
Source= FAOSTAT 2013

The biotechnology based processes involving dead or live microbial cells or their components, as biota agents are more user friendly under such conditions, as these restrict the introduction of new forms of chemicals in the environment. Mushroom cultivation is an eco-friendly method of converting a wide range of agro-residues and agro-industrial wastes in to a protein rich food in the form of mushrooms. After several cycles of mushroom cultivation, the mushroom productivity decreases and the residual by-product, generated in the form of spent mushroom substrate (SMS) required to be properly disposed of to maintain hygiene and avoid environmental problems. If not properly disposed of, it leads to environmental problems, such as soil and water contamination, due to high load of organic carbon, nitrogen and salt in SMSs of different mushrooms. The biological component of SMS is also very important,

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 2. Different species of edible mushrooms cultivated in India and worldwide



as it is constituted of mushroom mycelial biomass along with high population of heterotrophic bacteria, actinomycetes and the fungi having potential to produce full range of ligninolytic enzymes (Singh et al., 2013a, 2013b). The past studies have also supported the role of laccase, lignin peroxidase and manganese dependent peroxidase along with some more enzymes in decolourisation of colouring dyes. Highly immobilized microbial cultures in the form of SMS tend to have a higher level of bioremediative activity and are more resilient to environmental perturbations such as pH and toxic chemicals than the suspended cultures. Besides this, the immobilized cultures offer other advantages like reusability of the same biocatalyst, control of reactions, and the non-contamination of products. Immobilized form of living microorganisms have also been described more effective in biological wastewater treatment and treatment of polyaromatic hydrocarbons than the suspended form of microorganisms. The overall objective of this book chapter is to introduce with the effective management of agriculture waste residue for mushroom composting and waste generated from mushroom can be efficiently used for treatment of textile wastewater and polyaromatic hydrocarbons or others pollutants which led to bioremediation of environmental pollutants and generation of green technology.

2. CURRENT STATUS OF MUSHROOM CULTIVATION

Worldwide, the top three mushroom species cultivated are the white button mushroom (*Agaricus bisporus*), shiitake (*Lentinula edodes*) and oyster mushroom (*Pleurotus* spp.) (Suguimoto et al. 2001; Li 2012). Cultivation of these mushrooms represents a major industry in the countries of Southeast Asia (Mehta et al. 1990; Ragunathan & Swaminathan 2003). Amongst the different cultivated species, genus *Pleurotus* is an industrially important and occupying a third place in worldwide production of edible mushrooms, i.e., 16.3% of the total production (Chang, 1996). *Pleurotus* spp. can grow and produce fruit bodies in temperate and tropical zones and does not require any pretreatment of substrate. The production of *Pleurotus* spp. results in a large amount of protein (as extra-cellular enzymes) on substrates consisting primarily of wide agro-industrial and forestry waste materials (Poppe, 2000). In South Korea, the area of mushroom cultivation has increased to 1,102 km^2 and 117,600 t of mushroom was produced in 2000 (Ko et al., 2005). It has been reported that approximately five times of SMS is produced in South Korea annually, of which 58% is from *Pleurotus ostreatus* cultivation.

In the United States, the annual production of *Pleurotus* spp. has reached 880 t in 1996 and it has increased by 120-fold in 2002 (Royse et al., 2004). In 2010/2011, the oyster mushroom production has exceeded 3,700 tonnes in the United States (United States Department of Agriculture 2012). In Ireland, mushroom production is an appreciable industry and has been estimated to contribute approximately £90 million to the economies of both Northern Ireland and the Republic of Ireland. In Northern Ireland, 24,000 t of mushrooms are produced annually, offering 3,000 jobs to the nation. (Russell et al. 2005; Williams et al. 2001).

3. PRESENT WORLDWIDE SCENARIO OF SPENT MUSHROOM SUBSTRATE

Wheat straw, the above-ground biomass remaining after wheat harvest, was estimated to be around 70.9 million tons only in the U.S (Johnson et al., 2006). Individually, yard trimmings and wheat straw have exhibited low degradability due to their lignocellulosic recalcitrance (Cui et al., 2011; Zhao et al., 2014a).Although paddy straw, wheat straw, soybean, wheat bran, chicken manure are the traditional substrates for*Agaricus* spp.*Pleurotus* spp., different biological efficiencies (BE) have been reported by various authors (Ragunathan et al., 1996; Zhang et al., 2002). Other non-traditional substrates used alone or in combination with the traditional substrates include cotton stalks (BE, 32.69–41.42%) maize stover (BE, 25.18–35.39%), coir pith (BE, 26.11–27.33%), sorghum stover (BE, 32.17–36.84%), saw dust (BE, 73.5%), banana leaves (BE, 10.25%), mango leaves (BE, 5.96%), bagasse (BE, 34.29–41.31%), peanut shell, corn cobs, coffee pulp, *Eupatorium adenophorum, Populus deltoids* etc. (Ingale & Ramteke 2010; Moonmoon et al. 2010; Patrabansh & Madan 1997; Ragunathan & Swaminathan 2003). *Pleurotus sajor caju* is grown commercially on supplemented rubber-wood sawdust. For every 200 g of mushroom produced, about 800 g of spent mushroom substrate (SMS) is available. An average farm discards about 24 tons of SMS per month. The SMS consists of mycelium, extracellular enzymes produced by fungus during growth and unutilized lignocellulosic substrate. The disposal of SMS is a major problem to farmers. Of the total spent compost produced in Malaysia, 69% is dumped in landfill sites, 28% is applied to agricultural land and remaining 3% is incinerated (Vigneswaran et al., 1997). However, most spent compost is produced in large urban areas and it can be extremely expensive to transport it to farming areas where it is given free to farmers. A further difficulty is that farmers only require compost at certain

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

times of the year whereas spent compost is produced all year round. On the other hand, the incineration of compost is an alternative method of disposal whereby it offers a large reduction in the volume of the solid waste to be disposed of, along with the elimination of nuisance from biological decomposition. The method of incineration requires smaller space, relatively to land application but has the disadvantage of generation of ash (25 - 40% of the incoming load on a dry basis) which can have high polluting qualities (Vigneswaran et al., 1997). As both the main methods currently employed for the disposal of compost has some drawbacks, it becomes necessary to explore new applications of the spent mushroom compost.

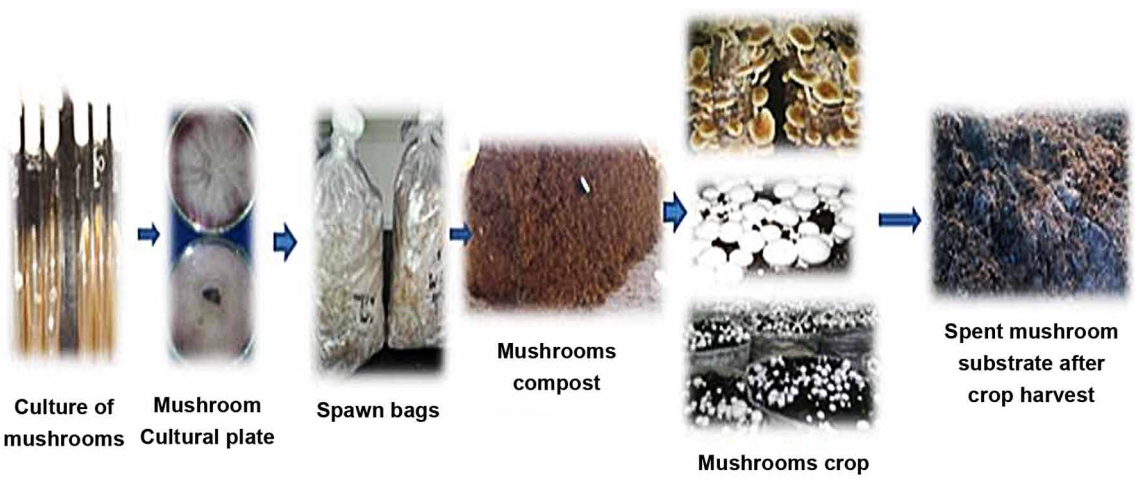
SMS is commonly made from renewable agricultural residues such as sawdust, sugarcane bagasse, oil palm empty fruit bunch, wheat straw-bedded horse manure, hay, poultry manure, ground corncobs, cottonseed meal, cocoa shells, gypsum and other substances (Jordan et al., 2008). One of the main difficulties in the management of SMS is the lack of waste management supervision (Magette et al., 1998).

The current largest mushroom producer of mushrooms, China has attained more than 20 mt and accounted for over 80% of the world's mushroom production (Li, 2012). An average farm discards about 24 t of SMS per month (Singh et al. 2011). In Ireland, approximately 254,000 t of SMS is generated each year (Barry et al. 2012) and in The Netherlands, more than 800,000 t of SMS is produced per year (Oei & Albert 2012). In some countries, waste management of SMS is a major problem faced by farmers. Apparently, the obvious solution is to increase the demand for SMS through exploration of new applications for utilization (Figure 3).

4. PHYSICO-CHEMICAL PROPERTIES OF SPENT MUSHROOM SUBSTRATE (SMS) OF DIFFERENT MUSHROOMS

The major physico-chemical properties of fresh spent mushroom substrate of different mushrooms were determined and the pH of spent substrates varied between 7.7 in *Agaricus bisporus* to 6.8 in *Pleurotus sajor-caju* SMS. Moisture content was higher (64%) in SMS of *Agaricus bisporus*, followed by spent

Figure 3. Schematic diagram for development of mushroom culture, spawn, compost, cultivation and spent mushroom substrate generation



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

substrate of *Pleurotus sajor-caju* (55%). Moisture content (64%), Nitrogen (1.8%), Sodium (105 ppm), Potassium (275 ppm) and Calcium (1045 ppm) were higher in spent substrate of *A. bisporus* (Table 2) compared to SMS of *P. sajou-caju* with an exception of Carbon (33.2%). The values of Carbon, Nitrogen, Sodium, Potassium and Calcium were 42%, 1.7%, 48 ppm, 134 ppm and 896 ppm, respectively in spent substrate of *Pleurotus sajor-caju.* These results indicate that spent substrate of both *Agaricus bisporus* and *Pleurotus sajor-caju* provides good nutrient source for the growth of different bacteria and fungi (Table 2).

5. MICROFLORA OF SPENT MUSHROOM SUBSTRATE

SMS is the left over substrate after harvesting mushrooms; it is harboring both bacteria and fungi. The microorganisms from SMS were characterised as *Enterobacter sp, Bacillus polymxa, Micrococcus roseus, Citrobacter fruedi, Bacillus subtilis, Clostridium perfringens, Pseudomonas aeruginosa, Bacillus cereus, Bacillus licheniformis, Escherichia coli* (Table 3)and the fungi fromSMS were characterized as *Trichoderma hazianum, Trichoderma polysporum, Trichoderma viride, Pencillium janthinellum, Mycogene perniciosa and Aspergillus bisporus* (Viji et al., 2003). All the three SMS namely, *Agaricus bisporus*, *Pleurotus* spp., and *Volvariella volvacea* have fungal isolates namely *Penicillum* spp, *Rhizopus* sppand *Aspergillus niger* with potential for dye decolourization (Table 4). Among these,*Aspergillus niger* showed greaterdecolourization potential during 16 days incubation. Decolourization may be due biosorption,which is dependent on functional groups in the dye molecule in fungal biomass. The SMSisolates are able to decolourize and detoxify highly concentrated effluent (Manikandan et al., 2012). The catalytic stability is often improved by immobilization, microorganisms may degrade higher concentration of toxic components than their free cell counterparts.

6. BIOREMEDIATION OF POLYAROMATIC HYDROCARBONS BY SPENT MUSHROOM SUBSTRATE

Bioremediation of PAH-contaminated soils is based either on the biostimulation of the indigenous microbiota (Sayara et al., 2010) or on the addition of exogenous microbes, the latter approach being

Table 2. Physico-chemical properties of spent mushroom substrate (SMS) of different mushrooms

Physico-Chemical Properties	Spent Mushroom Substrate	
	Agaricus bisporus	*Pleurotussajor-caju*
Moisture (%)	64.00	55.00
pH	7.70	6.80
Total Nitrogen (%)	1.8	1.70
Total Carbon (%)	33.2	42
Sodium (ppm)	105.00	48.00
Potassium (ppm)	275.00	134.00

referred to as bioaugmentation (Haritash & Kaushik, 2009). Bioaugmentation with lignin-degrading fungi (LDF) to perform the clean-up of PAH-contaminated soils has received increasing attention in recent years due to its reported efficacy (Covino et al., 2010b; Federici et al., 2012a). LDF are known to produce extracellular lignin-modifying enzymes (LME) with low substrate specificity which enables them to degrade a wide range of organic pollutants, including PAH (Covino et al., 2010c). The main LME enzymes include multi-copper oxidases, such as laccase, and heme-peroxidases (Mn-peroxidase (MnP), versatile peroxidase and lignin peroxidase).Contaminant degradation by Lignin degrading fungi (LDF) in soil requires the addition of lignocellulosicmaterials either as amendments, or inoculum carriers (Covino et al., 2010a). The use of these additives has been found to have a favorable impact on the resident microbiota, including specialized populations (Federici et al., 2012a). PAH degradation via bioaugmentation with LDF has been shown to involve either synergistic or antagonist interactions between the fungi added and the autochthonous microflora.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

The use of spentmushroom substrate of some ligninolytic fungi as a source of viable inocula for soil clean up applications has been proposed (Li et al., 2012). However spent *Agaricus bisporus* substrate (SAS), without previous treatment, has never been used for bioremediation of PAH polluted soil. Spent substrate of *Agaricus bisporus*, has been shown to enhance the ability of the fungi to endure the toxic effects of both cadmium and lead in a PAH-contaminated substrate (García-Delgado et al., 2013a). Marín-Benito et al., (2014) reported the ability of pesticide degradation by spent substrate of *Agaricus bisporus*used as composted with spent substrate of *P. ostreatus*(75:25) and its adsorption capacity for fungicides with low polarity that reduce their mobility in the environment. In addition, spent substrate of *A. bisporus* has been reported to be an excellent source of LME, mainly laccase that were able to biodegrade PAH in aqueous solutions (Mayolo-Deloisa et al., 2011). The annual production of this organic waste in Europe has been estimated at 3.5 × 106 t (Pardo-Giménez & Pardo-González, 2008) consequently its potential use in bioaugmentation applications would certainly help to reduce this amount (Table 5).

This needs a variety of manipulations of the waste prior to its application, to gain more insight into its ability to act as an organic amendment, fungal carrier or a supplier of exogenous complex microbiota or microflora.The addition of the sterilized spent *A. bisporus* substrate to polluted site was effective in stimulating the resident soil bacteriawhich resulted in higher levels of 3-ring PAH being removed. Bio-augmentation treatments with spent substrate of *A. bisporus*, were more effective in removing 5, 6-ring PAH. The wide availability of this agro-waste combined with its proved efficacy in PAH biodegradation make its use technically feasible for environmental remediation purposes. Another field of the use of spent mushroom substrate from commercial production of edible fungi is bioremediation of soil contaminated with different organopullutants. Spent substrate of *A. bisporus* was successfully used in remediation of soil contaminated with chlorophenols, hydrocarbons and volatile organic compounds (Semple et al., 2001). The ability to degrade chemically different compounds was attributed to the extracellular enzyme systems (lignin peroxidase, manganese-dependent peroxidase and laccase) and production of reactive free radicals (Field et al., 1993). Several species of cultivated and medicinal mushrooms (e.g. *Pleurotus ostreatus*, *Agrocybe aegerita*, *Kuehneromyces mutabilis*, *Trametes versicolor, Stropharia rugosoannulata* were also found to be able to degrade different organopollutants (Sack & Fritsche, 1997; Song, 1999).

Many factors influence the effectiveness of fungal soil bioremediation and one such include the concentration of respective pollutants in the soil. Eggen (1999) successfully applied spent oyster mushroom substrate to remediation of soil with initial concentration of poly -aromatic hydrocarbon of 1900 mg/kg. In this study we used a similar substrate for remediation of soil in which PAH concentration was three times as high. Polycyclic aromatic hydrocarbons (PAHs) belong to a class of organic compounds that are persistent and recalcitrant in the environment. Biodegradation of PAHs especially by white-rot fungus *Pycnoporus sanguineus* is considered environmentally friendly when compared to the conventional physical–chemical remediation which might lead to secondary contamination and the need for additional post-treatment (Annuar et al. 2009). Similarly, Vikineswary et al., (2006) have shown that a higher laccase productivity (7.60 U/g substrate) during solid substrate fermentation of sago hampas was achieved as compared to oil palm frond parenchyma tissue (7.52 U/g substrate) and sawdust (5.68 U/g). The capacity of *P. sanguineus* to remove PAHs like anthracene, phenanthrene and pyrene was attributed to the enzyme laccase secreted (Munusamy et al., 2008).

Now, the potential of SMS in bioremediation of PAH has attracted more attention. Bioremediation by employing crude extracts containing PAH-degrading enzymes from SMS are supposed to be more economical compared to pure enzyme/s. Purification of pure enzyme is often expensive and has limited application in bioremediation. However, it could not be a one-to-one relationship between PAH degra-

dation rate and a particular enzyme activity, since crude extracts contained more than one enzyme. An intergraded waste management approach by combining ozone oxidation pre-treatment and SMS-mediated aerobic biological treatment of benzo(α)pyrene was granted successful (Russo et al. 2012). The matrix of *Pleurotus pulmonarius*-degraded paddy straw consist predominantly –OH groups which hypothetically contributed by the cellulosic cell wall of plant matter and they facilitated the biosorption of PAHs (Lau et al., 2003). Laccase was found in the SMS of *P. pulmonarius* and its activity was 1.5-fold higher than that of manganese peroxidase (MnP). More recently, pilotscale PAH removal capacity of spent substrate of *P. ostreatus* in Nigerian oil-based drill cuttings has been investigated and after 56 days, the degradation of total PAHs was as high as 92.38% (Ayotamuno et al. 2010). Besides that, the highest total degradation rate of 15 PAHs were achieved by adding crude extracts from spent substrate of *Pleurotus eryngii*, followed by *A. bisporus*, *P. ostreatusand Coprinus comatus* (Li et al. 2010). Interestingly, laccase activity from the crude extracts of spent substrate from *P. eryngii* was not the highest amongst all. This showed

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

that the laccase activity was not positively correlated to the PAH degradation rate, implying that natural mediators present in different crude extracts might contribute to the degradation rate, rather than laccase alone. Oxidation of phenol by crude extracts of spent substrate from *A. bisporus* was reported and laccase was identified as the main enzyme responsible for the oxidation (Trejo- Hernandez et al. 2001).

7. COCKTAIL OF LIGNINOLYTIC ENZYMES GENERATED FROM SPENT MUSHROOM SUBSTARTE

Mushroom enzymes reported in the literature are derived from mycelia of macro-fungi grown in submerged fermentation. Enzymes can also be extracted from solid substrate fermentation technology which is a process mimicking nature (Pandey et al. 2000). After mushroom crop harvesting, the spent mushroom compost will have plenty of extra-cellular enzymes. Of all the enzymes, laccase (EC 1.10.3.2) is the most reserved and common in spent substrate from *Agaricus bisporus* (Mayolo- Deloisa et al. 2009), *Pleurotus sajor-caju* (Kumaran et al. 1997; Singh et al. 2003), *P. ostreatus*, *Lentinula edodes*, *Flammulina velutipes* and *Hericium erinaceum* (Ko et al. 2005). However, lignin peroxidase productivity (per microgram of SMS) was found to be the highest from the spent substrate of *P. sajor-caju* (Singh et al. 2003) and it was two-, 22-, 30-, 86-fold higher than that of β-glucosidase, laccase, xylanase and cellulase, respectively. It is believed that the type of enzymes produced by mushroom during cultivation is directly affected by the ingredient of growing substrates and the species of mushrooms (Ball and Jackson 1995).A total of eight dyes from the triphenylmethane, azo and polymeric/heterocyclic dye group were decolourized by enzyme cocktail extracted from five month old spent compost of *Pleurotus sajor-caju* with lignin peroxidase as the main enzyme (Singh et al., 2010).So far spent compost of *Agaricus bisporus* has been employed for the recovery of laccase (Ball & Jackson, 1995; Mayolo-Deloisa et al., 2009). The decolourisation of Remazol brilliant blue R by laccase from the spent compost of *Lentinus polychrous* Lev. has also been reported (Khammuang & Sarnthima, 2007). Spent mushroom compost of *Pleurotus* spp. which represent the second largest group of cultivated basidiomycetes, has only been implicated in the bioremediation of polyaromatic hydrocarbons (Chiu et al., 1998; Eggen, 1999; Lau et al., 2003).

However, the potential of enzymes from the spent compost of *Pleurotus* spp. for the decolourisation of dyes has not been explored. However, there has been an earlier report on the extraction of high titers of lignin peroxidase (LiP) from the spent compost of *P. sajor-caju* and its potential in thedecolourisation of selected synthetic dyes (Avneesh et al., 2002). Decolourisation of azo dyes by the cultures of *P. sajor caju* has already been reported (Chagas & Durrant, 2001). Since azo dyes make the largest group of synthetic colourants used in textile industries which were released into the environment, decolourization of azo dyes by the enzyme cocktail from the spent compost offers economical bioremediation alternative.

Simona Di Gregorio et al., 2010 also demonstrated that the enzyme showed also a significant stability with respect to the temperature of incubation, and all the characteristics previously de-scribed make the laccase from spent substrate of *P. ostreatus* showed extremely attractive for industrial application, suggesting the exploitation of the SMS not only as a low cost substrate with oxidative capacity, but also as a source of robust laccase. In this context, the induction of laccase production could be advantageous for enzyme-purifying purpose, even though, in the experimental condition here explored, an effect of induction of the chromo baths on the ligninolytic battery of enzymes eventually associated to the SMS was absent.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

8. ROLE OF SPENT MUSHROOM SUBSTRATE IN DYES DECOLOURISATION

Mushrooms are ligninolytic fungi and represent an important organism in natural recycling events and in bioremediation (Gadd 2001). The enzyme systems of mushrooms contain lignin peroxidase, laccase and manganese-dependent peroxidase which catalyses metabolisation of many ligninlike structures, for example, PAHs and phenols. However, only in this decade, greater attention has been drawn to reuse SMS and the enzymes recovered from it as an economical approach in bioremediation of such pollutants (Eggen & Sasek 2002).

Textile industry is one of the largest water consuming industries in the world. The manufacturing and use of dyes and pigments is a multibillion-dollar industry. The use of these chemicals is an integral part of almost all manufacturing processes. Dyes are synthetic chemical compounds having complex aromatic structures, which are extensively used in the textile, cosmetics, plastic, food, paper printing, colour photography and pharmaceuticals industries (Forgacs *et al.,* 2004). Approximately 10,000 different dyes and pigments are used at industrial scale and over 0.7 million tonnes of synthetic dyes are produced annually, worldwide (Knapp *et al.*, 1997). United States Department of Commerce has predicted a 3.5 fold increase in textile manufacturing by 2020 (Ganesh *et al.,* 1994; Walsh *et al.,* 1980). In India, an average textile mill producing 60 x 10^4 m of fabric per day is likely to discharge approximately 1.5 Megalitres per day (MLD) of effluents (COINDS, Comprehensive Industry Document Series, 1999-2000). During industrial dyeing process a substantial amount of dye is lost in the waste water. It is estimated that nearly 40% of the total dyes used in the dyeing process may find their way in wastewater (Vaidya *et al.,* 1982).Evenin modern days of industrialization, an industrial waste effluent is being often discharged into water bodies without any adequate pre treatment. When such wastewater effluent is discharged onto the land adjoining the agriculture crops, it causes the gradual deterioration of land quality and ultimate reduction in crop yields. This has led to an enhanced concern and awareness, forcing Government of India to strict legislations for controlling the discharge of untreated effluents into the environment, may it be land, water or air.

Major classes of synthetic dyes are azo, anthraquinone and triaryl methane, and majority of them are toxic and even carcinogenic with long turnover times. With the increased use of a wide variety of dyes, pollution due to dye wastewater is becoming increasingly alarming. Colour is the first recognised contaminant in textile wastewater and has to be removed before discharging it into receiving water body (Padamavathy *et al.,* 2003). The presence of high level of heavy metals viz., copper, zinc, cadmium, chromium in wastewater further aggravates the problem (Pagga & Taeger, 1994). Textile industry is also one of the water intensive industries, which consumes large quantity of water for various processes and discharges equally large volume of wastewater containing a variety of pollutants. According to an estimate, a mill having production capacity of 35,000 m cloth per day consumes 1,000 kl water and produces effluents of 800 kl day^{-1}. Textile industry in India is one of the oldest industries. Large textile mills are (Fig. 1) mainly situated in Ahmadabad, Surat, Mumbai, Coimbatore, Kanpur and Delhi.The exact data on the number of processing houses operating in the cottage and household sector is not available and it has remained by and large unorganized. The textile units are scattered all across the country and out of 21,076 units, Tamilnadu tops with 5,285, whereas Maharashtra has the next highest number of units (ISPCH, 1995).

Physical processes if followed by chemical or biological process have shown good results. However, wide variation in BOD and other parameters necessitates the requirement of equalization of various physio-chemical processes viz., chemical coagulation / flocculation, adsorption, ion exchange, etc.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Chemical coagulation employing various chemical coagulants followed by setting, have proven to be highly efficient in removing solids, BOD and COD from textile effluents and attained its reliability as physical and chemical unit (Mohan *et al.,* 1997; Robinson *et al.,* 2001 a). Removal of colour from the effluents is difficult by using conventional physico-chemical treatment system. However, biological treatment may be the best alternative, as the operational costs involved in it are relatively low compared to conventional technologies (Arutchelvan *et al.,* 2003).

Mushroom cultivation is an eco-friendly method of converting a wide range of agro-residues and agro-industrial wastes in to a protein rich food in the form of mushrooms. After several cycles of mushroom cultivation, the mushroom productivity decreases and the residual by-product considered as spent mushroom substrate which required to be properly disposed off to maintain hygiene and avoid environmental problems. If not properly disposed off, it leads to environmental problems, such as soil and water contamination, due to high load of organic carbon, nitrogen and salt in SMSs of different mushrooms.

Syntheticdyes find application in different industrial divisions including textile industry. An annual consumption of about 0.7 million tons of synthetic dyes has been reported (Deveci et al., 2004).Textile industry alone ac-counts for two-thirds of the total dyestuff market. Accordingly, discoloration of textile wastewaters is one of the major environmental concerns since last decades. However, it is worth to mention that *P. ostreatus* and many other basidiomycetes are edible mushrooms and their industrial cultivation produces a significant amount of spent mushroom substrate (SMS), reported as harboring high levels of residual oxidative enzymatic activity (Ball et al, 1995). Thus, SMS would be a low cost source of ligninolytic enzyme and their use for bioremediation for environmental pollutants (Trejo Hernandez et al., 2001; Karla et al., 2009). Gregorio et al., 2010 also studied that the low cost organic substrate, the SMS deriving from the cultivation of the basidiomycetes *Pleurotus ostreatus*, is able to discolor anthraquinonic, diazo and monoazo-dyes when incubated in dying chromo-reactive and chromo-acid baths containing surfactants and anti-foams, where the concentrations of the different dyes are exceeding the one recovered in the corresponding wastewaters.

9. BIOREMEDIATION OF FUNGICIDE/INSECTICIDES

Disposal of Spent Mushroom Substrate (SMS) generated after button mushroom cultivation is a matter of great concern as it is produced nearly five times to the quantity of mushrooms produced. The bulk of SMS makes its disposal more arduous besides the involvement of finance for its disposal. Moreover, unplanned disposal causes considerable land and water pollution along with nuisance in the surroundings. SMS have potential to bioremediate several agricultural grade fungicides and pesticides (Ahlawat *et al*., 2010, 2011).

10. DISCUSSION

Many fungal species are cultivated either for culinary or medicinal purposes, and some of the fungi are produced on large scales. The spent substrate left after fruit body collection is partly recycled in open field agriculture, but partly it causes environmental problems as bulk waste material. However, the spent substrates might represent a potential tool to cure polluted environment especially soils. Up to now spent mushroom substrate from only from few species i.e. *Agaricus bisporus*, *Lentinula edodes*, *Pleurotus*

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

spp., *Trametes versicolor* have been studied either under lab conditions or in field scale. In the research work performed, spent oyster mushroom substrate demonstrate higher degradation capability to degrade 3-ring PAH compounds even in soil with initial concentrations.Of many different spent substrates from edible and medicinal mushroom cultivation. Only a few have been tried in soil remediation up to now. Results obtained are variable; on one side, encouraging data on depletion of PCP and PAHs from contaminated soil using spent substrate of *Lentinula edodes*, *Pleurotus pulmonarium* and *P. ostreatus* have been published (Okeke et al., 1993, 1996; Chiu et al., 1996; Eggen, 1999). The advantage of the use of spent mushroom substrate in soil restoration is rgar it is a cheap inoculums source and its application can to some extent reduce the cost of its disposal.

11. CONCLUSION

It could be concluded that the enzymes extracted from the spent compost of *P. sajor-caju* offers an economical advantage of obtaining industrially important enzymes, which have potential in the bioremediation of synthetic dyes. Furthermore, the utilization of spent compost for the extraction of enzymes can also offer a possible solution for the problem posed due to the disposal of large amounts of spent mushroom compost. It has being shown that enzymes extracted from the spent compost of *P. sajor-caju* have potential in the decolourisation of chemically different dyes. In addition, the effect of certain physical parameters on the rate of decolourisation of each dye was also shown. The study also provided insight on how the knowledge of these parameters can help in the optimization of processes employing enzymes for bioremediation on an industrial scale. Moreover, the *in vitro* treatment of environmental pollutants with crude ligninolytic enzymes of white rot fungi represents a simpler and effective method as compared to the direct application of the fungi by eliminating the need to grow biomass and absorption effects of the pollutants on the mycelia. The utilization of SMS for the extraction of enzymes offers an economical advantage of obtaining industrially important enzymes without long incubation periods and additional cost of specialized fermentations.

Chapter 56
Bioremediation of Pharmaceutical Wastes

Alka Bali
Panjab University, India

ABSTRACT

The astounding increase in the use of pharmaceuticals in the last decade has raised concerns over their occurrence in the soils and wastewaters posing potential dangers to the general public health and environment. Considering the limitations of chemical remediation measures in treatment of recalcitrant xenobiotics, several bioremediation measures are being currently investigated and proposed for removal of pharmaceutical contaminants from the environment. Several bacterial, fungal and plant species have shown promising bioremediation potential with regard to the removal of pharmaceuticals. Varying configurations of anaerobic and aerobic reactors have been utilized for pharmaceutical wastewater treatment. This chapter is intended to give a compilation and overview of the various types of bioremediation measures currently being employed or investigated to remove the pharmaceutical pollutants.

INTRODUCTION

Pharmaceuticals comprise the broad group of synthetic as well as naturally obtained chemicals, intended for human or veterinary use as medicines. The use of pharmaceuticals and personal care products (PPCPs) has shown an astonishing increase in the last decade. Pharmaceutical industry production involves a wide range of raw materials, solvents, antibiotics, drugs and cosmetic products and hence, pharmaceutical effluents contain a wide variety of potentially harmful constituents (Dixit & Parmar, 2013). Pharmaceuticals enter the waste water, ground water, surface waters and soil through various means (Deziel, 2014). These include the sewage carrying excreta of patients on prescription or over the counter medicines, uncontrolled and unaccountable disposal of drugs by individuals as well as organizations, errant production houses lacking proper facilities for the disposal of drug waste, etc. The most frequently detected classes of pharmaceuticals in wastewater are NSAIDs, antibiotics, beta-blockers, lipid-regulators, steroids, antiepileptics, X-ray contrast media and tranquilizers (Drewes, 2007). The

sewage treatment plants employed for treating wastewaters have been found to act upon the previously conjugated pharmaceutical residues (bound to a bile acid) excreted from the patients. The latter undergo de-conjugation, yielding higher levels of free pharmaceutical substance in the plant outlet than in its incoming water. Wastewater reuse in areas with water scarcity leads to contamination of drinking water with pharmaceuticals like sulphamethoxazole, ibuprofen and carbamazepine in low levels (Luo, Guo, Ngo, Nghiem & Hai, 2014). Limited studies have shown that presence of these low level pharmaceutical contaminants in wastewaters can be potential dangers to human health (Pomati et al, 2006).

Further, the continual input of antibiotics into the environment is leading to emergence of newer antibiotic-resistant strains of microorganisms (Larsson, 2014). Currently, the antibiotic contamination is being recognized as a global environment issue. The recalcitrant nature of antibiotics sprouting from their inherent resistance to biodegradation due to their antimicrobial properties further complicates the issue in comparison with other classes of pharmaceuticals. This antibiotic contamination can promote the mobilization as well as the fixation of resistance genes among human and animal commensal bacteria along with other environmental and clinically-relevant species (Baquero, Tedim, & Coque, 2013; Kristiansson et al, 2011)). Several studies have shown the harmful effects of wastewater contamination on various animal species. Hormonal drugs have demonstrated capability of feminizing or masculinizing fish (Gilbert, 2012). Further, the non-steroidal anti-inflammatory drug (NSAID) diclofenac, can cause damage to the gills and lungs in fish populations (Gilbert, 2012).

The concerns regarding the presence of pharmaceuticals in the environment are many (Patneedi & Prasadu, 2015), and concrete remedial measures are yet to gain momentum but, this relatively recent field is rapidly acquiring eminence with several bioremediation measures being investigated and proposed for removal of pharmaceutical contaminants from the environment. Chemical methods can possibly lead to the generation of newer xenobiotics which can persist in the environment and may not be amenable to biological transformation. Biological processes utilizing microorganisms, plants and enzymes represent an eco-friendly approach towards the removal of pollutants from the environment. This book chapter is intended to explore and compile the various types of bioremediation approaches currently applicable (or holding considerable future promise) to successfully treat pharmaceutical industry effluents.

PHARMACEUTICAL WASTES AND THEIR ENVIRONMENTAL IMPACT

In recent times, concerns are being raised over the occurrence of pharmaceuticals in the environment and their potential adverse effects on general public health, flora and fauna and the aquatic environment. The pharmaceuticals may be categorized into four classes based on their occurrence in environment and their risk effects as:

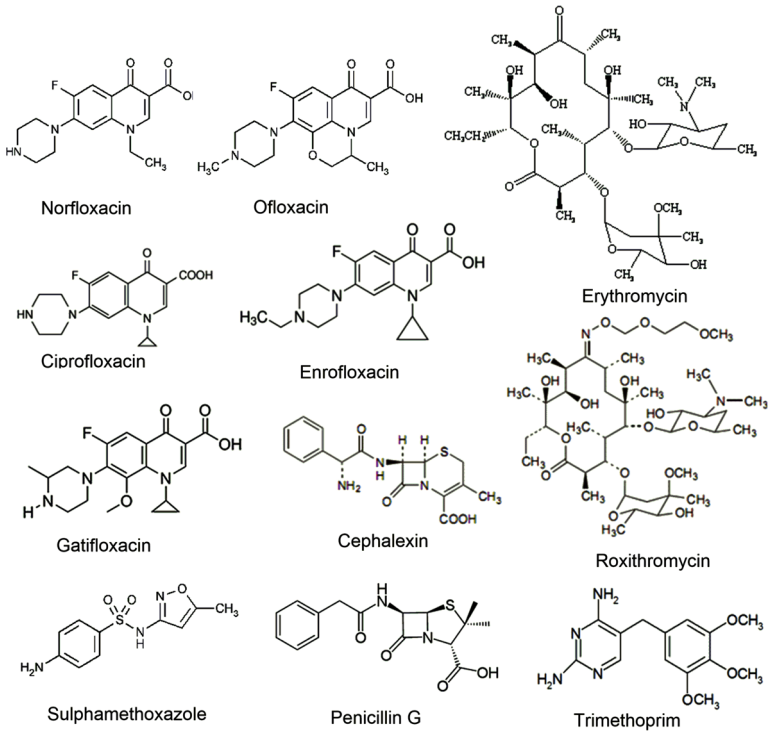
1. Hormonal drugs and their derivatives, found in effluents at nanogram levels but pose a health risk due to their high potency and potential effects as endocrine disruptors,
2. Antineoplastics (anticancer) agents, with cytotoxic, carcinogenic, mutagenic and embryotoxic potential on account of their high reactivity,
3. Anti-infective agents, including antibiotics, and
4. Halogenated compounds such as X-ray contrast media, which are highly resistant to biodegradation and hence, highly persistent in the environment and food chain.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Several studies have highlighted the toxicity concerns of pharmaceuticals in wastewater, particularly, their potential to induce DNA damage and to cause lipid peroxidation effects (Mansour, Mosrati, Barillier, Ghedira, & Chekir-Ghedira, 2012). The US-EPA and other international agencies have listed the antibiotics (Figure 1), analgesics and other drugstore products (Figure 2) as top priority pollutants. The large scale production and use of antibiotics both in clinical and veterinary medicine, aquaculture, horticulture and agriculture has led to significant discharges of antibiotics into the environment. The bacterial isolates in the pharmaceutical effluents get exposure to sub-optimal dose of antibiotics produced by the factories and these constitute a major threat to public health. Many antibiotics are known to be persistent in the environment (Zuccato, Calamari, Natangelo, & Fanelli, 2000). A three year study conducted on seventy two pharmaceuticals and personal care products concluded that the half-lives for antibiotics when they reach agricultural soils can be phenomenally high, e.g., 55 to 578 days for tetracycline and 120 to 2310 days for ciprofloxacin (Walters, McClellan, & Halden, 2010). There have been several reports on isolation and characterization of newer antibiotic-resistant bacterial strains from pharmaceutical industrial wastewaters demonstrating varying patterns of multi-drug resistance (Tahrani et al., 2015).

A wide array of chemical as well as biological treatment methods are being employed by pharmaceutical industries for disposal of wastewater (Deegan et al., 2011). These include the use of ozone, Fenton's method, coagulation, electrocoagulation (Dixit & Parmar, 2013), pH correction, oxidation, sand filtration (Saleem, 2007), sedimentation, membrane separation, UV irradiation, photelectrocoagulation, peroxi-photelectrocoagulation, peroxi-electrocoagulation, adsorption, chlorination, distillation, reverse osmosis, bacterial treatments (Madukasi, Dai, He, & Zhao, 2010), phytoremediation methods including algal treatment, methods using membrane bioreactor (MBR) (C. Chang, J. Chang, Vigneswaran, &

Figure 1. Antimicrobials (antibiotics and sulphonamides) as pharmaceutical wastes



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Kandasamy, 2008), fungal treatment (Spina, Anastasi, Prigione, Tigini, & Varese, 2012), anaerobic fixed film reactor (Rao, Naidu, Prasad, Rao, Mohan, Jetty, & Sharma, 2004), aerobic sequencing batch reactor (ASBR) (Patil, Kulkarni, S. Kore, & V. Kore, 2013), membrane-aerated biofilm reactor (MABFR) (Wei et al., 2012) and activated sludge method (Mayabhate, Gupta, & Joshi, 1988).

Chemical/physicochemical purification methods utilize costly chemicals and treatment units, which are difficult to manage at the industrial unit level and they can also possibly generate additional by-products with complex pharmacological/toxicity profiles, e.g., chlorination of phenols resulting in more toxic chlorinated products (Krug, Ziegler & Straube, 1985; Lee, Lu, & Chuang, 1994). Microorganisms play a critical role in the degradation of xenobiotics and in maintaining the steady-state concentration of chemicals in the environment (Misal, Lingojwar, Shinde, & Gawai, 2011). Their incredible versatility to catabolize, degrade or transform various contaminants has been increasingly investigated for removal of different types of non-pharmaceutical and pharmaceutical contaminants. The development of various types of aerobic and anaerobic biological reactors employing these microorganisms has revolutionized this field and this has become a prime area of research today. Further, phytoremediation and enzyme based approaches are being explored and encouraging results are generating novel leads in this area which can open up newer avenues in future.

BIOREMEDIATION APPROACHES OF PHARMACEUTICAL WASTES

Different types of bioremediation approaches for treatment of pharmaceutical wastewaters rely on specific strains of bacteria and fungi which have the capability to degrade or transform the pharmaceutical pollutants under anaerobic or aerobic conditions. Various types of anaerobic and aerobic reactors have been designed employing bacterial and fungal consortia as bioremediation measures. Besides these, plants and certain enzymes have also been explored as a means of removal of pharmaceuticals from industrial effluents and wastewaters.

BACTERIAL BIOREMEDIATION

Several bacterial strains like *Pseudomonas, Enterobacter, Streptomonas, Aeromonas, Acinetobacter* and *Klebsiella* have been shown to demonstrate upto 44% reduction in the chemical oxygen demand (COD) in anaerobically treated spent wash (Ghosh, Verma, Mengoni, & Tripathi, 2004). Soil bacteria such as *Arthrobacter* and *Pseudomonas* predominantly present in rhizospheric soil, possess a special phenolic biodegradation potential. Numerous bacteria from the genera *Comamonas, Rhodococcus and Ralstonia* have been shown to degrade phenolic and other complex organic compounds and hence, have potential utility in degrading the pharmaceutical pollutants as well. Some *Clostridium* species (fermenting bacteria) can degrade resorcinol (Kavitha & Beebi, 2003). Thermophilic bacterium *Bacillus thermoglucosidasius* A7 has been shown to degrade phenols/cresol at 65^0C *via* the meta-cleavage pathway (Duffner, Kirchner, Bauer, & Muller, 2000). The bacterium *Pseudomonas fluorescence* has also been reported to demonstrate the capability to degrade phenols and chlorophenols (Agarry & Solomon, 2008). Biodegradation kinetics of phenol and catechol has been studied using *Pseudomonas putida* MTCC 1194 (A. Kumar, S. Kumar, & S. Kumar, 2005). Phototropic bacterium *Rhodobacter sphaeroides* has been used for treatment of pharmaceutical wastewater and 80% COD removal was achieved (Madukasi et al., 2010).

The specific bacterial species acclimatized in presence of the compounds needing remedial methods can be assets in bioremediation approaches and several of these have been investigated. Many researchers have worked on the isolation and identification of species from the sludge of biological treatment plants in pharmaceutical industries and have used those bacteria for utilization of other pharmaceutical ingredients. Bacteria highly resistant to a large number of antibiotics and non-antibiotics have been identified in such studies. The same bacteria, however, have also been seen to demonstrate a good potential to degrade and bioremediate some other non-antibiotic pharmaceutical effluents (Basu, Dastidar, Mukhopadhyay, & Gangopadhyay, 2012). Effective bioremediation of pharmaceutical waste water by *Pseudomonas putida* mt-2 has been recently reported (Mansour et al., 2012; Mansour, Dellai, & Ayed, 2012). *P. putida* was found to be very efficient in reducing the chemical oxygen demand (COD), total dissolved solids (TDS), and turbidity of solution (85.5, 89.1, and 81.5%, respectively). Further, genotoxicity evaluation studies on the effluent showed that the chromosomal aberrations and lipid peroxidation effects induced by the pharmaceutical wastewater (PW) were significantly reduced on bioremediation with *P. putida. Pseudomonas putida* IFO 14671 has also been isolated, and identified from the *Gomeya*/cow dung microbial consortium as a high-potential phenol degrader (Rao et al., 2004; Singh & Fulekar, 2009). *P. putida* isolated from cow dung microflora has been demonstrated a potential to degrade benzene (Singh

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

& Fulekar, 2010). Bioremediation of effluents with *P. putida* has been shown to completely remove the murine chronotoxicity to pharmaceutical wastewater (Dridi, Bchir, Zouiten, Tahrani, & Mansour, 2013). Recently, biodegradation of the pharmaceutical waste, 4-nitrophenol has been shown with *P. putida* (Guleria, 2014).

Antibiotics, on account of their inherent properties, pose problems to bioremediation measures. However, there are several reports where these have been biodegraded in presence of consortium of microbes under specific conditions such as the absence of alternative sources of carbon and nitrogen, presence of moisture, etc. (Drillia et al., 2005; Gartiser, Elke, Radka, & Kümmerer, 2007). Streptomycin and cycloheximide have been reported to be biodegraded by soil bacteria and fungi (Badalucco, Pomaré, Grego, Landi, & Nannipieri, 1994). In a recent study, the bacteria and fungi from aquatic environment have been shown to degrade a mixture of two broad spectrum antibiotics, ciprofloxacin and erythromycin (Nnenna, Lekiah, & Obemeata, 2011).

Gomeya/cow dung has been used traditionally as an excellent, cheap and effective bioremediation measure against harmful pollutants. Randhawa and Kullar (2011) have reviewed the available studies on the bioremediation of a vast range of pharmaceuticals, pesticides, and petrochemicals with gomeya/cow dung. Manure (cattle dung) has been shown to effectively degrade the antibiotic enrofloxacin due to the presence of the known strains of coprophilous basidiomycetes, particularly, *Cyathus stercoreus* (Freer & Detroy, 1982; Wicklow, 1992). Reports are there in literature showing degradation of the antibiotics such as erythromycin, streptomycin, penicillin and bacitracin present in manure within 30 days (Gavalchin & Katz, 1994; Wang, Bradford, Zheng, & Yates, 2006). The sulphonamide drug sulfadimethoxine is shown to undergo biodegradation in manure and its degradation kinetics has also been studied (Wang et al., 2006).

FUNGAL BIOREMEDIATION (MYCOREMEDIATION)

Several fungal strains play an important role in the bioremediation of industrial effluents. Fungi, especially, the white-rot fungi are ubiquitously present in nature and these have adaptability to extreme conditions, thus, making them good biodegraders. These produce enzymes like lignin peroxidase, laccase and manganese peroxidase which are involved in degradation of lignin in their natural lignocellulosic substrates. This ligninolytic system of white rot fungi is directly involved in the degradation of various xenobiotics including pharmaceutical drugs and dyes by causing one-electron oxidation of aromatic compounds, with subsequent formation of aryl cation radicals, which spontaneously decompose by various pathways. (Christian, Shrivastava, Shukla, Modi, & Vyas, 2005; Tripathi, Harsh, & Gupta, 2007). Manganese peroxidase catalyzes the oxidation of Mn^{2+} to Mn^{3+}, which in turn can cause oxidation of several phenolic substrates (Sayad and Ellouz, 1995). However, fungal bioremediation (mycoremediation) measures suffer from certain drawbacks in terms of long growth cycle and spore formation.

Studies have shown that some fungal strains like *Bjerkandera adusta* MUT 2295, *Aspergillus niger, Aspergillus fumigatus, Penicillium decumbens* and *Penicillium lignorum* are effective in causing COD reduction in industrial effluents (Jayaraman, Muthuswamy, & Swaminathan, 2003; Mohammad et al. 2006). A comparative study was conducted by Spina et al. (2012) in which effectiveness of fungal treatment (Bjerkandera adusta MUT 2295) was compared with the activated sludge for treatment of pharmaceutical industrial wastewater. A 91% reduction in COD was noted with the fungal method, which was significantly higher than that observed from the activated sludge (78%). The degradation of enrofloxacin,

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

a fluoroquinolone antibacterial drug used in veterinary medicine, has been investigated with the brown rot fungus *Gloeophyllum striatum* presumably by an oxidative mechanism. The findings suggest that the brown rot fungi are capable of producing highly reactive hydroxyl radicals, which can transform the xenobiotics by oxidative metabolism (Wetzstein, Schmeer, & Karl, 1997). Azo dyes are used extensively in the pharmaceutical and other industries and these are known to possess potentially mutagenic and/or carcinogenic properties. *Phanerochaete chyrosporium,* a major wood rotting fungus is capable of degrading a wide range of recalcitrant xenobiotics including azo-dyes through its non-specific hydrogen peroxide dependent extracellular lignin degradation enzyme system (Aust, 1990; Cripps, Bumpus, & Aust, 1990). *Aspergillus niveus,* a litter degrading fungus has been found useful in the biotreatment of distillery effluent (Angayarkanni, Palaniswamy, & Swaminathan, 2003). Recently, degradation of pharmaceuticals in non-sterile urban wastewater by white-rot fungus *Trametes versicolor* was reported in a fluidized bed bioreactor (Cruz-Morató et al., 2013). In a similar study, a fungal bioreactor based on *Trametes versicolor* pellets was reported as a new alternative for pre-treatment of hospital wastewater resulting in efficient removal of pharmaceuticals and endocrine disruptor compounds (Cruz-Morató et al., 2014). Further, the degradation of pharmaceuticals by *Trametes versicolor* has been found to be enhanced by addition of external nutrients (Badia-Fabregat et al., 2015). Very recently, *Trametes versicolor* has been applied for the removal of pharmaceuticals from a veterinary hospital wastewater and sixty-six per cent removal was achieved in a non-sterile batch bioreactor inoculated with *T. versicolor* pellets (Badia-Fabregat et al., 2016). Biodegradation by the fungus *Pycnoporus sanguineus* is another promising method for the mineralization of recalcitrant compounds present in pharmaceutical effluents (Watanabeet al., 2012).

Periconiella species of fungus isolated from cow dung has been reported to be an excellent degrader of biomedical waste and thus, represents a cheap, safe, and environment friendly method of biomedical waste disposal (Pandey & Gundevia, 2008). The efficiency of two white-rot fungi, *Trametes versicolor* and *Ganoderma lucidum*, to eliminate thirteen pharmaceutical pollutants has been recently investigated. Total removal of the drugs diclofenac, gemfibrozil, ibuprofen, progesterone and ranitidine was noted with the method whereas, lower removals were achieved for 4-acetamidoantipyrin, clofibric acid, atenolol, caffeine, carbamazepine, hydrochlorothiazide, sulfamethoxazole and sulpiride (Vasiliadou et al., 2016).

ENZYMATIC BIOREMEDIATION

In the last two decades, the application of enzymes as biocatalysts for environmental remediation has been widely studied as these offer advantages over living systems like microbes or fungi with respect to high reaction kinetics of degradation under subtle conditions of pH or temperature. Further, these are selective and are not affected by the biological activity of the targeted compounds. Enzymes can act on specific recalcitrant pollutants to remove them by precipitation or transformation to other products. The enzymes like oxidoreductases EC1 (*i.e.*, peroxidases, polyphenol oxidases (PPO), hydrolases EC3 (*i.e.*, proteases, esterases, lipases and cellulases) and lyases EC4 have been recommended for various wastewater treatment applications including pharmaceutical wastewaters and their effectiveness extends to wide range of pharmaceutical substances like phenolic drugs, antibiotics and other drugs. The application of oxidoreductive enzymes to catalyze the removal of phenol from wastewater has been investigated extensively. An example of such a method employs hydrogen peroxide and an immobilized derivative of soybean peroxidase, covalently bound to a glass support in a continuous tank reactor to remove phenol from aqueous solutions with 80% removal efficiency (Gómez et al. 2008). A recent article discusses the

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

effectiveness of peroxidase based enzymatic treatment for continuous removal of phenol from wastewater (Chiong, Lau, Khor, & Danquah, 2014). A pharmaceutical effluent has been bio-remediated using yeast and amylase as the active agents (Uwadiae, Yerima, & Azike, 2011). Based on this technology, several types of enzymatic reactors have been designed (EMRs).

PHYTOREMEDIATION

Phytoremediation of wastewater is an emerging low-cost technique which utilizes the natural or transgenic green plants to bio-accumulate hazardous substances, particularly, metal ions such as lead and cadmium, and other xenobiotics (Campos, Merino, Casado, Pacios, & Gómez, 2008). The method has an advantage over microbial techniques as the microorganisms don't absorb heavy metals easily. This technique has a great potential for commercialization particularly in Europe and United states (Campos et al., 2008; McIntyre & Lewis, 1997; Watanabe et al., 1997). The method is still in preliminary stage and some reports on usage of aquatic plants as bioremediation measures are there. A recent review has addressed phytotoxicity of common pharmaceuticals and bioremediation potential of plants (Carvalho, Basto, Almeida, & Brix, 2014).

- **Aquatic Plants:** Phytoremediation through aquatic macrophytes treatment system for the removal of pollutants and contaminants from various natural sources is an accepted environmental protection technique. The biosorption capacity of the water hyacinth (*Eichhornia crassipes*), a highly invasive aquatic weed, in minimising various contaminants present in the industrial wastewater has been extensively studied (Priya & Selvan, 2014). Water hyacinth and the plants *Typha latipholia* and *Phragmitis karka* have been used in some studies to demonstrate their usefulness in reducing COD, BOD levels in pharmaceutical wastewaters (Billore et al., 2001). The algae are effective in hyper-accumulation of heavy metals and can bring about bio-degradation of xenobiotics (Suresh & Ravishankar, 2004). *Dunaliella* algae have been found effective in causing biological removal of heavy metals from wastewater at concentrations of about 85 mg/l (Qari & Hassan, 2014). Biodegradable adsorbents are being developed for the treatment of contaminated waters due to their low cost and greater efficiency in the removal of organic and inorganic pollutants. The application of marine algae and derivatives as potential adsorbents for pharmaceutical products is being studied as an inexpensive and eco-friendly alternative. Different types of marine algae and hydrogel beads of alginate and chitosan have been reported for the bio-removal of antibiotics such as amoxicillin, enrofloxacin, penicillin G and other non-antibiotic drugs such as caffeine.
- **Aerial Plants**: Several plants are being investigated for their potential to remove xenobiotics from soils. The phytoremediation potential of *Cicer arietinum* (black chick pea) has been evaluated for aspirin (Gahlawat, Makhijani, Chauhan, Valsangkar, & Gauba, 2014) and tetracycline (Makhijani, Gahlawat, Chauhan, Valsangkar, & Gauba, 2014) under hydroponic conditions. Recently, Gahlawat & Gauba (2016) have evaluated the phytoremediation of aspirin and tetracycline by *Brassica juncea.*
- **Plant Root Remediation:** Peroxidases (EC 1.11.1.7) are versatile heme-containing biological catalysts that have been used for wide spectrum applications in a number of enzyme based industrial processes to preserve water quality (Ashraf & Husain 2010). Hairy roots in various plants offer an attractive cost-effective alternative to enzyme-based methods in this regard, as their exudates

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

contain enzymes like peroxidase, and some metal chelating compounds to sequester harmful inorganic or organic pollutants, including phenol (Angelini, Orejas, Medina, & Agostini, 2011). Plant root remediation of contaminated soils and groundwater is being recognized as having a great potential for future development due to its environmental compatibility and cost-effectiveness (Zhou, Tang, & Wu, 2013). Phytoremediation of 2,4-dichlorophenol and phenol by *Brassica napus* hairy roots cultures has been reported (Agostini, Coniglio, Milrad, Tigier, & Giulietti, 2003; Angelini et al., 2011; Coniglio et al., 2008). Phytoremediation of phenol at pilot scale has been carried out by tobacco hairy roots and various parameters suggested that these could provide adequate matrix for the successful removal of phenol (Sosa Alderete, Ibáñez, Agostini, & Medina, 2012).

- **Constructed Wetlands:** Constructed wetlands have been viewed as a promising approach for the removal of pharmaceuticals from waters and wastewaters (Li et al., 2014). Constructed wetlands are engineered wetlands that utilize natural processes involving wetland soil, vegetation, and consorted microbial aggregations to assist in treating polluted waters (Helt, Weber, Legge, & Slawson, 2012). Five different wetland plant species have been evaluated for their efficiency in scavenging commonly used recalcitrant fluoroquinolone antibiotics ciprofloxacin, gemifloxacin mesylate, ofloxacin and gatifloxacin from aqueous medium. *Taxodium distichum* was found to be the most suitable for the removal of ofloxacin, gatifloxacin and ciprofloxacin and *Canna indica* was the most effective in the removal of gemifloxacin mesylate (Tandon et al., 2013).

A particular concern in viewing the phytoremediation methods as viable alternative bioremediation techniques is that several of the reported studies have not clearly addressed the relation between the xenobiotic removal and plant uptake of pharmaceuticals. In such studies, photo-degradation and oxidative degradation could also be additional possible contributors and their contribution needs to be ruled out as a possible cause of drug removal. Results from phytoremediation plants show that in many cases, the plant uptake usually represents a low percentage of the mass depleted from the systems. However, it has been debated that phytoremediation depends both on the plant uptake and the rhizospheric microbial communities; therefore, removal efficiencies must be analysed in terms of the overall processes involved (Carvalho et al., 2014).

IMPORTANT BIOREMEDIATION TECHNOLOGIES

Biological treatment technologies in pharmaceutical industrial wastewater treatment are broadly based on aerobic and anaerobic methods (Deegan et al., 2011). Several high-rate reactors have been designed for the biological treatment of pharmaceutical effluents at full-scale operation.

Aerobic Methods

Activated Sludge Process

The conventional activated sludge process (CAS) uses a microbial biomass to treat the influent wastewater. The typical configuration consists of a primary clarifier, aeration tank, a secondary clarifier and a process for returning a portion of the secondary sludge. In the aeration tank, the wastewater is mixed and aerated with the microbial suspension. Under well-controlled operating conditions, the classical

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

aerobic AS reactors can be relatively efficient for the removal of poorly biodegradable persistent drug pollutants diclofenac, sulfophenylcarboxylates and antibiotics, like tetracycline or erythromycin, and hardly-degradable micropollutants, such as carbamazepine.

Several researchers have reported the aerobic biological treatment of pharmaceutical wastewater (Altaf and Ali, 2010; Khan and Mostafa, 2011; Lapara, Nakatsu, Pantea, & Alleman, 2001) with significant reductions in the chemical oxygen demand (COD) and biochemical oxygen demand (BOD) amounting to 75-98%. The use of activated sludge process (ASP) for treatment of wastewater from herbal pharmaceutical industry resulted in 68.98–91.02% reduction in COD, 76.90–97.26% reduction in BOD and 74.61–95.54% reduction in suspended solids (Vanerkar, Satyanarayan, & Dharmadhikari, 2013). The **aerobic** sequencing batch reactor (ASBR) and activated sludge process are the most commonly employed aerobic methods for the treatment of industrial wastewater.

Sequencing batch reactors (SBRs) carry out the activated sludge process in a sequential, time-oriented manner employing a single vessel for all the phases of the process. These offer advantages over the ASP in being more cost-effective due to lower operating costs, amenability to online control, a reduced site space, and adaptability to suit variable wastewater compositions and flow rates (Al-Rekabi et al., 2007). Sequencing batch reactor (SBR) has been used to treat the mixed pharmaceutical industrial resulting in significant removal in BOD (approximately 85%), COD (approximately 87%), ammonia (approximately 96%), suspended solids (approximately 98%), and phosphate (approximately 5%) (Ileri, Sengil, Kulac, & Damar, 2003). Another similar study with sequential batch reactor (SBR) has been reported by Altaf and Ali (2010). Optimization of SBR operating conditions for treatment of high-strength mixed pharmaceutical wastewater with reduction in BOD (94%) and COD (83%) has been carried out by Elmolla et al. (2012).

Rotating Biological Contactor (RBC) Biofilm Process

The rotating biological contactor (RBC) biofilm process is an important biofilm process (attached growth process) in existing treatment facilities for municipal and industrial wastewater treatment with medium strength (COD concentration is 600–2000mg/l) of organic substances but has not been applied yet to pharmaceutical effluents (Akunna & Jefferies, 2000; Vidal, Ba˜nares-Alc´antara, Rodr´ıguez-Roda, & Poch, 2002). The RBC process has the advantages of a high microbial concentrations in good condition, high suitability for fluctuations in flow rate and organic concentration and high efficiency for organic degradation (Chen, Wen, Wang, & Li, 2006; Wang, Liu, Zhang, & He, 2009). RBC also has the advantages of simultaneous nitrification and denitrification accompanied by carbon removal (Hiras, Manariotis, & Grigoropoulos, 2004; Tawfik, Klapwijk, El-Gohary, & Lettinga, 2005). Further, low water content in the sludge causes it to easily settle, allows easy operation and its lower energy consumption makes it a economically viable option as well (Taseli, G¨okc¸ay, & G¨urol, 2008; Torkian, Yazdani, & Alinejad, 2003). Recently, high-strength antibiotic pharmaceutical residual liquid mixed with ordinary wastewater has been treated by a simple three-stage RBC system with resultant COD removal efficiency of 45% and BOD removal efficiency of 85% at low ambient temperatures thus, showing the effectiveness of RBC for such an inherently bio-recalcitrant wastewater (Su et al., 2015). Another study has been reported involving a two-stage RBC for biological removal of the pharmaceuticals belonging to different therapeutic classes including caffeine, sulfamethoxazole, ranitidine and carbamazepine and the maximum removals achieved for all the drugs were greater than 85% (Vasiliadou, Molina, Martínez, & Melero, 2014).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Nitrifying Activated Sludge (NAS) Method

An alternative procedure employing nitrifying bacteria (e.g., *nitrosomonas europaea*) is the nitrifying activated sludge (NAS) method which has been demonstrated to be more effective in the removal of pharmaceuticals. This method has been successfully employed to remove ethinyl estradiol (Vader et al., 2000) and other estrogens (Anderson, Siegrist, Halling-Sorensen, & Ternes, 2003; Kanda & Churchley, 2008) in sewage treatment plants. Batt et al. (2006) have reported higher removal of the drugs iopromide and trimethoprim in the NAS compared to conventional AS method in lab batch reactors as well as full-scale plants. Another comparative study has shown the complete removal of trimethoprim (poorly removed by AS and primary sewage treatments), sulfamethazine, sulfamethoxazole and sulfathiazole in NAS batch experiments on laboratory scale (Perez, Eichhorn, & Aga, 2005). Tran et al (2009) have also reported higher laboratory scale removal of ten APIs (clofibric acid, gemfibrozil, ibuprofen, fenoprofen, ketoprofen, naproxen, diclofenac, indomethacin, propyphenazone and carbamazepine) by the NAS method compared to CAS method. Good removal of the drugs fluoxetine, citalopram, ethinyl estradiol, ibuprofen, naproxen, diclofenac, carbamazepine, trimethoprim, roxithromycin, sulfamethoxazole, erythromycin, galaxolide, tonalide, celestolide and diazepam has been reported with NAS system (Suarez, Lema, & Omil, 2010).

Anaerobic Methods

Anaerobic treatment of the pharmaceutical industrial wastewater (PIWW) involves the step-wise decomposition of the organic material into gaseous methane and CO_2 with the help of microorganisms in the absence of molecular oxygen. Anaerobic treatment systems do not require an energy consuming aeration system and offer several additional advantages over aerobic methods such as good removal efficiency even at high loading rates and low temperature, slow sludge production, need of low nutrient amount and production of biogas (>50% methane) which can be utilized as a renewable energy source for energy production (Nandy & Kaul, 2001; Seghezzo, Zeeman, van Lier, Hamelers, & Lettinga, 1998). Typically, pharmaceutical wastewater is characterized by high chemical oxygen demand (COD), and some pharmaceutical wastewaters can have COD as high as 80,000 mg/l. Due to their high organic content, anaerobic technology is being viewed as a promising alternative for treatment of pharmaceutical effluents. Various reactor configurations are available such as up-flow anaerobic stage reactor (UASR), upflow anaerobic sludge blanket reactor (UASB), anaerobic filter, anaerobic contact reactor (ACR), fluidized bed reactor (FBR) and anaerobic fixed film reactor (AFFR) to treat wastewaters from different industries.

Up-Flow Anaerobic Stage Reactor (UASR)

An up-flow anaerobic stage reactor (UASR) has been investigated as a pre-treatment system at an existing pharmaceutical production plant to reduce the antibiotics in the trade effluent. The pharmaceutical wastewater originally containing macrolide antibiotics (Tylosin and Avilamycin) showed 95% reduction in Tylosin concentrations on UASR treatment (Chelliapan, Wilby, & Sallis, 2006).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Up-Flow Anaerobic Packed Bed Reactor

A fully packed up-flow anaerobic packed bed provides a quiescent inlet region for large dense biomass aggregates to develop, which are not prone to washout. Furthermore, the reactor provides a surface to facilitate biofilm accumulation. This assures a shorter start-up period due to greater amount of retained inoculum. An anaerobic packed bed reactor has been recently designed and employed to treat highly polluted of pharmaceutical wastewater of Samarra Drug Factory (SDI) in Iraq showing best hydraulic retention time (HRT) of 24 hours for anaerobic stage and removal efficiencies of COD and BOD as 87% and 90% (Hashimi, Al-Ali, & Abbas, 2011). A similar treatment of highly polluted pharmaceutical wastewater employing an anaerobic packed bed reactor has also been reported by Chelliapan et al., (2011). An Up-Flow Anaerobic Packed Bed reactor has been employed to treat pharmaceutical wastewater containing recalcitrant antibiotics. Results from the study showed a COD reduction of 60–70% at an organic loading rate (OLR) of 1.5–4.6 kg $COD.m^{-3}.d^{-1}$, suggesting that the biomass had acclimated to the antibiotics (Chelliapan & Golar, 2011). Antibiotic wastewaters containing a high proportion of spent fermentation broths usually require long HRT for efficient treatment (Lapara et al., 2001), presumably, on account of their complex organic carbon content. Hence, this factor can limit the performance of the packed bed reactor at lower HRT (2 d).

Wastewaters from pharmaceutical industry usually contain a high concentration of sulphate as a result of sulphate use during down-stream processing of fermentation broth. The production of sulphide during anaerobic treatment of sulphate containing wastewaters can inhibit methanogens and can precipitate the nutrients required by the methanogens (Ozdemir, Cirik, Akman, Sahinkaya, & Cinar, 2013). An anaerobic reactor system has been developed employing phase separation (especially at high OLRs) by accomodating different microbial populations in different stages according to their favourable substrate conditions. This two-stage anaerobic digestion system has been recently utilized for anaerobic treatment pharmaceutical wastewaters with high sulphate content (Chelliapan & Sallis, 2015).

Upflow Anaerobic Sludge Blanket (UASB) Reactor

A hybrid upflow anaerobic sludge blanket (UASB) reactor is a single tank process in an anaerobic centralised or decentralised industrial wastewater or blackwater treatment system achieving high removal of organic pollutants. A UASB reactor operates as a suspended growth system where microorganisms attach themselves to each other or to small particles of suspended matter to form agglomerates of granules which settle easily. The latter form an active suspended sludge blanket that filters and treats the wastewater as it flows upwards through it. The process combines the advantages of the UASB and anaerobic filter (AF) concepts. This method has been widely used for the treatment of wastewater from the beverage, brewery, food and tannery industries (To´th, Gergely F, & Mizsey, 2011) and is reported as a preferred option for certain chemical synthesis-based pharmaceutical wastewaters due to several operational advantages over other reactor configurations. These advantages include high organic loadings, greater efficiency, low energy requirements, shorter hydraulic retention time (HRT) and easy reactor construction. (Oktem, O. Ince, Sallis, Donnelly, & B. Ince, 2007). It is a popular anaerobic reactor for both high and low temperatures. Among the recently developed high-rate processes, it has attracted most commercial and research interests (Lettinga, van Velsen, Hohma, de Zeeuw, & Klapwijk, 1980). A study by Rodriguez-Martinez et al (2005) in an Up-Flow Anaerobic Sludge Bed (UASB) treating

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

pharmaceutical wastewater containing Penicillin G antibiotics has shown a COD removal efficiency of 90% at an OLR of 1.5 kg $COD.m^{-3}.d^{-1}$ and HRT 11 d. The performance of a pilot-scale UASB reactor, treating an antibiotic chemical synthesis-based pharmaceutical wastewater, has been recently evaluated under different operating conditions with good results (Rao, Habiulla, Prasad, & Anand, 2014).

The hybrid UASB reactor has been evaluated for efficacy in reduction of chemical oxygen demand (COD) and biochemical oxygen demand (BOD) of bulk drug pharmaceutical wastewater containing hazardous compounds like phenol, l,2-methoxy phenol, 2,4,6-trichloro phenol, dibutyl phthalate, 1-bromo naphthalene, carbamazepine and antipyrine. After the treatment, all the pharmaceutical compounds degraded almost completely except carbamazepine. Thermophilic *methanothrix* and *methanosaetae* like bacteria were present in the granular sludge (Sreekanth, Sivaramakrishna, Himabindu, & Anjaneyulu, 2009). Herbal pharmaceutical wastewater treatment has been reported by Satyanarayan et al (2009) by a pilot scale UASB reactor resulting in COD, BOD and suspended solids (SS) removal in the range of 86.2%-91.6%, 90.0%-95.2% and 62.6%-68.0% respectively.

Low-temperature or psychrophilic ($< 20^0$C) anaerobic digestion (PAD) has recently been demonstrated as a cost-effective option for the treatment of solvent containing pharmaceutical wastewater (Enright, McHugh, Collins, & O'Flaherty, 2005). Two UASB reactors with different operating temperatures, mesophilic (35 ± 1ºC) and thermophilic (54 ± 1ºC) have been studied for the treatment of a non-penicillin based product factory waste water (ISA, Kutty & Bin Abd Rahim, 2010) affording the highest percentage of COD removal for the mesophilic and thermophilic reactors as 95% and 93% respectively.

Structured Packing Rotating Biological Contactor (spRBC)

A removal process of the antibiotic enrofloxacin has utilized a biological treatment unit consisting of a structured packing rotating biological contactor (spRBC). The removal rate reached a maximum of 70% in this biological unit and removal efficiency for a combined system including spRBC and an ultraviolet radiation unit was 94% (Zamanpour & Mehrabani-Zeinabad, 2014).

Anaerobic Fixed Film Reactor (AFFR)

The anaerobic fixed film reactor (AFFR) possesses a biofilm support structure for biomass attachment. Utilization of the anaerobic fixed film reactor (AFFR) is reported to be more effective due to simplicity of construction, stability, higher threshold to absorb toxic shock load and faster recovery. An AFFR may employ glass beads, red drain clay, polyurethane foam, waste tyre rubber, splintered glass, polyacryl nitrile acrylamide, corrugated plastic, coconut coir, and charcoal or nylon fibre as a support media (Borja, Sanchez, Marin, & Jimenez, 1996; Garcia, Rivas, Figueroa, & Monroe, 1995; Perez, Romero, Nebot, & Sales, 1997). The laboratory scale bio-methanation of high strength herbal pharmaceutical wastewater has been achieved with anaerobic fixed film fixed bed reactor system (Nandy & Kaul, 2001) with COD removal efficiencies ranging from 76 to 98%. Studies have been carried out on the treatment of wastewater from a bulk drug industry employing an AFFR designed and fabricated in the laboratory The AFFR has been shown to be very efficient in lowering COD, total dissolved solids (TDS) and total suspended solids (TSS) (Rao et al., 2004).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Anaerobic Fluidized Bed (AFB) Reactor

The anaerobic fluidized bed (AFB) reactor comprises small media, such as granular activated carbon or sand to which the bacteria attach. High flow rate around the particles results in decreased clogging. The large pore spaces formed through bed expansion and high specific surface area of the carriers significantly improves the efficiency of the fluidized bed reactors. The expanded granular sludge bed (EGSB) reactor is a modification of the AFB reactor with a difference that the fluid's upward flow velocity is not as high which results in partial bed fluidization (Rittmann & McCarty, 2001). Bioaugmentation and anaerobic treatment of pharmaceutical effluent has been carried out in fluidized bed reactor affording maximum COD removal of 91.2% (Saravanane, Murthy & Krishnaiah, 2001a). The treatment of cephalexin drug-based pharmaceutical effluent in an upflow anaerobic fluidized bed system coupled with bio-augmentation also resulted in 88.5% COD removal (Saravanane, Murthy & Krishnaiah, 2001b). A large quantity of concentrated effluent resulting from the production of cephradine, a cephalosporin antibiotic (COD of 14000-18000 mg/l) has been treated using a fluidized bed reactor under anaerobic conditions with bioaugmentation (Saravanane, Murthy & Krishnaiah, 2001c). Degradation of phenol has been studied in anaerobic fluidized bed reactors (AFBR) packed with polymeric particulate supports including polystyrene, polyvinyl chloride (PVC) and polyethylene terephthalate (PET). Excellent removal efficiencies of ranging from 90-100% have been demonstrated (Sancinetti et al., 2012).

Anaerobic Suspended Film Contact Reactor

Bio-treatability studies have been reported on the effluents from a bulk drug industry using an anaerobic suspended film contact reactor (Mohan, Prakasham, Satyavathi, Annapurna, & Ramakrishna, 2001). The COD reduction was found to be in the range of 60 to 80% for organic loading rates varying from 0.25 kg/m^3/day to 2.5 kg/m^3/day.

Membrane Bioreactors (MBR)

MBR technology is a combination of the activated sludge (AS) process with a micro- or ultrafiltration membrane system (Mutamim, Noor, Hassan, & Olsson, 2012). The activated sludge treatment is responsible for the biodegradation of the organic waste compounds, and the membrane system (pore diameter 0.01-0.1 μm) physically separates the solids from the liquid (Hoinkis et al., 2012). The membrane bioreactors (MBR) have been reported to be much more efficient than classical AS systems (Kimura, Hara, & Watanabe, 2007; Radjenović, Petrovic, & Barcelo, 2009). At worst, these systems perform as well as activated sludge treatment (Clara et al., 2005; Joss et al., 2005). Recently, several reports have come up emphasizing the relevance of this technique in the current bioremediation scenario. Membrane bioreactor (MBR) has been used for the large-scale wastewater treatment of industrial wastewater in the pharmaceutical industry (C. Chang, J. Chang, Vigneswaran, & Kandasamy 2008). MBRs can operate at high suspended solid concentrations because the membrane separation step is not limited by sedimentation capacity, which will result in longer solid retention times (SRTs) (Cirja, Ivashechkin, Schäffer, & Corvini, 2008). These conditions can be favourable for API (active pharmaceutical ingredient) biodegradation as more diverse microbial population can flourish at longer SRTs resulting in diverse biodegradation pathways (Clara, Kreuzinger, Strenn, Gans, & Kroiss, 2005). Moreover, the extended contact time gives the bacterial biomass an opportunity to acclimate to certain xenobiotics by broadening their enzymatic

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

(Suarez et al., 2010) or metabolic capabilities (Ternes, Joss, & Siegrist, 2004). An external loop airlift membrane bioreactor (ELAMBR) has been applied for treatment of a synthetic pharmaceutical wastewater and the performance of this system was evaluated in removal of acetaminophen as the main pollutant of the pharmaceutical wastewater. The removal efficiency was found to be significantly higher in the ELAMBR system compared to the AS process and 100% of the acetaminophen was removed within two days (Shariati et al., 2010). Another comparative study has been conducted with a laboratory-scale MBR and the AS process on pharmaceutical wastewater containing several drugs like diclofenac, ketoprofen, ranitidine, gemfibrozil, bezafibrate, pravastatin, ofloxacin, ibuprofen, naproxen, acetaminophen, paroxetine, and hydrochlorothiazide. Pharmaceuticals were, in general, removed to a greater extent by the MBR integrated system than by the AS process (Radjenović et al., 2009). Treatment of pharmaceutical wastewater containing three NSAIDs (acetaminophen, ketoprofen and naproxen) and three antibiotics (roxithromycin, sulfamethoxazole and trimethoprim) has been reported in two MBRs with sludge retention times (SRTs) of 15 (MBR-15) and 30 (MBR-30) days over a period of 4 weeks. The NSAIDs were removed with higher efficiency compared to the antibiotics, and the MBR-30 afforded better removal efficiencies than the MBR-15 for all the drugs (Tambosi et al., 2010). A very similar study with similar results has been reported by Schröder et al. (2012) with wastewater containing three NSAIDs (acetaminophen, ketoprofen and naproxen) and three antibiotics (roxithromycin, sulfamethoxazole and trimethoprim) performed MBR-15 and MBR-30. Removal rates ranged from 55% (sulfamethoxazole) up to 100% (acetaminophen, ketoprofen). An efficient removal of ammonia, total organic matter and four corticosteroids, levonorgestrel, betamethasone valerate, betamethasone dipropionate (Betha-D) and medroxyprogesterone acetate, has been achieved in a laboratory-scale submerged membrane bioreactor (MBR) treating wastewater from a pharmaceutical industry. Chemical analysis of MBR effluent revealed that all the corticosteroids were removed at high percentages (> 93%) in all the cases (López-Fernández, Martínez, & Villaverde, 2012). The application of membrane separation technology (MBR) on pharmaceutical wastewater has been recently reviewed (Cazes, Abejón, Belleville, & Sanchez-Marcano, 2014; Fazal, Zhang, Zhong, Gao & Lu, 2015).

Combined Anaerobic-Aerobic Processes

Although, innumerable reports have come up relating to the successful organic removal from pharmaceutical wastewater employing varying configurations of anaerobic reactors, yet, there have been differences in anaerobic treatment performances possibly explained by the differing wastewater characteristics including salinity/toxicity and presence of refractory compounds poorly biodegraded under anaerobic conditions. In light of the tightening legislations on effluent water quality standards, a subsequent aerobic process is required for further removal of organic residues from the anaerobic effluents (Chen, Ren, Wang, Zhang, & Shi, 2008). Application of activated sludge system as an aerobic post-treatment process has been shown to further enhance the COD removal rate from 62% to 96.4% in the treatment of purified terephthalic acid wastewater (Pophali, Khan, Dhodapkar, Nandy, & Devotta, 2007). This sequential two stage process has been widely employed for the treatment of paper and pulp industry effluents (Tezel, Guven, Erguder, & Demirer, 2001), textile wastewaters, food solid waste leachates, etc. Agdag and Sponza (2005) have employed the combination of an anaerobic sludge blanket reactor (UASB) and completely stirred tank reactor (CSTR) systems for the treatment of municipal landfill leachate. Isik and Sponza (2008) have reported the anaerobic/aerobic treatment of a simulated textile wastewater. Recently, granular sludge was successfully cultivated employing an intermittent anaerobic

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

and aerobic reaction phase strategy using synthetic textile wastewater containing mixed dyes with 93% removal of COD and ammonia (Muda, Aris, Salim, Ibrahim, & Yahya, 2012). The application of sequential anaerobic/aerobic treatment to pharmaceutical wastewater treatment has been fairly recent and relatively fewer applications have been reported. In a recent study, pharmaceutical wastewater with high total dissolved solids (TDSs) and chemical oxygen demand (COD) content has been treated through a sequential anaerobic–aerobic treatment process. For the anaerobic process, application of up-flow anaerobic sludge blanket (UASB) resulted in COD removal efficiency of 41.3 ± 2.2% achieved with an organic loading rate of 8.11 ± 0.31 g COD/l/d. Significant improvement was achieved by treating the UASB effluent by a membrane bioreactor (MBR) and a sequencing batch reactor (SBR). Both the UASB + MBR and UASB + SBR systems have demonstrated an excellent organic removal efficiency, with COD removal of 94.7% and 91.8% respectively. Best performance was noted with UASB + MBR system in terms of organic removal as well as nitrification (Shi, Lefebvre, K. Ng, & H. Ng, 2014) The continuous sequential biological anaerobic/aerobic treatment of Samarra Drugs Factory wastewater has included a pilot plant of upflow anaerobic filter (UAF) (with mesophilic bacterial growth at a temperature range of 35-37 °C) for the anaerobic stage followed by an air diffuser for the aerobic stage. However, there was no significant advantage in terms of the removal efficiency of COD and BOD in anaerobic/aerobic stage (92% and 93% respectively) over the anaerobic stage alone (87% and 90% respectively) (Hashimi & Abbas, 2007). A pilot-scale system composed of an anaerobic baffled reactor followed by a biofilm airlift suspension reactor has been designed for removing organic matter from the high-strength pharmaceutical wastewater containing antibiotics ampicillin and aureomycin (Zhou, Su, Li, Qian, 2006). Recently, ozone and thermal hydrolysis pre-treatment has been employed to improve anaerobic digestion (AD) efficiency to reduce tetracycline resistance genes in municipal and pharmaceutical waste sludge. Thermal hydrolysis pre-treatment was found to be more efficient than ozone for reduction after AD (Pej, Yao, Ren & Yu, 2016).

Coupling Bioremediation with Alternative Techniques

Bioremediation measures have also coupled with other alternative or conventional wastewater management processes to ensure more effective removal of the pollutants. An example is provided by a recent report wherein, distinct laboratory scale biological processes: suspended activated sludge and attached-growth biomass or moving bed biofilm flow-through reactors have been investigated for wastewater treatment to remove pharmaceuticals including ibuprofen, naproxen, ketoprofen, carbamazepine and diclofenac and an active metabolite of the lipid regulating agent clofibric acid. The suspended activated sludge process resulted in 74% removal of ibuprofen, naproxen and ketoprofen but removal of clofibric acid, carbamazepine and diclofenac was inconsistent. However, the coupling of the attached-growth biomass biological treatment with UV treatment and hydrodynamic cavitation/hydrogen peroxide process afforded excellent removal efficiencies for clofibric acid (>90%) and carbamazepine and diclofenac (>98%), while the remaining compounds were reduced to levels below their limits of detection (LOD). A combined treatment process (solar photo-Fenton + immobilized biomass reactor) was utilized for the treatment of pharmaceutical industrial wastewater containing nalidixic acid (an antibiotic pertaining to the quinolone group), which is not easily biodegraded. This process resulted in 95% reduction in COD out of which, 62% reduction was accounted for by the immobilized biomass reactor (Sirtori et al., 2009). The coupling of solar photo-Fenton process with aerobic sequencing batch reactor attained COD removal of 98% in pharmaceutical wastewater (Adishkumar, Sivajothi, & Banu, 2012).

FUTURE RESEARCH DIRECTIONS

The emerging field of bioremediation of pharmaceuticals is quite challenging due to the plethora of information still waiting to be explored not only in relation to their removal from to the environment but also for gaining insight into their chemical characteristics and susceptibilities. The structural diversity of the pharmaceuticals encompasses a vast organic chemical space, hence, diverse range of approaches are required to be explored for their effective and complete removal from the environment. There is a need to have comprehensive information on the most common pharmaceutical contaminants in the environment. Further, there is limited information on the deleterious impact of low level pharmaceutical contaminants on human and animal health. As drug selection in different geographical regions varies depending upon economic and social factors, the potential bioremediation measures need to be customized according to the contaminants present. Generation of comprehensive database of common pharmaceutical pollutants in different geographical regions of the world should be the first step in this direction. In-depth and accurate analysis of industrial effluents and wastewater and ground water needs to be carried out in order to assess the most common pharmaceutical pollutants present. Particularly recalcitrant and stubborn drugs and pharmaceuticals need to be identified in terms of their prevalence in wastewater, groundwater and soils to chalk out a future course of action for devising specific bioremediation measures. Pharmaceutical research is a fast evolving field and with the introduction of newer pharmaceuticals in therapeutic arena, newer challenges will arise for their safe disposal.

CONCLUSION

Presence of wide variety of pharmaceuticals in the environment is a cause of concern on account of their harmful effects to the humans and also due to their deleterious effects on terrestrial as well as aquatic plant/animal life. Bioremediation of pharmaceuticals is still an emerging field. In recent times, there has been a growing awareness about this global issue but the real gravity of the problem is yet to be recognized and understood completely. The chemical diversity of pharmaceuticals, frequent introduction of newer pharmaceuticals into the market and poor existing information about the susceptibility of different types of plant and animal species to their toxic effects adds up to the complexity of the problem. Several bioremediation measures have been proposed in the recent times utilizing the versatility of various types of microorganisms such as bacteria and fungi to catabolize or degrade different types of pharmaceutical contaminants. Several configurations of anaerobic and aerobic reactors have been devised which have demonstrated their potential to detoxify pharmaceutical industrial effluents by removing the various drugs, solvents and other non-pharmaceutical raw materials used in the pharmaceutical manufacturing. Enzyme based studies have also yielded encouraging results but their costs involved could preclude their wide applicability. Phytoremediation has been utilized for removal of a number of non-pharmaceutical industry effluents but recently, this is gaining prominence for its potential to degrade pharmaceuticals as well. All these represent green or eco-friendly approaches towards conservation of the environment and in the coming times, this field in expected to grow tremendously because the scientific community as well as the general population is getting increasingly sensitized towards alleviation of this problem.

KEY TERMS AND DEFINITIONS

Aerobic: A process requiring the presence of oxygen.

Anaerobic: A process occurring in the absence of oxygen.

Bacterial Bioremediation: Treatment of wastewater with bacteria having the capability to consume or digest the chemical contaminants including drugs and pharmaceuticals.

BOD: Biochemical oxygen demand or biological oxygen demand. It is an important water quality parameter representing the amount of dissolved oxygen needed for biodegradation of organic material present in a given water sample at certain temperature over a specific time period.

COD: Chemical oxygen demand is a water quality parameter (unit mg/L) based on chemical oxidation methods employing strong oxidizing agents.

Membrane Bioreactor: Wastewater treatment process in which a membrane filter process like microfiltration or ultrafiltration is integrated with a biological process like suspended growth bioreactor yielding high quality treated effluent.

Mycoremediation: Bioremediation method employing fungi to degrade or accumulate organic and heavy metal contaminants in the environment.

Phytoremediation: Use of green plants and solar energy for degradation and removal of environmental contaminants.

Chapter 57
Legislation for Solid Waste Management

Azhar Abdul Halim
Universiti Kebangsaan Malaysia, Malaysia

Siti Hafizan Hassan
Universiti Sains Malaysia, Malaysia

ABSTRACT

The legal and institutional framework, as well as the international trends in solid waste management, serves as the basis for the formulation of a policy framework that seeks to improve solid waste management (SWM) practices in the future. Recently, SWM has become a global concern, especially for urban environments such as Malaysia, whose economy could potentially be adversely affected. To address these issues, the authors has reviewed several laws, including the Federal Constitution 1957; Local Government Act (Act 171) 1976; Town and Country Planning Act (Act 127) 1976; Environmental Quality Act (Act 127) 1974; Street, Drainage, and Building Act (Act 133) 1974; and Solid Waste and Public Cleansing Management Act 2007. Relevant international norms and principles at the federal, state, and local levels have also been reviewed. Exploring this topic generates an overview of SWM implementation in the context of Malaysia and the rest of the world.

INTRODUCTION TO SOLID WASTE MANAGEMENT

Scope and Focus of the Chapter

This chapter outlines the legislation for solid waste management (SWM) in Malaysia and the world. The background of SWM legislation, including the types of solid waste and SWM controls are provided. The development of waste management control is discussed with a focus on the waste hierarchy principles, such as reduction, reuse, recycling and composting, energy recovery, and treatment and disposal. The solid waste legislation under the review of SWM for the past and currently applied in Malaysia is then discussed.

The SWM Act of Malaysia, which covers the period from 1950 to the present, is described in this chapter as well. The establishment, governance, jurisdiction, and operational issues are addressed. An overview of the Malaysian Legal Framework in Integrated Solid Waste Management is also highlighted. The roles of federal and states agencies as well as international trends in SWM, including those in the U.S, Europe, and Sweden, are discussed. The chapter ends with a brief conclusions regarding the Malaysian legislation on SWM.

Types of Solid Waste

The US Environmental Protection Agency (2013) stated that Municipal Sold Waste (MSW) consists of everyday items that are used and then thrown away; MSW includes product packaging, grass clippings, furniture, clothing, bottles, food scraps, newspapers, appliances, paint, and batteries. The sources of such waste are homes, schools, hospitals, and businesses. MSW is a term usually applied to a heterogeneous collection of wastes produced in urban areas, the nature of which varies from region to region (UNEP, 2005).

The Malaysia Solid Waste and Public Cleansing Management Act (2007) defines solid waste as controlled solid wastes that include commercial solid waste, household solid waste, institutional solid waste, and public solid waste. "Solid waste" includes the following:

1. Any scrap material or other unwanted surplus substance or rejected products arising from the application of any process.
2. Any substance required to be disposed of as being broken, worn out, contaminated, or otherwise spoiled.
3. Any other material that according to this Act or any other written law is required by the authority to be disposed.

The Act also categorizes controlled solid waste as follows:

1. **Commercial Solid Waste:** Any solid waste generated from any commercial activity such as shoplots supermarkets etc. (e.g. plastic packaging, food residues etc.)
2. **Construction Solid Waste:** Any solid waste generated from any construction or demolition activity, including improvement, preparatory, repair or alteration works.(e.g. wood, bricks, concretes, gypsum board, tiles etc.)
3. **Household Solid Waste:** Any solid waste generated by a household, and of a kind that is ordinarily generated or produced by any premises when occupied as a dwelling house, and includes garden waste (e.g. HDPE bottles, food residues, broken plates etc.)
4. **Industrial Solid Waste:**
    a. Processed Solid Wastes
        - Wastes generated from manufacturing process (product rejects, trimmings, surplus etc.)
        - Wastes generated from packaging of products, raw materials (wood pallets, carton boxes, plastic sheets etc.)
        - Could be very specific type and homogenous.
    b. Non-Process Solid Wastes
        - Wastes generated from canteens / food courts (food wastes, plastic bottles, tin cans etc.)

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

- Wastes generated from office (computer papers, magazines, plastic bags, aluminium cans etc.)

5. **Institutional Solid Waste:** Any solid waste generated by:
   a. Any premises approved under any written law or by the State Authority for use wholly or mainly for religious worship or for charitable purposes.
   b. Any premises occupied by any Federal or State Government department, any local authority or any statutory body.
   c. Any educational premises.
   d. Any healthcare facilities including hospitals, clinics and health centres.
   e. Any premises used as public zoos, museums, libraries and orphanages.
6. **Imported Solid Waste:** Any solid waste generated in other countries and imported to Malaysia for processing or disposal.
7. **Public Solid Waste:** Any solid waste generated by public places, which are under the supervision or control of any local authority. This include any open spaces, parking spaces, garden, recreation and pleasure ground or square etc.

Development of Waste Management Controls

Improving waste management is aimed at reducing the generation of waste and the amount of materials disposed in landfills. This objective is part of the overall goal of improving the quality of the environment and encouraging sustainable practices. The main goal of good waste management practices is to use materials resourcefully and consequently decrease the amount of waste in the final disposal. Implementing the waste hierarchy principle, such as to reduce, reuse, recycle, recover, and dispose, is an example of a good waste management practice that can be employed by clients. The implementation of best practices in waste management should thus involve the consideration of the waste hierarchy. In this way, the amount of waste generated in projects and subsequently disposed of in landfills is reduced (Wimalasena, 2011).

The Malaysian Solid Waste and Public Cleansing Management Act 2007 (MSWPCM) Act defines "waste hierarchy" as the ranking of waste management operations in accordance with their environmental benefits in the following order of priority: (1) reduction of waste generation, (2) reuse of waste materials, (3) recycling of waste materials for similar or new products, (4) utilization of energy from waste, and (5) disposal of waste such as landfilling. As presented in the hierarchy, the most environmentally friendly alternatives are ranked first (at the top) while the most undesirable option is ranked last.

Sources Reduction

Avoidance is the best approach with regard to material waste; however, this may not be possible or practical in most cases (Wimalasena, 2011). Source reduction is the next best alternative in regulating waste generation. Source reduction is defined as "the design, manufacture, purchase or use of materials to reduce their quantity or toxicity before they reach the waste stream" (USEPA). According to Vesilind et al., (2002), waste reduction may be implemented by three methods: (a) reducing the amount of material used per product, (b) increasing the lifetime of a product, or (c) eliminating the need for the product. Waste reduction also means the reduction of waste at the user level. The USEPA suggests that source reduction can;

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

A. Save natural resources,
B. Conserve energy,
C. Reduce pollution,
D. Reduce the toxicity of our waste, and
E. Save money for consumers and businesses alike.

Reuse of Existing Materials

Reuse means using the materials exactly as it was originally intended to be used. It is the most valuable form of recycling. The reuse of waste materials is regarded as an effective technique for improving resource utilization before disposal (Wimalasena, 2011).

Recycling and Composting

The USEPA (2014) stated that recycling comprises a series of activities, including collecting used, reused, or unused items that would otherwise be considered waste; sorting and processing the recyclable products into raw materials; and remanufacturing the recycled raw materials into new products. Consumers provide the last link in recycling by purchasing products made from recycled content. Specifically, recycling prevents the emission of many greenhouse gases and water pollutants, saves energy, supplies valuable raw materials to industries, creates jobs, stimulates the development of greener technologies, conserves resources for our children's future, and reduces the need for new landfills and combustors. Guerrero et al. (2013) stated that the success of recycling depends not only on participation levels but also on the efficiency of the equipment and infrastructure.

Energy Recovery

The US Environmental Protection Agency (2014) defined energy recovery from waste as the conversion of non-recyclable waste materials into useable heat, electricity, or fuel through a variety of processes, including combustion, gasification, pyrolization, anaerobic digestion, and landfill gas recovery. This process is often called the waste-to-energy process.

Treatment and Disposal

Landfills are the most common form of waste disposal and make up an important component of an integrated waste management system. Landfills that accept MSW are primarily regulated by state, tribal, and local governments. Methane gas, a byproduct of decomposing waste, can be collected and used as fuel to generate electricity. After a landfill is capped, the land may be used as recreation sites such as parks, golf courses, and ski slopes. The guidelines on solid waste disposal and landfill establishments identify and explain issues that should be addressed in proposals for solid waste disposal and establishment of landfill facilities for municipal and hazardous waste. Specific proposals must focus on key issues. The matter identified in these guidelines provides guidance for setting up of solid waste disposal and landfill facilities. Guerrero et al. (2013) stressed that improper waste collection systems due, among others, to the lack of infrastructure or municipal inefficiencies encourages people to search for other waste disposal solutions, including domestic burning (combustible materials) and composting the putrescible fraction of waste.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

The management hierarchy concepts should be enforced with the implemention of MSWPCM Act. The enforcement of the act should be implement for all the types of waste stated in the act. Managing the waste is crucial for Malaysia to be in line with the future sustainable development.

SOLID WASTE LEGISLATION

Introduction

Environmental protection and conservation is gaining significance in the long-term national development plan. In this regard, Malaysia has reaffirmed its commitment toward the protection and conservation of its environment (JKR, 2008). The activities performed for pollution prevention must be supported by a solid legal framework because such activities require legal powers, jurisdiction, and sanction for effective implementation (Zubaidah & Mustafa (2008)). The legal and institutional framework in Malaysia provides the basis for assessing the existing framework for the environmental management and SWM in the country. This framework is an indicator of where we are now, given that legal and institutional frameworks are the foundations from which policies and practices grow (Victor, 2001).

Malaysia

Malaysian Legal Framework for Solid Waste Management

In general, SWM in Malaysia involves various government agencies, from the federal to the state and local authorities (LAs). These government agencies are involved in SWM either directly or indirectly. Malaysia is governed as a parliamentary democracy with three tiers of government, namely, the federal government, the state government, and the LAs. It has 14 states and 144 LAs. The LAs include the Municipal Council, District Council, City Hall, and Town Board (Sakawi, 2011).

The development of the Solid Waste Management Act of Malaysia is considered informal because of the indirect legislation on the SWM enforcement prior to the establishment of the MSWPCM Act. The development process is considerably time consuming. The previous SWM legislation is derived directly or indirectly from the following:

A. Federal Constitution 1957
B. Local Government Act (Act 171) 1976
C. Town and Country Planning Act (Act 172) 1976
D. Environmental Quality Act (Act 127) 1974
E. Street, Drainage and Building Act (Act 133) 1974
F. Solid Waste and Public Cleansing Management Act 2007

The development of the MSWPCM Act is not the end of the legislation but the start of SWM enforcement. A few regulations have been developed as a result of the power conferred by the Act.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Federal Constitution 1957

The Ninth Schedule of the Federal Constitution divides the legislative power of the federal state into three lists.

A. Federal List (contains matters based on which the Parliament may make laws)
B. State List (contains matters based on which State Legislatures may make laws)
C. Concurrent List (contains common subject matters on which both the Parliament and State Legislatures have competence)

Operationally, the federal government is legally permissible to pass laws on all subject matters enlisted in the Federal List. These subject matters involve national policies, taxes, education, national defense, and internal security.

State governments are in charge of matters stated in the State List. Such matters may include religious affairs, lands, rivers, forests, and waterways. In terms of application, these laws have restricted applicability. Unlike federal laws, state laws are only applicable within the boundaries and territories of a particular state (Article 74i). As for the Concurrent List, the federal and state governments can share legislative powers and jurisdiction over matters such as culture, sports, antiquities, town and village planning, and conservation of wildlife (Yusof, 2013).

According to Victor (2001), the term "solid waste" or "municipal waste" does not appear in the Constitution, and an explicit reference on solid waste is unavailable. This statement was supported by Yusof (2013), who stated that the term "environment" is surprisingly unlisted in any of the legislative lists of the Federal Constitution. In addition, the term is not clearly listed in the Federal List, State List, or Concurrent List. This exclusion is probably due to the general state of Malaysia in previous years, back when Malaya, the former name of Malaysia, was largely an underdeveloped country. However, under the Concurrent List of the Constitution, solid waste is indirectly mentioned under public health, sanitation, and prevention of disease (Victor, 2001).

Victor (2001) contended that the general matters pertaining to local governments, such as sanitation and SWM, fall under the state's jurisdiction. However, the provision under Article 95A (National Council for Local Government) and the fact that sanitation is alluded in the Concurrent List indicate that SWM may indirectly fall under the jurisdiction of the federal and state governments. The provisions under Article 76 (1) also mean that for the sake of promoting uniformity in management, the federal government may enact a legislation on solid waste for the entire country, but such legislation must be accepted by each state government.

Local Government Act (Act 171) 1976

The Local Government Act 1976 was enacted in March 1976 and is applicable only in Peninsular Malaysia. The Act enumerates the powers and functions of the LAs. Generally, under the legislation, the LAs are responsible for the control and conservation of the environment, sanitation and public health, prevention of epidemial diseases, and the general welfare of the residents within the LAs area. However, the functions of the LAs can be extended to other areas.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Victor (2001) stated that the Act indirectly refers to SWM in Sections 9, 69–72, 84, and 102. Generally, the Act empowers the state governments to provide direction on policies and the operational management of the areas under the jurisdiction of the LAs. The following are the areas in which the local authorities are empowered by the Act to carry out their duties pertaining to SWM:

A. The Act prohibits the disposal of any waste in any form into any drains, streams, or watercourses within the jurisdiction of the LAs.
B. The Acts empowers LAs to maintain public health in areas under its administration. The LAs are also specifically empowered to perform sanitary services, such as the removal of rubbish and other kinds of waste.
C. The Act empowers the LAs to make, amend, or revoke by-laws for the proper management and operation of sanitary services, such as the removal of rubbish and other kinds of waste.
D. The Act empowers the LAs to carry out legal actions against any person that may cause a nuisance willfully or through ignorance within the area of the LAs. The term nuisance can be broadly interpreted to cover the indiscriminate disposal of rubbish or waste.
E. The Act provides for the regulation and control of industries or activities that are obnoxious or could be a source of nuisance.

For example, Section 42 of the Act prohibits anyone from placing building materials on the road without a written permission from the LAs. In fact, the Act requires the occupier of a premise to clean the road in front of the entrance to the premise. Generally, littering or disposing of unwanted materials at public places within any LA area is prohibited by the Local Government Act and punishable through fines or jail time, or both.

This Act is probably the most significant SWM legislation. It generally empowers the LAs to take charge of SWM in their areas of jurisdiction. The areas of empowerment appear broad and comprehensive to cover SWM, operational activities, and the formulation of by-laws and prosecution guidelines. The current job function of the LAs in terms of SWM appears to be largely derived from this Act.

Town and Country Planning Act (Act 172) 1976

Act 172, or the Town and Country Planning Act, was enacted in 1976 to ensure proper control and regulation of town and country planning and development in Local Authority (LA) areas. Zubaidah and Mustafa (2008) explained that this act imposes a statutory obligation on the local planning authority to ensure that effective planning controls are introduced within its locality. Sinha and Kew (2004) supported this account and added that the act requires the preparation of a draft structure plan which, among other things, defines measures to improve the physical environment and communications of planning authorities.

Victor (2001) summarized that the act designates LAs as the local planning authorities for their respective areas. Generally, the act includes a provision for the planning and development of an area by the formulation of Structure and Local Plans. These plans are development control plans that determine whichareas should be developed and how, by studying the physical, social, economic, and environmental issues. These development plans are legally binding documents that provide general guidance on the direction and strategies to be employed to develop geographically large areas such as districts.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Environmental Quality Act (Act 127) 1974

The Environmental Quality Act was enacted in 1974 for the prevention, abatement, and control of environmental pollution,as well as to enhance the general quality and ensure proper management of the environment.

The term "waste" could be defined as Scheduled Waste or other solid, semi-solid, and liquid substances, which could cause environmental pollution,as stated in Section 2. The act also provides the control or prevention of environmental pollution. Section 24 even specifies soil pollution to include refuse dump, garbage tip, or other solid wastesbased on their negative effect on human beings. Open burning of waste, which usually includes solid waste, is also regulated by Section 29 of this act.

According to Victor (2001), an important feature of this act is that it requires an Environment Impact Assessment (EIA) for prescribed activities before such activities can be carried out. The list of prescribed activities include the construction of infrastructure for municipal solid waste, such as incineration plants, composting plants, recovery/recycling plants,and solid waste landfill facilities. Lastly, the act empowers the Minister to issue regulations to control, prohibit, and improve the general quality of the environment (Section 51). Under this provision, the Minister may regulate the establishment of sites for the disposal of solid or liquid waste on or in any land.

Street, Drainage and Building Act 1974

The Street, Drainage and Building Act was enacted on 13 June 1974. The Streets, Drainage and Building Act (SDBA) was enacted to consolidate the legislation governing the streets, drainage and building in local authority areas. Victor (2001) explained that this act empowers the management of solid waste in public areas. Though this may seems redundant, but the act especially focuses on the cleanliness of public places as compared to solid waste management in general.

Solid Waste and Public Cleansing Management Act 2007

The history of the SWMPC Act as a major solid waste legislation was fraught with numerous challenges. According to Yahaya and Larsen (2007), in September 1995, the Government decided that solid waste management was to be privatized. After 10 years of privatization, the National Strategic Plan for Waste Management (NSP) was then endorsed by the Government in July 2005. In the same year, a Solid Waste Management Division was formed in the Ministry to prepare for the implementation of the plan. Less than a year after the adoption of the NSP, the Government approved the National Solid Waste Policy, which provides the overall direction of solid waste management. Act 672, or the SWMPC Act, was passed by the Parliament in July 2007 and published in the national gazette in August 2007. This act was administered by the Ministry of Housing and Local Government and was enforced on September 1, 2011 for every state in Peninsular Malaysia except Penang and Selangor. The main objectives of the act are to provide and regulate public cleansing and the management of controlled solid waste to maintain proper sanitation.

Act 672 requires all operators of solid waste and public cleansing management services and facilities to apply for license from the Director General of the National Solid Waste Management Department. The Act also requires prior written approval from the Director General of the National Solid Waste Management Department before any construction, alteration, or closure of prescribed solid waste management facilities. Furthermore, Act 672 covers the following:

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

A. Control of solid waste generators and persons in possession of controlled solid waste;
B. Enforcement; and
C. Reduction and recovery of controlled solid waste.

Act 672 empowers the Federal Government to shoulder the management of solid waste and public cleansing from the LAs throughout Peninsular Malaysia and the Federal Territories of Putrajaya and Labuan. The implementation of Act 672 and its relatedregulations on solid waste and public cleansing management is expected to drive a major change in the modus operandi of solid waste and public cleansing management in Malaysia. Upon the enforcement of Act 672, all works on solid waste and public cleansing management will be handled fully by the Solid Waste and Public Cleansing Management Corporation (SWPCMC). Such enforcement involves the immediate takeover of solid waste and public cleansing management responsibilities from all LAs, as the LAs will lose jurisdiction over the collection and disposal of garbage, as well as the cleansing of public roads, public places, public toilets, and drains. SWPCMC will then assume the management and operation of all landfill sites previously under the LAs, including identifying and evaluating sanitary landfills, transfer stations, incineration technologies, and plant management.

Upon this Act's coming into effect, the Federal Government shall have executive authority with respect to all matters relating to the management of solid waste and public cleansing throughout Peninsular Malaysia and the Federal Territories of Putrajaya and Labuan.Yahaya and Larsen (2007) explained that with the enactment of the SWMPC Act 2007, the two previously existing Acts, which provided legal authority to the LAs on solid waste management, must be amended. Hence, in the same session, the Parliament approved the amendments on the relevant provisions in both the Local Government Act of 1976 and the Street, Drainage, and Building Act of 1974, therefore deleting any reference on Solid Waste Management.

Such amendments are necessary to ensure smooth implementation of the new act and to avoid any confusion during implementation. Another important piece of legislation that was also amended is the Town and Country Planning Act of 1976 (TCPA). Although both of the earlier legislations had the relevant sections deleted, the TCPA hada new provision inserted. The inserted provision is to ensure that a local planning authority will consider the provisions of the SWMPC Act of 2007 when addressing an application for planning permission. This provision is a long-term measure to ensure a coordinated approach to Solid Waste Management.

Enforcement of the Act

Additionally, certain regulations have been developed by the National Solid Waste Management Department to implement the power conferred to it by the SWMPC Act of 2007, which became operative on September 1, 2011. Such regulations include:

A. Solid Waste And Public Cleansing Management (Manner Of Appeal) Regulations 2011
B. Solid Waste And Public Cleansing Management (Prescribed Solid Waste Management Facilities And Approval For The Construction, Alteration And Closure Of Facilities) Regulations 2011
C. Solid Waste And Public Cleansing Management (Compounding Of Offences) Regulations 2011
D. Solid Waste And Public Cleansing Management (Licensing)(Management Or Operation Of Prescribed Solid Waste Management Facilities) Regulations 2011

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

E. Solid Waste And Public Cleansing Management (Licensing) (Undertaking Or Provision Of Collection Services For Household Solid Waste, Public Solid Waste, Public Institutional Solid Waste And Solid Waste Similar to Household Solid Waste) Regulations 2011
F. Solid Waste And Public Cleansing Management (Licensing) (Undertaking Or Provision of Transportation Services By Long Haulage) Regulations 2011
G. Solid Waste And Public Cleansing Management (Licensing) (Undertaking Or Provision Of Public Cleansing Management Services) Regulations 2011
H. Solid Waste And Public Cleansing Management (Scheme For Household Solid Waste And Solid Waste Similar To Household Solid Waste) Regulations 2011

The another strategies added in order to be included with the enforcement were;

A. A two year grace period would be given to the public to get used to the practice before fines were imposed on those who failed to do so.
B. Within these two years, the three concessionaires in charge of solid waste management in the country will have to raise awareness on separation of waste at source.
C. All hosehold owners must know their duty to segregate their own waste before dumping it.

The most valuable finding from this section is the latest information gained from Yahaya and Larsen (2007) regarding the amendment of related acts as a result of the enactment of the SWMPC Act of 2007. A summary of the final findings is provided below.

A. All references on Solid Waste Management in the Local Government Act of 1976 and the Street, Drainage, and Building Act of 1974 were deleted. Such amendments are required to ensure smooth implementation of the new act and to avoid any confusion during implementation.
B. A new provision was inserted into the Town and Country Planning Act of 1976 (TCPA) to ensure that local planning authorities will comply with the provisions of the SWMPC Act of 2007 when dealing with an application for planning permission.
C. The establishment of the SWMPC Act of 2007 changed the modus operandi of solid waste and public cleansing management in Malaysia. Upon the enforcement of Act 672, all works on solid waste and public cleansing management will be assumed by SWPCMC, which includes the immediate takeover of solid waste and public cleansing management responsibilities from all LAs. This change is because the LAs will no longer have jurisdiction over garbage collection and disposal, as well as the cleansing of public roads, public places, public toilets, and drains.

All legislation related to solid waste management, such as the Local Government Act of 2007 (Act A1311) (as amended), the Street, Drainage, and Building Act of 2007 (Act A1312) (as amended), and the Town and Country Planning Act of 2007 (Act 1313) (as amended), are now vested upon the federation by Act 672. The uniformity of these Acts is imposed throughout Peninsular Malaysia and the Federal Territories of Putrajaya and Labuan (Abas and Seow, 2014).

Managing waste is an issue for all households and businesses. The SWMPC Act has a well developed waste management act that generates significant enforcement and regulation for the collection, transportation, and processing of waste. The waste hierarchy remains an important principle in the SWMPC Act. This ensures that SWMPC Act presents a holistic waste management enforcement from the initial

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Table 1. Summary and area of jurisdiction for the legislation

Legislation	Area of Jurisdiction
Federal Constitution, 1957	• Basis for the formulation of the NCLG and other related solid waste management legislation.
Local Government Act, 1976	• Authorizes the State government and the LAs to be responsible for solid waste management.
Town and Country Planning Act, 1976	• Authorizes the LAs to plan for the development of their area which also includes solid waste management especially in siting of waste management facilities.
Environmental Quality Act, 1974	• Regulates pollution from solid waste and the implementation of waste management facilities through the requirement of an EIA
Streets, Drainage and Buildings Act, 1974	• Authorizes the LAs to regulate and prohibit solid waste disposal in its area.
Solid Waste and Public Cleansing Management Act 2007	• To provide and regulate public cleansing and the management of controlled solid waste to maintain proper sanitation. - Control of solid waste generators and persons in possession of controlled solid waste; - Enforcement; and - Reduction and recovery of controlled solid waste.

Modified from Victor (2001)

generation of waste through to its ultimate disposal with chances to reduce waste at each step of the hierarchy. The implementation of SWMPC Act will benefit from more sustainable waste management. The summary and area of jurisdiction of legislation was presented in the Table 1;

Institutional Framework in Solid Waste Management

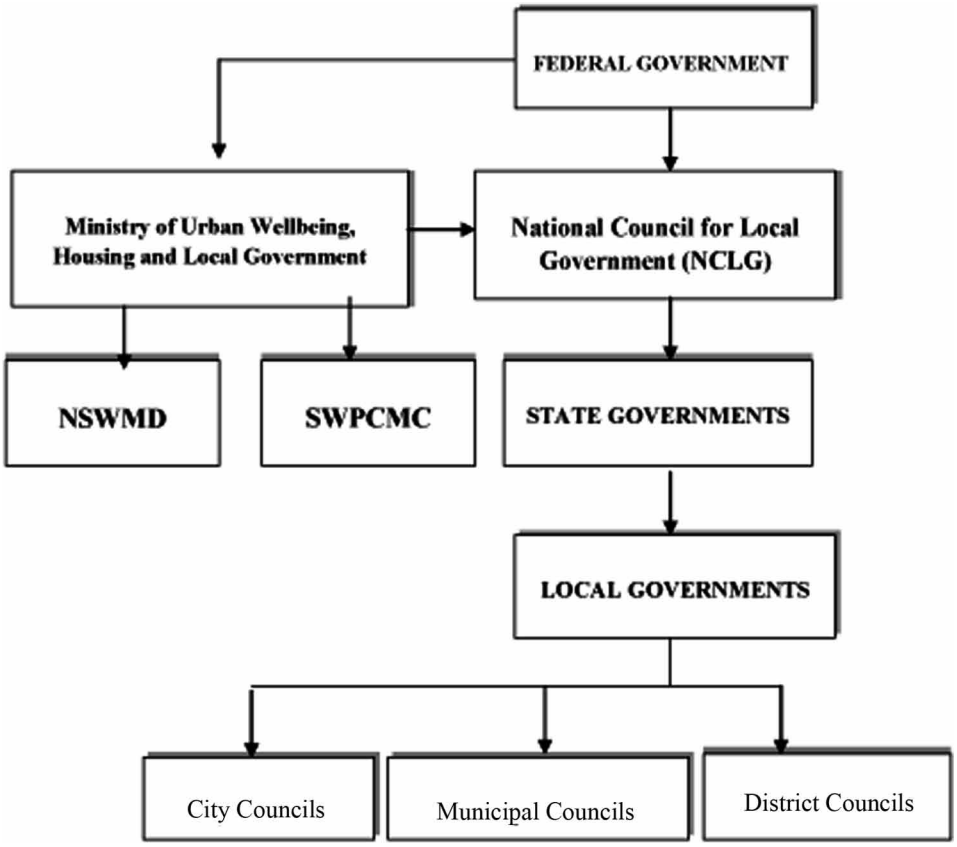
This section is an overview of the main parties involved in solid waste management in Malaysia. According to Victor (2001), these institutions comprise the main mechanism by which the legislative framework is translated to operate and manage solid waste on the ground.

The overall institutional framework of the Malaysian government is headed by the Cabinet, which comprises of various Ministers, who are elected as the representatives of Malaysian citizens. Several councils assist the Cabinet in guiding the development of the country by formulating policies and providing directions for growth. These councils comprise various members of the Cabinet, as well as representatives from the State governments. Some of these councils function as liaisons between the Federal and State governments.

Under the Federal Government, the administration of Municipal Solid Waste Management (MSWM) is under the purview of the Ministry of Housing and Local Government (MHLG). This ministry has two units involved directly with MSWM, namely, the National Solid Waste Management Department (NSWMD) and the Solid Waste and Public Cleansing Management Corporation (SWPCMC). The roles of the Federal Government in MSWM are principally of an advisory and coordinating nature. This chapter presents the roles of NSWMD and SWPCMC as the primary federal agencies responsible for this matter. Summary of framework was presented in Figure 1.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 1. The Institutional Framework of the Malaysian Government
Sources from Razak A. A (2014)



National Solid Waste Management Department (NSWMD)

The NSWMD was established under the SWMPC Act of 2007 to integrate the solid waste management system at the national level. This Act provides executive authority to the Federal Government to carry out the responsibilities of solid waste and public cleansing management.

Before the establishment of NSWMD, the SWM function fell within the Engineering Division of Environmental Health and Project Implementation Division, Department of Local Government. When Act 672 and Act 673 were passed, this function was transferred to NSWMD and the Solid Waste and Public Cleansing Management Corporation (SWMPC). Such functions include:

- To propose policies, plans, and strategies for solid waste and public cleansing management;
- To formulate plans for solid waste management including location, type, and size of new treatment facilities, coverage areas of solid waste management facilities, solid waste management schemes to supply controlled solid waste to the solid waste management facilities, and the time-scale for the implementation of the plans;
- To set standards, specifications, and codes of practice relating to any aspect of solid waste and public cleansing management services;

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

- To exercise the regulatory function specified in Act 672 and in any regulation made under the Act;
- To grant licenses and approvals under Act 672; and
- To carry out such other activities for the implementation of the Act.

Solid Waste and Public Cleansing Management Corporation (SWPCMC)

The SWPCMC was established to complement and ensure the successful implementation of the National Solid Waste Management Policy. In general, the policy aims to provide a comprehensive, integrated, cost-effective, and sustainable solid waste management system that caters to the demand for environmental conservation and public well-being.The Corporation was established under the Solid Waste Management and Public Cleansing Corporation Act of 2007 (Act 673) and commenced its operations on June 1, 2008 under the MHLG.

The Corporation has the power to administer and enforce solid waste and public cleansing management laws and matters related thereto. The role of the corporation is to ensure that solid waste and public cleansing management services are efficient and integrated and meet the expectations of consumers. The corporation's roles include the following:

- To recommend policies, plans, and strategies for solid waste management and public cleansing services to the National Solid Waste Management Department.
- To implement and promote public participation and awareness through various programs on solid waste management and public cleansing.
- To establish systematic recycling and waste segregation practices with an emphasis on sustainable development and incorporating economic, political, and social aspects.
- To process applications for new licenses and for renewal, including the revocation or suspension of solid waste management service provider licenses and submission of recommendations to the National Solid Waste Management Department.
- To monitor the performance of the concessionaires involved in providing solid waste management and public cleansing services.
- To identify environmentally friendly technologies that are safe and cost-efficient, and to conduct research on the development of solid waste management and public cleansing.
- To implement and enforce the laws and regulations on solid waste management and public cleansing.

Private Waste Manager

Privatization in Malaysia was initiated as a national policy in 1983 to address the economic problems at that time. The *Economic Times* defines privatization as a transfer of ownership, property, or business from the government to the private sector. In privatization, the government ceases to be the owner of the entity or business. This process involves three main areas; responsibility, assets, and personnel management. The Economic Planning Unit of Malaysia lists the objectives of the national privatization policy as follows:

1. To facilitate the economic growth of the country;
2. To reduce the financial and administrative burden on the Government;

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

3. To reduce the presence of the Government in the economy;
4. To reduce the level and scope of public spending; and
5. To allow market forces to govern over economic activities and improve efficiency and productivity in line with the National Development Policy.

Privatization in the local government sector involves the delivery of public services such as sewerage, transportation, and solid waste management. In particular, the Malaysian government initiated the privatization of urban solid waste management in 1993. Such privatization included the storage, collection, transportation, processing, and disposal of solid waste. The objective was to provide an integrated, effective, efficient, and technologically advanced solid waste management system as part of Vision 2020. This move primarily aimed to reduce and recover waste and therefore, minimize the need for final waste disposal.

Furthermore, privatization was expected to restructure the existing solid waste management system of the LAs into a system that incorporates efficient recycling and environmental management measures. The privatization was also expected to address and resolve problems in solid waste management that were faced by the LAs such as finance, lack of expertise, illegal dumping, open burning, and the lack of proper solid waste sites (Abas & Seow, 2014).

The enforcement agency appointed by the government was the Solid Waste and Public Cleansing Management Corporation. Therefore, three private waste management consortiums were appointed for the entire country, namely:

1. Alam Flora Sdn Bhd, which is responsible for WP Kuala Lumpur, WP Putrajaya, and Pahang.
2. SWM Environment Sdn Bhd, which is responsible for Johor, Melaka, and Negeri Sembilan.
3. Environment Idaman Sdn Bhd, which is responsible for Kedah and Perlis.

However, several states such as Penang, Selangor, and Perak have refused the collection of the concessionaires. This crisis occurred because local authorities were not satisfied with the quality of services and costs of operation (Abas & Seow, 2014).

Non-Governmental Organizations (NGOs)

Non-governmental organizations such as Malaysian Environmental NGOs (MENGO), Treat Every Environment Special (TrEEs), Environmental Protection Society of Malaysia (EPSM), Lions Club, and the Rotary Club play an important role in the solid waste management process. These NGOs are often involved at the community level and organize activities such as recycling and environmental awareness programs that ultimately drive community participation in solid waste management.

INTERNATIONAL TRENDS

International trends in solid waste management provide a benchmark for the evaluation and future directions of integrated solid waste management in Malaysia (Victor, 2001). Other countries are more advanced than Malaysia in handling this particular issue. As such, the relevant development efforts, technologies, facilities, and initiatives can be modeled from the experiences of other countries. This chapter reviews some countries' relevant policies for benchmarking of solid waste management initiatives.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

US

The Congress passed the Solid Waste Disposal Act of 1965 to address the issue of growing solid waste volume in the US. Proper waste management is also ensured through this Act. The Act defined environmentally responsible methods to dispose trash of the household, municipal, commercial, and industrial levels. The Solid Waste Disposal Act of 1965 marked the beginning of a series of regulations that emphasized clean air and resource management. Significant amendments were made to the Act with the passage of the Resource Conservation and Recovery Act of 1976 (RCRA).

Resource Conservation and Recovery Act (1976)

The Resource Conservation and Recovery Act is commonly referred to as the RCRA, which is the US' primary law governing the disposal of solid, hazardous waste. The Congress approved RCRA on October 21, 1976 to address the increasing problems that the nation faced from the rising volume of municipal and industrial waste. RCRA, which amended the Solid Waste Disposal Act of 1965, set the national goals to achieve the following:

- Protection of human health and the environment from the potential hazards of waste disposal
- Conservation of energy and natural resources
- Reduction in the amount of waste generated
- Management of waste in an environmentally sound manner

Europe

Directive 2008/98/EC (2008)

Directive 2008/98/EC explained the basic concepts and definitions related to waste management, such as the waste management hierarchy (e.g., recycling and recovery).'Waste' means any substances or object which the holder discards or intends to discard or is required to discard (M.Gharfalkar et al., 2015). The waste hierarchy comprising of five measures; prevention, preparing for reuse, recycling, other recovery and disposal.

Sweden

The Ministry of Environment established the Swedish Environmental Protection Agency as the central government agency tasked to coordinate and implement environmental policies and protection (Tam, 2014). Under the Ministry of the Environment are county administrative boards and municipal executive boards that function as the respective regional and local authorities to conduct inspections and enforcement of environmental laws in Sweden. Local municipalities are also responsible for collecting and treating household waste, as well as setting their own sanitation plan and regulations for local waste management.

The waste management policy in Sweden is primarily governed by the Environmental Code and the Waste Ordinance. The Environmental Code sets out the framework for promoting sustainable development through the protection of human health and the environment, as well as the effective use of resources. It also contains specific provisions governing waste collection and disposal, resource management,

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

permit system, supervising authority, and penalties for breaching relevant rules. The Waste Ordinance complements the Environmental Code by establishing general provisions for the regulation of waste management (Tam, 2014).

Tam (2014) explained that Sweden is also governed by the Industrial Emissions Directive issued by the EU, which commits its member states to controlling and reducing the impact of industrial emissions on the environment. The Directive is transposed into Swedish law through amendments to the Environmental Code and the implementation of six new regulations. Among the new regulations, waste incineration is primarily governed by the Regulation on Waste Incineration, the Environmental Regulation, and the Industrial Emissions Ordinance.

The Regulation on Waste Incineration establishes the emission limits of pollutants and the corresponding measurement requirements, whereas the Environmental Regulation sets the rules on the control, planning, and permission requirements for environmental activities, such as waste treatment. The Industrial Emissions Ordinance introduces the duty of operators to prepare a baseline report, as well as ensures the strict implementation of environmental inspections (Tam, 2014).

Japan

According to Borongan and Okumura (2010), the Waste Management and Public Cleansing Law, enacted in December 1970, stipulates that each municipality shall collect, transport, and dispose the municipal wastes generated within its area. The national government develops the fundamental policy for waste reduction and the development plan for waste treatment facilities, as well as provides technical and financial assistance to municipalities.

The Ministry of the Environment (MOE) is responsible for MSW management administration at the national level. The recycling of some types of municipal wastes is implemented in accordance with specific individual recycling laws, such as the following:

- Container and Packaging Recycling Law (enacted in June 1995, administered by the MOE and the Ministry of Economy, Trade and Industry (METI))
- Home Appliances Recycling Law (enacted in June 1998, administered by the MOE and the METI)
- Food Waste Recycling Law (enacted in June 2000, administered by the MOE and the Ministry of Agriculture, Forestry and Fishery)
- End-of-life Vehicle Recycling Law (enacted in July 2002, administered by the MOE and the METI)

In keeping with the "Mottainai" spirit, Japan exhibits good practices in the development of a sound material-cycle society through the 3R (reduce, reuse, and recycle) principle. Mottainai is a long-established Japanese concept, which means that something wasted without having made full use of its potential is a shame (Borongan and Okumura, 2010).

Singapore

Borongan and Okumura (2010) present in their report that Environmental Public Health Act (EPHA) developments are required to develop the necessary refuse storage and collection system, which will include refuse bin centers in premises for the proper management of refuse. The EPHA also provides

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

the legislative framework for the licensing and regulation of waste collection and the establishment of approved waste disposal and recycling facilities. The EPHA includes several revisions to enforce sanctions for offenses on the illegal dumping of waste. The following regulations related to solid waste management supplement the EPHA:

- Environmental Public Health (General Waste Collection) Regulations
- Environmental Public Health (Public Cleansing) Regulations
- Code of Practice on Environmental Health
- Code of Practice for General Waste Collectors

Singapore has established an integrated solid waste management system that ensures all non-recycled wastes are collected and disposed of safely at waste-to-energy plants or at offshore sanitary landfills in the case of non-incinerable waste.

South Korea

Borongan and Okumura (2010) stated that all municipalities in South Korea know and practice the 3R principle. The ultimate goals of waste management in Korea are to ensure a clean environment for the people and the natural ecosystem by minimization of waste generation, optimization of waste recycling, and treatment of waste generated in an environmentally sound manner. A strategic approach to promote the 3R principle is ensured as the core measure to achieve the goals in the country. Therefore, all municipalities understand and try to practice this plan, despite their limited facilities for waste segregation/sorting, collection, and treatment in their respective areas. The regulations applied in South Korea include the following:

- Waste Control Act, 8 Mar, 1991
- Act on the Promotion of Saving and Reutilization of Resources, 8 Dec, 1992
- Act on the Promotion of Construction Waste Recycling, 21 Dec, 2003

CONCLUSION

Compared with other countries, Malaysia still has a long way to go in developing sustainable environmental principles for the Malaysian people. Several actions need to be taken, and these will start with the implementation and enforcement of existing waste management laws in the country and in all stages of waste created. The solid waste management challenges and issues that should be considered while framing solid waste policy include proper waste generation, segregation or separation at sources, collection, transportation, and disposal methods, landfill management, hazardous and other toxic material management, treatment, incineration, recycling and other technology standards, monitoring, evaluation, and continuous improvement methods. The most important challenge is on the change the mindset of the Malaysia community to reduce the waste at the sources. In addition to these issues, policy needs to address the short- and long-term economic, environmental, and social costs and benefits, funding methods, and roles of various stakeholders. The joint projects between municipalities and stakeholders bring

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Malaysia forward in terms of implementing recycling concepts. This initiative may reduce the amount of waste that goes to landfills. Partnerships and the continued cooperation of various stakeholders in municipal waste management efforts should be enhanced in the provision of resources for the effective implementation of waste management.

ABSTRACT

Overpopulation is no doubt worldwide concern as it brings different problems to urbanization process as well as environment. Waste is number one side product of overpopulation. Waste generation is ever increasing in both urban and suburban area and has led to many environmental issues. Many of the waste generated have potential to be transformed into value added products. By recycling, reusing and re-purposing these wastes, we are actually reducing the amount of waste produced and at the same time helping to solve waste disposal problem as many of the wastes exhibit strong energy producing potential. Overpopulation may be an issue of its own; nonetheless, it also provides us an army of human power in tackling environmental issues. Population is a valuable asset. The potential of that amount of man power, especially youth, combining with various awareness campaigns and 3R campaigns introduced by government and NGO are important in targeting these problems.

INTRODUCTION

Disposal of high quantity of waste is an unparalleled environmental issue. Increase in population directly influences the waste generated per unit area as percentage of the population increases especially in urban areas. More and more people are moving into the city referable to economic activities, social

activities and the quality of life available here. With increasing rate of population and urbanization, land available is not enough for proper waste disposal. This means the location of the residential area is getting closer to the vicinity of waste disposition area such as landfills and waste incinerators, which is in fact inevitable. Exposure to harmful pollutants around the area of waste disposal site especially waste incineration plants also raises health concerns.

There is no more doubt that increase in population translates to higher generation of waste (Agamuthu and Fauziah, 2011) and waste generation strongly varies depending on economic and geographical status of an area. Till 1993, waste generation in Malaysia was between 0.34-0.85kg per capita per day. However, at present, in Kuala Lumpur, capital of Malaysia, waste generation of household waste per capita is 0.80-1.30 kg per day (Abdul Jalil, 2010). In 2006, methods of waste disposition in Malaysia were:

- Recycling (5%),
- Composting (1%),
- Inert landfill (3.2%),
- Sanitary landfill (30.90%) and
- Other disposal sites (59.40%).

However, the government is targeting to increase recycling to 22% and composting to 8% by the year 2020 (Periathamby et al., 2009). Composition of waste in Malaysia is mainly composed of municipal solid waste (64%). A heavy percentage of the municipal solid wastes is recyclables (80%) and is disposed at landfills (Ministry of Housing and Local Government (MHLG), 2006). Landfill is still the most commonly used method of solid waste management in Malaysia due to its cost effectiveness (The Ingenieur, 2009). Nevertheless, landfill may soon give problem as it approaching its maximum capacity and simultaneously constructing a new landfill site is out of the question due to land scarcity with the increase in population (Latifah et al., 2009; Moh & Abd Manaf, 2014).

Recycling is the collection and processing of waste separation, the result being new consumer products. Recovery is the separation of mixed waste, with the final outcome of producing new raw materials for industries. Recently, waste-to-energy approach is emerging as a promising way of handing ever rising amount of waste especially in developing countries. Waste-to-energy (WTE) approach uses thermal and biological conversion technologies to release potential of usable energy contained in solid waste (Johri et al., 2011). Exceeding 800 thermal WTE plants are operating worldwide (Martin, 2012). Country such as Germany is using WTE to handle 35% of the total waste treatment (EU's average is 24%) and waste that was land filled comprises only 1% of the total waste (Eurostat, 2014). Population hike changes waste generation pattern and we are in need of more proficient waste handling methods and should not rely solely on one method. Malaysia has started the implementation of WTE mainly for agricultural waste and forestry residues in recent decades. It provides alternative for renewable energy for Malaysia (Tan et al. 2014). However, implementation of WTE on municipal solid waste is still not common. Nevertheless, agricultural industries in Malaysia are generating tonnes of waste that have massive potential as resource material for waste-to-energy approach.

Overpopulation may bring various challenges towards waste management. Nevertheless, for every nation to face this challenge, especially in urban areas provides infinite potential for handling the problems caused by overpopulation. Rules and regulations for waste management require manpower to implement them. Consequently, overpopulation does not solely bring negative impact towards the environment, but can however be seen as one of the most useful resources, in transforming the waste management situation.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

About nine out of ten people between ages 10 and 24 live in less developed countries. Total population in Malaysia in the year 2014 was 30.2 million, and population back in 1950s was 6.1 million (see figure 1). About 66.3% of population in Malaysia is between the ages of 15-59. In Malaysia, according to statistics, percentage of 10-24 years old is 20 to 29% in the year 2015 (UNFPA, 2014). This age group is the group of population that is more willing to accept and practice the concept of environmental friendly practices such as recycling, compared to the older generation.

Today, many modernized cities which are highly populated such as Stockholm and Adelaide are endeavoring to adapt zero waste practice, a more cost effective and sustainable approach. "Zero waste city" has the perception of attaining 100% recycling rate and resources recovery from waste materials generated in the city (Zaman & Lehmann, 2011). The five waste management settings include:

- Social,
- Economic,
- Political,
- Technological and
- Environmental, and many stakeholders are involved.

They are interconnected and mutually dependent (Zaman & Lehmann, 2011). With human factor potential exhibiting from abundance of young population in the country, "zero waste city" may not only be a concept, but will become something that can be implemented.

Hence, overpopulation may not necessary be bringing only negative impact towards waste management in this modern era, particularly with proper awareness and technology.

Figure 1. Total population of Malaysia

SOURCES OF SOLID WASTE FOR SUSTAINABLE ENERGY

Waste generation rates are affected by socio-economic development, degree of industrialization, and climate. More often than not, the hike in the percentage of urban population induced by economic prosperity will lead to higher solid waste generation.

Generally, classifications of solid wastes are proposed as reported by its origin into four major types:

- Municipal solid waste (MSW),
- Agriculture solid waste (ASW),
- Industrial solid waste (ISW), and
- Healthcare solid waste (HW) (Sawalem et al., 2009; Eddine and Salah, 2012; Sadek et al., 2013).

Municipal Solid Waste (MSW)

Tonnes and tonnes of household waste are gathered every year and the main part comprises off disposal that ends in landfill such as food waste, cloth, paper waste, glass and et cetera. About 80% of the total municipal solid waste collected is biomass resource, such as putrescible waste and paper. These wastes have high potential in energy conversion via combustion, through by anaerobic digestion by the digester installed in landfill site. Gas obtained from the landfill site (50% methane and 50% carbon dioxide approximately) is derived from municipal solid waste that undergoes natural decomposition. It is scrubbed and cleaned and then fed into internal combustion engines or gas turbines for generating heat and power. The organic fraction of MSW is stabilized anaerobically by a high-rate digester with the intention of obtaining viable biogas for generating electricity and steam.

Agricultural Solid Waste (ASW)

Extensive amounts of crop residues are generated worldwide, and are undoubtedly not fully utilized. The most rampant agricultural residue is rice husks which is 25% of rice by mass. Other agricultural residues consist of"

- Sugar cane fibre,
- Cereal straw,
- Coconut husks and
- Shells.

In current farming practise, farmers either plough these agricultural residues back to the soil, burn the residues, left it for decomposition or grazed by cattle. Various studies on agricultural and biomass have clearly concluded that utilising portion of the crop residue for energy making is appropriate and viable as these residues hold the potential of being processed into liquid fuels for generating energy and heat.

Animal Waste

There are an extensive variety of animal wastes which can be utilised as biomass energy sources. The most extensively recognized sources are the animal and poultry manures. In the past this waste was

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

recuperated and mostly sold as compost or just spread onto land, yet the announcing of new environmental control policy has resulted the requirement of certain level of waste management. This has then provided incentives for waste-to-energy approach. The common technique of converting these waste materials into value added product is via anaerobic digestion that produces biogas which can be used as fuel especially for internal combustion engines, for small gas turbines and even for space and water heating. Food processing and abattoir wastes are also exhibiting potential in anaerobic digestion feedstock (Eddine & Salah, 2012; Sadek et al., 2013)

Sugar Industry Wastes

Sugar cane industry creates extensive volumes of bagasse every year. Baggasse is a dominant source of biomass that has high potential to be employed as boiler feedstock for generating steam which can be utilized for processing heat and electricity production. Most of the sugar cane mills process their baggases to produce and supply the energy for their own needs and some sugar cane mills are capable to export significant amount of electricity to the power grid.

Forestry Residues

Forestry residues are created by operations for example, diminishing of plantations, clearing for logging roads and streets, separating stem-wood for mash and timber and natural attrition. Furthermore, wood processing also generates high amount of residues such as sawdust, off-cuts, bark and woodchip rejects. These wastes are often not utilized at all and are often disposed or left to decompose on site. Nevertheless, they are possible to be utilized after collection in biomass gasifier for producing hot gasses for steam production.

Industrial Solid Wastes (ISW)

Food industry is often the industry that generated a prominent number of residues on top of by-products that generally can be utilised as biomass energy sources. Waste materials are produced from every sectors of food industry; from meat production to confectionery is all producing waste that has potential as energy source. Other solid wastes in food industry include:

- Fruit and vegetables peelings and scraps,
- Food products that do not meet food control standards,
- Pulp and fibre from sugar and starch extraction,
- Filter sludge and
- Coffee grounds.

These wastes are usually not utilised and are often disposed of at the landfill.
Liquid wastes are also generated from:

- Washing of meat,
- Fruit and vegetables,
- Blanching of fruit and vegetables,

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

- Pre-cooking meats,
- Poultry and fish,
- Cleaning and processing operations
- as well as wine making.

Content of starches, sugar and other dissolved and solid organic matter are high in these waste waters. These waste waters may be potentially processed via anaerobic digestion for producing biogas or to be fermented for ethanol production. Sadek et al. (2013), reported several industrial examples of waste-to-energy approaches that are already in existence.

Biomass

Biological material often termed as biomass can be used as a fuel source for energy generation. Technology to convert biomass to large amounts of electricity has been put in place by the Malaysian government. Simultaneously, small scale versions such as wooden stoves or furnaces are also being used. Biomass conversion also produces bio-fuels, such examples are ethanol, methanol, bio-oil, and bio-diesel. Among all domestic renewable energies, biomass energy is the greatest source. In Malaysia, the wood, rice, sugar and palm oil industries have been exploiting their biomass as fuel to offset (partially or fully) their energy needs. Malaysian oil palm biomass contributes about RM 6379 million of energy yearly. Even though it is already in practice, there is still a lot to done to optimize the usage of biomass for cogeneration in Malaysia (Sumathi et al 2008).

Steam is produced by the direct burning of feedstock which is used to power generators by the turbines. Empty fruit bunch (EFB) is most often used, among the other wastes of the oil palm industry for the generation of heat energy via combustion (Husin et al., 2005). Most palm mills burn oil palm fibre and shells as boiler fuel to generate steam for the extraction of crude palm oil and a small amount of electricity for internal use. EFB has a calorific value of about 18,838 kJ kg^{-1} and is able to produce an approximate of 7.65Mt (million tonnes) of power. The Chubu Electric Power in Sabah, Malaysia plans utilizes the empty palm bunches to generate the output of a 10,000 kW. This fulfils the EU standard guidelines (2002) for CO_2 emission and trading system for greenhouse gas emission allowances. Also proposed was the power plant in Pantai Remis, to generate 11.5 MW of electricity. It is to be fueled by EFB, supplying electricity to a distributor.

In the coming years, there is likelihood of depletion of oil and gas reserves, and in order to ensure the security of energy supply, the demand towards the establishment of hydrogen economy has come to the fore front. This has brought together scientists to seek for other means of extracting the energy from biomass. Studies in Malaysia are looking in to the production of hydrogen from POME using microflora isolated from POME sludge (Atif et al., 2005; Krishnan, 2006) The standard biogas hydrogen generation was observed to be of 57±2% with 7 d HRT. The generated biogas was free from methane which is a success.

POME can also be used to produce bio-gas via anaerobic digestion in which bacteria in organic matter decomposed without the presence of oxygen; resulting in extractable methane, a source of energy. 20 tonnes of FFB, generates 100 tonnes of POME, which yields about 400 m^3 of biogas and 10.8 MW of power (Sumathi et al 2008).

OTHER LESS-FOCUSED POTENTIAL SOURCES OF BIOMASS FOR ENERGY GENERATION IN MALAYSIA

Paddy straw is found in large amount from paddy paddy field while rice husk is generated in great amount in the rice mill. Straw was utilized to produce biomass energy in China through direct combustion, anaerobic digestion and gasification. Utilization of crop straw via direct combustion was inefficient and at the same time has led to many ecological and environmental problems. However, with anaerobic digestion, the energy output in biogas contains the heat value of $2.5x10^4$ kJ m^{-3}, which is also equivalent to 0.76kg of standard coal. The amount of household biogas digesters has reached 7.64 million by the end of 2000 (Zheng et al., 2007). In gasification process, biogas produced using air and steam/air as gasifying agent was of low calorific value (CV) with an essential component of carbon monoxide (McKendry, 2002). Utilizing oxygen and steam as gasifying agent produces biogas with medium CV and the main elements are CH_4 and H_2 which can also be employed as fuels. Biogas with high CV can be produced via using hydrogen and hydrogenation as gasifying agent (Zheng et al., 2007).

The common practice in Malaysia was to send to landfill or open burning. However, lately, two rice mills in northern Malaysia have started to practice the usage of their residues to generate electricity (Shafie et al., 2012). Both of these mills were able to use up to 86,400t per year in generating power (700-1500kW). Cogeneration program of rice husk was initiated by European Commission (EC) and Association of South East Asian Nation (ASEAN). With the implementation of this program in rice mills, issues on rice husk management was solved and it has also provided the extra benefit of selling off the ash which can be used as construction materials (Karim Ghani et al., 2008) and electricity generated (Shafie et al., 2012).

Pineapple waste is also another main commodity in Malaysia as it is one of the oldest agro-based export-oriented industry dating back to the 19th century. Almost all of the pineapple waste is not utilized and the only mean of disposal is burning. Only 20% of the pineapple is processed into can food for consumption usage (Rosma & Ooi, 2006) and the residues (as much as 30-50% of total fruit weight) including the skin, core, base and crown are all directly disposed as waste during the canning process (Ong et al., 2014).

Potential of durian waste as raw material for second generation bioethanol production relies on its production and amount of waste generated. Considering that the durian production in Malaysia is showing an upward trend, tremendous amount of durian waste is foreseen to be left un-used. Amount of waste from durian seed and rind was reported to be 87,555.3 and 171,303.9 tonnes respectively in year the 2013 (Aditiya et al., 2015; Amid & Mirhosseini, 2012). If the potential of utilizing these wastes for energy production is made viable, significant improvement in waste management for sustainable environment, as well as renewable energy production are expected.

CURRENT ENERGY POLICY SCENARIO IN MALAYSIA

In Eighth Malaysia Plan, biomass, biogas, municipal waste, solar and mini-hydro were highlighted as valuable renewable resources and further promoted in Ninth Malaysian Plan (2005-2010) which has also underlined the focus on promoting the export of palm biodiesel (Abdul-Manan et al., 2014). We are in the era which is facing a pressing concern towards moving from heavily relying on fossil fuels to opening up new avenues for bio-based material. First Malaysia natural biofuel policy (NBP) was developed in

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Table 1. Energy potential of various agricultural biomass components in Malaysia

Biomass component	Calorific value (kJ/kg)	Potential energy generated (Mt)	References
Palm Empty fruit brunches (EFB)	18,838	7.65	Shuit et al., 2009
Palm Fiber	19,068	4.37	UNDP, 2007
Palm Shell	20,108	2.84	Sasaki et al., 2009
Palm Kernel	18,900	0.95	Asureira, 2002; Sumathi et al., 2008
Rice husk	15,324	0.17	Pütün et al., 2004; Aditya et al., 2015
Rice straw	13,620	0.28	Krishna & Babu, 1998

2006 and championed by the Ministry of Plantation Industries and Commodities Malaysia (MPIC). The Malaysia NBP anticipates the use of environmental friendly approach and sustainable resources derived energy to lessen the dependency of drastically depleting fossil fuels (Abdul-Maman et al., 2015). In 2009, National Renewable Energy Policy was introduced for rectifying the failure of attaining the target of 5% renewable energy in the energy mix. This policy also highlighted the applications of indigenous renewable energy resources through increased contributions of renewable energy for national power generation mix (KeTTHA, 2010). In 2005, National Biotechnology Policy was drafted in Malaysia with the aim of transforming Malaysian economy into a high-income, inclusive and sustainable one. This then lead to the launching of its very own bioeconomy program known as Bioeconomy Transformation Program (BTP) in year 2012. It works as a platform provided by government for private sector to maximize commercial opportunities. It is also designed specifically to benefit Malaysian society through cultivating commercialization of bio-based products from the industry (Bioeconomy Malaysia, 2014; Albrecht & Ettling, 2014).

With the abundance of agriculture residue, agricultural waste derived biofuel is the most promising form of renewable energy.

POPULATION INCREASE AND WASTE GENERATION SCENARIO IN MALAYSIA AND ASIA REGION

Increase in population used to be the key to economic growth and development. However, today, overpopulation has become a major problem especially in developed countries. Waste is typically population attributed. Depletion of resources and environmental destruction that come along with population growth are inevitable.

In West Asian countries; Nepal, Pakistan, India and Bangladesh the current and projected waste generation rates range from 0.12 -0.84 kg capita^{-1} day^{-1} in 2012 to 0.70 – 1.05 kg capita^{-1} day^{-1} in 2025. This is much lower as compared to East Asian countries; Thailand, Vietnam, Malaysia and Philippines as illustrated in Figure 2. China also contributes 1.02 kg capita^{-1} day^{-1} (2012) to an estimated 1.70 kg capita^{-1} day^{-1} in 2025. Malaysia is the second largest waste producers of the region (1.52 kg capita^{-1} day^{-1}) and is expected to increase by 20% in 2025. The expected increase in population in Malaysia (33.2 million) coupled with the increased pace of urbanization, would lead to large quantities of solid waste

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

generated by 2025. It is obvious that, in near future, increase in waste generation is directly linked with the increase in populatio. Despite the effort in continuous research and development in waste derived energy, waste generation is still higher than the amount of waste that is being utilized.

With urbanization that is actively going on in all countries around the world, land scarcity is undoubtedly a fact. Land filling will soon become not viable despite its operation cost may still be lower if compared to other methods. Researchers worldwide are proactively looking for possible alternatives. Besides researching for alternatives, to face this issue, education and awareness campaigns have to play their roles with the intention of better handling the waste management crisis.

Figure 2. Current and projected waste generation rates (kg capita^{-1} day^{-1}) of selected countries
*Source: Hoornweg and Bhada-Tada (2012) *Projected value of year 2025.*

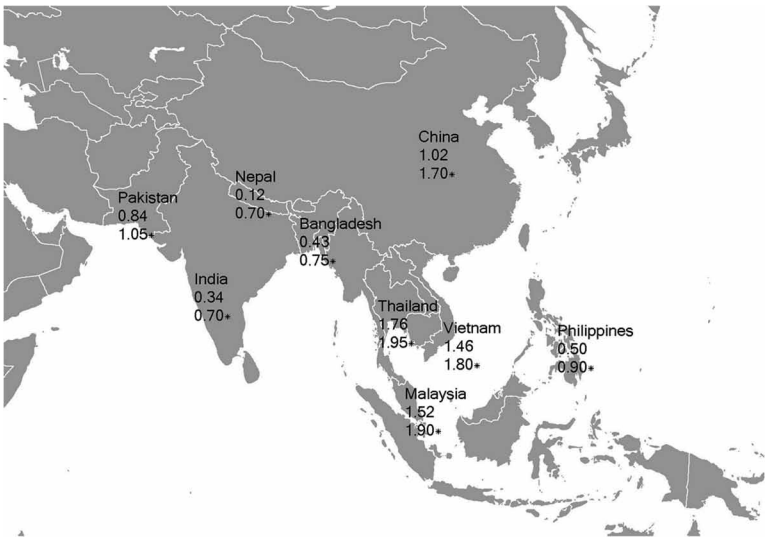

Table 2. Overview of urban population, waste generation and total energy use of selected countries in South East Asia

Current available data						2025	
Country	**Income level**	**Total urban population (thousand)**	**Population aged 10-24 in year 2014 (million) (UNFPA, 2014)**	**MSW per capita (kg capita^{-1} day^{-1})**	**Total energy use (kt of oil equivalent) (2011) (UN, 2015)**	**Projected urban population 2025 (thousand)**	**MSW per capita (kg capita^{-1} day^{-1})**
Malaysia	UMI	14,429	8.4	1.52	75,907	27,187	1.9
Thailand	LMI	22,453	13.5	1.76	119,147	29,063	1.95
Indonesia	LMI	117,456	66.1	0.52	209,009	178,731	0.85
Singapore	HIC	4,849	1.1	1.49	33,447	5,104	1.8
Vietnam	LI	24,001	23	1.46	61,210	40,505	1.8

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Malaysia is classified as upper middle income (UMI) country by World Bank (2012) with the total urban population of 14 million and waste generation (MSW) of 1.52 kg capita^{-1} day^{-1}. It is projected that by 2025, the MSW generated will increase to 1.9 kg capita^{-1} day^{-1} as shown in Table 2. If we are to look at total energy use, Malaysia, which has lower urban population compared to Vietnam, has higher energy consumption than Vietnam (United Nations, 2015). Hiking in waste generation per capita is also raising concern as Malaysia is showing ascending trend in both population and waste generation. Urban population in some countries in South East Asia (Malaysia, Thailand, Indonesia, Singapore and Vietnam) all indicate increment in year 2025 as projected by World Bank (2012).

In Tenth Malaysia Plan (2011-2015), the urgency of increasing public awareness and commitment for green technology application and adoption was highlighted as one of the key emphasis. Other than that, new mechanisms on renewable energy are also one of the areas of interest (Foo, 2015).

Commercial viability of renewable energy technologies especially the applicability of waste derived energy is receiving poor perception and awareness. This is also clearly reflected by limited numbers of research and development in both industrial and institutional research in Malaysia. In consequence, these possess significant drawbacks in government's effort in promoting renewable energy (Oh et al., 2010)

RECOMMENDATIONS

Increasing population, booming economy, urbanization and improvement in living standards have all contributed to solid waste generation (Guerrero et al., 2013). Many researchers have studied and looked into issues regarding overpopulation. However, the direct linkage between waste production and worldwide population growth is not commonly reviewed. With our current technology, waste symbolized misallocated resources. Waste management hierarchy (Figure 3) introduced by EPA has included management strategies and arranged according to environmental preference (US EPA, 2016). Reduction and reuse approaches are preferred over others. Treatment and disposal are the least favoured options. Local communities should have a role in carrying out reduction, reusing waste as well as recycling as they are the first tier in waste management. This will also allow public to be aware of their waste generation, including types of waste and amount of waste they generated. Rather than promoting waste reduction and recycling at community level, various schemes have been introduced by NGOs as well as industries to further strengthen the effort in a larger scale.

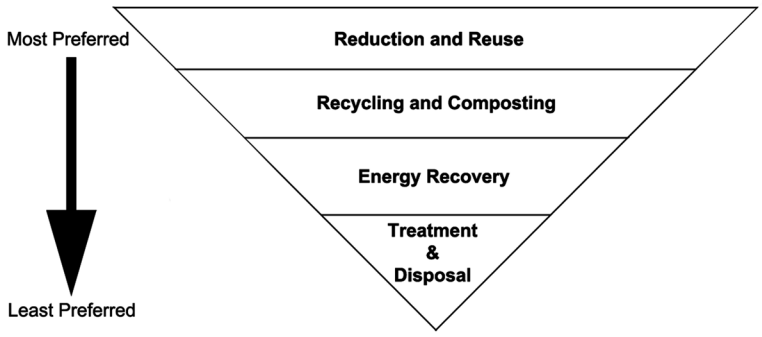
Youth Empowerment

Efforts in educating youth in sustainable waste management is utmost important as they are the group of population that are educated, and are more willing to accept the idea of sustainable approaches in waste management for better environment.

We are homing close to 1.8 billion of young people between ages of 10-24 and this group of population is the fastest growing of all (UNFPA, 2014). As part of the household, youth too contribute to waste problem. Youth are better equipped to reach their full potential when they are healthy and educated. Sadly, youth is also falls under the most vulnerable group towards the ill effects of improper waste management. Therefore, educating youth will definitely increase the practice of environment friendly approaches. Despite the advancement in technology that have granted us waste management technology such as landfill and waste to energy approach, the conventional 3R (Reduce, Reuse and Recycle)

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 3. Waste management hierarchy
Modified from US EPA (2016)



is still the cornerstone of lots of waste disposal problem. Imagine this scenario, if majority of youth practise 3Rs and promote in their localities, we are indirectly having a green army that may turn the tide of environmental degradation. In Kenya, waste collection and a number of other public services was initiated by the Government in 2009. The Kazi Kwa Vijana (Work for Youth) programme was aimed at employing both urban and rural youth. We should not neglect youth in the battle against environmental degradation as a matter of fact, they are our strongest human force that are able to achieve the most.

Make a Difference Through Public Awareness

Environmental awareness allows us to better understand how delicate our environment is. Waste segregation, recycling programs and repurposing waste products and by-products may sound low-tech. However, these are the effort that may really bring drastic impact to our environment particularly in the long run.

Malaysia has recently introduced federal waste segregation programme based on the Solid Waste and Public Cleansing Management Act 2007 (Act 672) that was first approved by the Malaysian Parliament on July 17, 2007, and gazetted on Aug 30, 2007. Selected states and federal territories (Kuala Lumpur, Putrajaya, Pahang, Johor, Malacca, Negeri Sembilan, Perlis and Kedah) are involved in this new waste segregation program. However, if the waste segregation set up can be further developed, more waste, especially electronic waste can also be effectively segregated.

Various NGOs and companies have recently joined the forces of promoting the importance of recycling. The Emirates Environmental Group (EEG) has launched many community projects over the years especially waste collection campaign (neighbourhood recycling campaign) that reaches out to everyone categorised as households, schools, small organisations, hotels and factories. Certificates are given based on the largest collector in the different categories all over the UAE (green awards). Tax rebate from government is also given to encourage more participation (EEG, 2015).

Other than the conventional recyclable materials such as PET bottles, glass, aluminium can and papers, due to the ever growing fashion industry, several major clothing companies have started clothes recycling campaign. Fast-fashion, the clothing equivalent of fast food, has created sharp rise in amount of waste. The fast fashion's rapid-response production system which strongly relies on low-wage production in some of the poorest countries on earth has in a way, fueled the throwaway culture as the clothing is cheap (Ringstrom, 2015). A recent survey has revealed that most of the women's garments are worn only for seven times before being left out or tossed into the garbage (Cline, 2016).

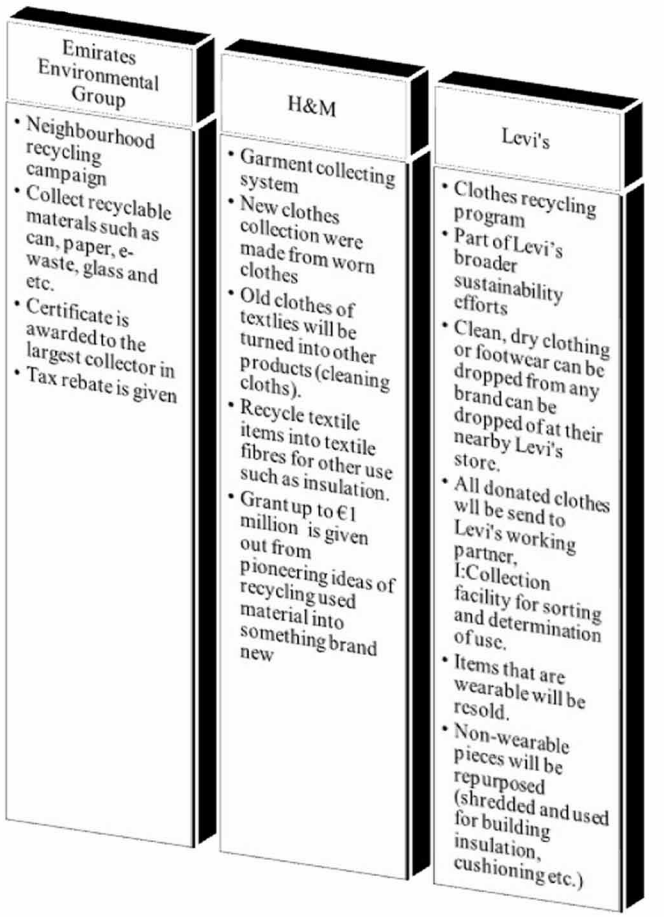
EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Studies revealed that an estimated 21% of annual clothing purchases stay in the home. This represents a potentially abundant of unseen waste that will gradually enter our solid waste stream. Meanwhile, according to the EPA office of Solid Waste, more than 68 pounds of clothing and textile per year per person are thrown away. Clothing and other textiles represent about 4% of the municipal solid waste and its showing rising trend (Claudio, 2007).

Sadly, recycling cotton clothes is not easy. Old cotton clothes will need to be chopped up and turned back into raw material which tends to lower the cotton's quality. However, several fashion industry tycoons have started several approaches on recycling clothing. Some efforts by NGOs and corporate are shown in the Figure 4.

Combining population as an asset and public awareness, improving waste management in all levels is not difficult. The potential of wastes generated should be fully utilized. Policy maker should learn from successful stories of other country and come up with proper plans and campaigns that are appropriate for their people. Increase in waste generation is a global problem, everyone is responsible. Through cooperation, everything can be made possible.

Figure 4. Examples of recycling program from non-government organisation and clothing companies



EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

CONCLUSION

With the progression of technology, life expectancy is now longer than previous. Increase in population is indeed a foreseen issue. It has become unavoidable for all countries in the world especially developing countries. The word population is always linked with environmental issues as waste is generally population attributed. Many countries such as Malaysia have the advantage of well-developed agriculture industry which generates high amount of agricultural waste that contains potential in generating energy through different technologies. With regard to environmental benefits, utilization of waste for energy generation is undoubtedly a good alternative in handling vast number of agricultural waste that exhibit promising energy potential. Despite the evidence that the waste derived energy may not be able to compete with the performance of fossil fuels, waste derived energy still deserve attention as the potential is massive. Technology advancement may be solving a lot of problems for us these days, however, please bear in mind that other efforts such as the 3R approaches and repurposing waste are playing a vital role too as they are the most direct method in addressing waste management problem that everyone can be involved in. After all, government policy, together with cooperation of public and other organization are utmost vital in effectively handling such issues. No single management approach is suitable in managing all types of waste. However, waste reducing and reuse are still the most effective ways of tackling the problem of increasing waste generation. Youth, as the most promising group with highest potential, should be encouraged in participating waste recycling and reusing program. By educating them, we shall have a group of people who are highly aware of the current environmental problems, and understand the effort they can provide in targeting these problems. Segregating waste for reduction in sending off waste to landfill, recycling the recyclable materials and composting biomass should be introduced into daily waste handling approach. Public should be aware of the current waste generation scenario in order to realize the hazard it brings.

Chapter 59
Leachate Pollution and Impact to Environment

Oluwakemi Kehinde Fagbenro
Ladoke Akintola University of Technology, Nigeria

ABSTRACT

Pollution prevention is a step towards obtaining a green environment, and no amount of effort in that direction should be considered too great. To this effect, the pollution by leachate and the resultant impact on the environment is discussed in this chapter. Types and sources of pollution, their transfer and effect have been discussed, so as to give a background understanding on pollution and hence provide a platform for its control. The age old waste disposal practice of open dumps and landfilling is discussed, highlighting the dangers of indiscriminate waste dumping and uncontrolled landfilling practices. Although other sources of leachate generation are highlighted, the chapter focuses on leachates from municipal landfills and the effect of its migration. Engineered landfills also known as sanitary landfills have performed better in curtailing the movement of leachates, hence the use of artificial liners or low permeability soils such as the well compacted clayey soils, to eliminate or minimize leachate migration.

INTRODUCTION

Generation and disposal of waste is considered absolutely normal and a part of everyday living, but the crux of the matter is the means by which the waste should be disposed safely to avoid pollution and ensure a healthy environment.

Open dumping of waste on land or in water bodies has been practiced from ancient times, but it is imperative that continuous awareness be made of the pollution effect, especially because some of the polluted water served various purposes including household uses and irrigation among others. Also, the indiscriminate dumping of waste on the ground constitute an eye sore and produces stenches which was offensive to human senses.

Because of the aforementioned reasons, landfills are now more commonly used, in which wastes are buried in the ground. Unfortunately however, many so called landfills in the less civilized nations may just be regarded as 'glorified open dumps'. Landfills must be controlled to remove the demerits of uncontrolled landfills, especially regarding the generation of wastewater called leachates, bad odors and related problems that may lead to the pollution of the environment.

THE ENVIRONMENT AND SUSTAINABILITY

The environment may be considered in two primary forms; the natural and built environments. While the natural environment includes all the living and non-living things on the earth, existing in their natural state, the built environment is essentially a modified form of the natural environment. This may occur even from very simple and unbiased agricultural practices, construction exercises and mining, intended for human benefits. Therefore, it can be inferred that a natural environment hardly exists. Although, the building up of an environment may be with a noble intention, however, many of such practices may also lead to the pollution of the environment.

Environmental pollution is considered largely related to industrial revolution and urbanization (Xu, et al., 2014) with the emergence of many great factories; unprecedented air pollution and the discharges of very large volumes of industrial chemical waste.

Considering the plausible exposure of the built environment to contamination and degradation, all hands must be on deck towards achieving a sustainable environment. In essence, it should be possible to develop the environment for desired benefits without destroying the environment or negatively altering the natural state of the environment.

There are many types of pollution coming from various sources and of various consequences. A basic understanding of pollution would provide the awareness necessary to help individuals in the minimization of their contributions to the dangers of environmental pollution. Various pollution types and sources which may impact both the natural environment and human health negatively are discussed. However, the focus of this chapter is the effect of leachate pollution on soil, surface and ground waters, especially those located within the immediate environment of the site.

POLLUTION

Pollution is considered as the introduction of contaminants also called pollutants into any natural system thereby causing an adverse effect on the latter. In like manner, environmental pollution is the deterioration of the environment by the introduction of many factors occurring in forms such as chemical substances, and or energy sources including noise, heat, and light. The major forms of pollution and their specific contaminants are highlighted in Table 1.

Air Pollution

Air Pollution involves the contamination of the atmosphere by altering air chemistry and composition. Contaminants exist in the form of particulate matter like the dust, excess gases such as carbon dioxide (CO_2) and vapors that are not efficiently removed by natural cycles like the nitrogen cycle or carbon cycle.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Table 1. Major forms of pollution, causes and their contaminants

Forms of Pollution	Causes	Contaminants
Air pollution	Release of chemicals and particulates into the atmosphere	carbon monoxide
Noise pollution	Excess noise or unpleasant sound causing temporary imbalance in nature	Aircraft, industrial, roadway, and high intensity sonar
Soil pollution	Release of chemicals due to spills or underground leakage	Hydrocarbons, heavy metals, MTBE, herbicides, pesticides
Thermal pollution	Human influence resulting in temperature change in water bodies	Use of water coolant in power plant & hot waste water discharges
Water Pollution	Discharges of waste water from commercial & industrial waste (including spills)	Chemical contaminants from industrial & domestic sewage

Although many sources of air pollution exist, the most abundant of them include the following:

A. Exhausts from vehicles and manufacturing processes (Bauer, et al., 2015; Reşitoğlu, et al., 2015; Zhang & Chen, 2015).
B. Natural sources such as volcanic eruptions, dry soil erosion and especially forest fires (Corlett, 2014; Rapport, et al., 1985).
C. Building and demolition of structures (Gadeke, et al., 2014; Gladstone & Martin, 2014).

The effect of air pollution is dependent on the type of pollutant and the extent of exposure. Common effects include increased smog, rain acidity, crop depletion due to insufficient oxygen and higher rates of asthma occurrence (Delfino, et al., 2014). They could also include Lung cancer, cardiopulmonary mortality (Kim, et al., 2015). Recently also, scientists have considered global warming as being related to an increased air pollution. And an investigation on how pollutants could affect mortality showed that the main pathway could be that fine particles can lead to systemic inflammatory and oxidative response (Beelen, et al., 2014).

Water Pollution

Water is deemed one of the most important resources and is very essential to life. 70% of the earth's surface is covered by water. Its pollution involves contamination by particulate matter, chemicals, and bacteria matter that deteriorate the purity of water and its other qualities.

The spread of water pollution is possible because the different sources of water (e.g. rivers, lakes, oceans and underground reservoir) flow together and a possible pollution of any of the sources may eventually spread during their flow.

Possible causes of water pollution include the following:

A. Sedimentation due to soil erosion (Alexandridis, et al., 2015; Carkovic, et al., 2015; Rickson, 2014; Ryken, et al., 2015)
B. Inappropriate disposal of waste (Flanagan, 2015; Mahmood & Malik, 2014; Mudhoo, et al., 2015; Yang, 2015)

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

C. Leaching of soil pollution (Dudar, et al., 2015; Minhas & Yadav, 2015; Nassar, 2015).
D. Decayed organic matter in and related to agricultural activities (Li, et al., 2014; Wesström, et al., 2014).

Water pollution has far reaching effects which includes the following:

A. It diminishes the quantity and availability of potable water.
B. It lowers the supply of water required for agricultural purposes such as crop irrigation, fish farming, wildlife, etc.

Land Pollution

Land pollution also referred to as soil pollution involves the contamination of the soil from habitation, land cultivation or wildlife and game reserves. Land use pattern such as mining and agriculture may also be sources of exposure to soil or land pollution (Xu, et al., 2014).

Land pollution generally inhibits the natural growth and creates an imbalance in the land structure. Pollution can be deliberate such as landfills, or they may be unintentional, in which case they are more able to spread widely and their effects are also far reaching.

Pollution sources that may not be peculiar to only the land include the following:

A. Spills from sewers and hazardous waste (Ali, et al., 2015; Gavrilescu, et al., 2015).
B. Occasional use of inorganic pesticides and other temporary farming practices (Boison & Turnipseed, 2015; Donati, 2015; Gomiero, 2015; Teló, et al., 2015).
C. Destructive land practices such as strip mining and deforestation (Ncube-Phiri, et al., 2015; Ravi & Priyadarsanan, 2015).
D. Dumps and litters from the households (George, 2015; Musingafi, et al., 2015; Wachirawongsakorn, 2015).

The effects of land pollution include the following:

A. Deficient growth and lower crop yields.
B. Depletion of wildlife.
C. Possibility of water pollution.
D. Visual pollution.
E. Soil erosion and desertification.

Noise Pollution

Noise pollution refers to any undesirable level of sounds resulting from human activities that may interrupt the normal living standards. Urban noise pollution is considered to be associated with urban development (Bhave & Shaikh, 2014).

Sources of noise pollution include the following:

A. Manufacturing mills (Chakraborty, et al., 2014; Noweir, et al., 2014).

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

B. Construction and demolition exercises (Arthur-Aidoo, et al., 2014; Emmanuel, et al., 2014).
C. Traffic (Abbaspour, et al., 2015; Al-Mutairi & Al-Rukaibi, 2014).
D. Aircrafts (Ozkurt, et al., 2014).
E. Moving Trains (Kirillov, et al., 2014; Monazzam, et al., 2014).
F. Entertainment activities including cinemas and parties(Archibald, 2014; Sari, et al., 2014)

Noise pollution may be either of temporary or permanent sources. Effects of noise pollution include the following:

A. Impairment of hearing (Hammer, et al., 2014).
B. Interferences with wildlife existence.
C. A general degeneration of lifestyles and standards.

Radioactive Pollution

Although exceedingly hazardous, radioactive pollution is a highly uncommon type of pollution. However, very strict environmental regulations have been instituted by the government as a control and preventive measure to avoid the dangers of its occurrence. Although rare, there are yet occurrences of natural radioactivity (Krishnamoorthy, et al., 2014).

Sources of radioactive pollution include:

A. Accidental leakages from nuclear power plants.
B. Improper disposal of nuclear water.
C. Mining operations for radioactive substances like Uranium.
D. Radionuclides from rock phosphates used in industrial manufacture of fertilizers (Ajmal, et al, 2014).

The Effects of radioactive pollution include the following:

A. Possible birth defects.
B. Soil sterilization which may result in both air and water pollution.
C. Cancers and other related issues in both the wildlife and in humans.

Thermal Pollution

This is mostly a result of excessive heat which generates unpleasant consequences over a long period of time but having long term effects. Thermal pollution may be a frequent occurrence because of the earths' natural thermal cycles which regulate the atmospheric temperatures. Thermal pollution is often times confined to the immediate areas of pollution but may have a wider effect over a large geographic area.

Sources of thermal pollution include the following:

A. Power plants and refineries (Hanna & Oliva, 2014).
B. Particulates trapping heat.
C. Urban sprawl.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

D. Deforestation.
E. Temperature loss in moderating water supplies.

Possible effects of thermal pollution from increases in temperature include the following:

A. Mild climatic changes.
B. Swift changes may affect the wildlife.

Light Pollution

Any over illumination that obstruct visibility is considered to be a light pollution. Excessive artificial lighting may be a source of light pollution that degrades the environment (Gaston, et al., 2014; Pun, et al., 2014).

Sources of light pollution include:

A. Lighting from large cities (Pun, et al., 2014).
B. Advertisements and billboards (Pun, et al., 2014).
C. Cinemas, sports and other night time activities.

Effects of light pollution:

A. Light pollution may render the stars to be near invisible which may interfere with astronomical observations.
B. Light pollution around residential areas may affect the quality of life for residents.

Visual Pollution

These are primarily the things which constitute an eyesore. They are unappealing and also wanted. The sources of visual pollution include the following:

A. Billboards and advertisement.
B. Power lines.
C. Construction sites.
D. Polluted and neglected land area.

Although visual pollution has a fewer environmental and immediate health effects, the pollutants may have detrimental effects such as;

A. They may reduce the value of properties.
B. They may affect personal senses.
C. To lower the quality of life in affected areas.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Personal/Private Pollution

This pollution may not be easily felt or identified as it affects the individual body and lifestyles. The pollution of this sort may be caused by voluntary or involuntary actions such as:

A. Abuse of alcohol, drugs and smoking habits.
B. Physical and emotional abuse.
C. A poor habit and living conditions.
D. Poor personal attitudes.

It is worth noting that there is a connection of a chain type between all the types of pollution e.g. the electric plants have to burn more fossil fuels to generate the energy needed before light and the resulting pollution. Pollution from fossil fuel in air pollution may also be washed down to the earth as acid rain to increase water pollution. The pollution cycle may be indefinite; hence very deliberate efforts must be made at the management.

SOLID WASTES, OPEN DUMPS, AND LANDFILLS

Literally, solid waste may refer to any discarded solid materially. But technically, it encompasses the refuse, garbage or sludge resulting from any water and wastewater treatment or pollution control. They include any disposed solid, liquid or semi-solid material that may also contain gases. Essentially, solid waste may thus consist of solid, liquid and gaseous substances. The classification of solid waste based on the source of generation includes municipal, agricultural, industrial, construction and demolition, etc. For treatment purposes and to make sorting prior treatment to be easier, disposed wastes are categorized as listed in Table 2. But the percentage composition of each category differs from households to communities. Also, an attempt has been made by Omari, et.al. (Omari, et al., 2014) to distinguish the percentage composition of each category by nations and re-categorizing by the standard of living of the various nations as low, medium and high income.

Table 2. Classification solid wastes

The most common method of solid waste management include; prevention, minimization, re-use and re-cycle, energy recovery and landfill disposal, (UNDP, 2008). The open dumps were of course the earliest.

Open Dumps

Open dumping of waste has been in practice since ages past and is still very common in undeveloped and developing nations(Jayaweera & Bandara, 2014), but the attendant risk of pollution has necessitated the use of safer waste disposal techniques to avoid pollution and ensure a healthy environment. Figure 1 shows an open dump site.

Open, unmanaged and or uncontrolled waste dumps may have the following resultant effects:

A. Produce liquid waste (leachate) and gaseous emissions (landfill gas) that are potential environmental pollutants.
B. Disposal sites may become a breeding ground for many disease-bearing pests and micro-organisms.

Landfills

Landfills are considered the oldest form of treating waste in a method of disposal by burying in designated sites, (Singh & Ramanathan, 2010). Although not properly covered, Figure 2 shows a landfill site. Sanitary landfills are sites for the isolation and disposal of waste, either by burying underground or in large piles to be monitored very closely to prevent environmental pollution as much as possible.

It is very important that a landfill be managed properly, otherwise it may pose serious environmental hazard through the discharge of polluted wastewater as leachate and air pollution from stenches and release of poisonous and flammable gases. In view of these, advances in landfills have included the construction, operation and strict technical supervision to minimize environmental effects thereof.

Figure 1. An open dump site

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Figure 2. Landfill site in Matang, Taiping, Perak, Malaysia

Sanitary landfilling thus provides the means of a controlled waste disposal on land, hence, a properly managed sanitary landfill provides a control for the exposure of the environment and human to the harmful effects of waste dumps and landfills.

Sanitary landfill has been considered suitable for solid waste disposal in developing nations, because of their relative simplicity, flexibly of operation and relative cost effectiveness. It may be practical for industrialized nations to meet all the conditions of a sanitary landfill while it may be technologically and economically impractical for several developing nations. However, all possible efforts must be made to meet the most important criteria within the available set of technical and financial situations.

Although almost all waste can be disposed via landfill, the European Union, EU landfill sites must now be categorized as either; hazardous non-hazardous and or inert. Wastes are therefore checked and weighed to ensure compliance with landfilling operation permit. Minimal sorting may be of assistance where necessary. The waste is tipped into the landfill, compacted and covered to prevent littering, odor and pest infestations while the waste is gradually decomposed by microbes. Water infiltration, biological degradation of organic matter present in the waste, movement of dissolved or suspended material within the waste dump are to mention a few intricacies.

Although the sanitary landfill is more environmental friendly, the Southeast Asian countries and many less developed nations use more of the open landfills because of the inability to cope with the high volumes of waste generated and disposed each day (Ngoc & Schnitzer, 2009). Landfills may be classified on the basis of structure as highlighted in Table 3.

Stages of Solid Waste Decomposition

Solid waste decomposition that generates leachate within a landfill involves a series of complex physical, chemical and biological reactions which begins right after placement of waste and continue through the entire lifespan of the landfill. The rate of decomposition is dependent on the physical, chemical and microbiological conditions developed within the fill over the time considered (Andreottola & Cannas, 1992; Barlaz, 2006), as shown in Table 4. Landfill decomposition is divided into five phases as itemized in Table 5. The rate and characteristics of leachate produced from a landfill vary from one phase to another, and reflect the microbial mediated processes taking place inside the landfill.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Table 3. Categorization of landfill sites

S/No.	Category of landfill	Method of waste decomposition
i	Aerobic	Have leachate collection pipes and air flow pipes to make more aerobic than the semi-aerobic.
ii	Semi-aerobic	Have bigger leachate collection pipes than the improved sanitary. It has lower moisture content and air flow ducts are provided.
iii	Anaerobic	Wastes are tipped in excavated sites or valleys. Under anaerobic conditions, wastes are filled with water to decompose.
iv	Anaerobic sanitary	Wastes are sandwiched between soils.
v	Improved anaerobic sanitary	Similar to anaerobic except for the bottom laid leachate collection system and a lesser moisture content than the aerobic.

Source: Environmental Pollution Control Centre, Osaka Prefecture, 2009.

Table 4. Methods solid waste decomposition

Method	Process	Characteristics	Reference
Physical	Segregation, mechanical size and volume reduction	It excludes phase changes.	(Demirbas, 2011; Laner, Crest, Scharff, Morris, & Barlaz, 2012; Liu, Xu, Li, & Xu, 2011; Poznyak, Bautista, Chaírez, Córdova, & Ríos, 2008; Sarkar, Ghosh, Bannerjee, & Aikat, 2012)
Chemical	Include; combustion, pyrolysis and gasification	It involves phase changes of waste with a reduction in volume.	
Biological	Include; aerobic and anaerobic degradation	Phase changes, reduced BOD, increased pH.	

Table 5. Stages of landfill decomposition

Stage	Decomposition type	Characteristics	Reference
I	Initial adjustment	Involves the initial placement of waste and the buildup of moisture within the landfills.	(Ermolaev, 2015; He & Shen, 2006; Liao, Yang, Shen, & Long, 2013; Niemietz, 2008; A. Zaman, 2012; A. U. Zaman, 2010)
Ii	Transition	Increase in leachate generation, with measurable concentrations of chemical oxygen demand (COD) and intermediates such as volatile fatty acids (VFA).	
iii	Acidification	Continuous hydrolysis and fermentation of waste decrease in pH with dominant VFA.	
Iv	Methane fermentation	Decreased organic strength while the intermediate acids utilized by methane-forming consortia (methanogen bacteria) and converted into methane and carbon dioxide. Leachate pH is elevated to the level of biocarbonate buffering system.	
v	Maturation	Low concentrations of leachate

LANDFILLING AND LEACHATE

Leachate

Leachate refers to water or liquid flowing either vertically or laterally through the soil, landfill, etc. while collecting soluble and suspended materials along. It is the water and other soluble materials that have drained out of a deposit or tipped material. Figure 3 shows the leachate from a landfill site.

Leachate is generated during the decomposition of waste and drained or leached from land or any stockpiled organic waste material. Its composition is largely affected by the age of fill and type of waste. The liquid consists of both suspended and dissolved material. A breakdown of carbonaceous materials produces additional water and several other materials such as:

A. Methane gas.
B. Carbon dioxide.
C. Complex organic acids.
D. Aldehydes.
E. Alcohols.
F. Simple sugars.

Important factors influencing leachate generation are:

A. The rainfall, washing down the waste at dump sites.
B. Liquid wastewater produced from the breakdown of waste.

Figure 3. Landfill Leachate in a concrete tank

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

There is no standard or consistent chemical and microbiological composition of any landfill leachate and the factors influencing leachate composition include the following:

A. Physical composition of dumped wastes.
B. Environmental conditions.
C. Landfill operational management.
D. Waste decomposition dynamics.

Leachates can be classified on the basis of waste degradation as:

A. Acetogenic leachates are also referred to as young leachates. They are leachates from a young landfill. These are characterized by a high COD, BOD, and BOD/COD.
B. Methanogenic leachates are also referred to as old leachate derived from the older landfill. They are more extensively degraded than the acetogenic leachates and are characterized by lower COD, BOD and BOD/COD.

Leachate Pollution Problem

On the basis of the above definition and understanding, leachate may be from various sources such as farming areas, feedlots, cemeteries (Spongberg & Becks, 2000; Zychowski & Bryndal, 2014) and landfills. The most common is the leachate from the landfill (see Figure 3) which is the focus of this chapter. Potential leachate Pollution from beneath and around the landfill site is also considered. The indiscriminate dumping of refuse or dumping in uncontrolled landfills may adversely affect both human health and the environment (Kumar & Alappat, 2005; Lo, 1996). Landfill leachate is characteristically concentrated, variable in quantity and quality hence difficult to treat (Milke, 1995). A variety of pollutants contained in landfill leachate are potential contaminants that are able to affect the quality of both ground and surface waters (Christensen, et.al., 1994).

Also, methane gas released during the breakdown and decomposition of waste may be dangerous if it is allowed to build up. Landfill sites and the leachate produced are odorous with the potential to pollute the air. Associated problems include the following:

A. Odors from landfill sites.
B. Offensive and unsightly sites.
C. Possible air pollution from methane gas released during the breakdown and decomposition of waste.
D. Methane gas is flammable, hence the danger of explosion if it builds up in the landfill.
E. Possible water pollution in the event of a punctured landfill lining or a break or leak of the leachate which could migrate from the landfill to contaminate the surrounding soil and exposed water systems.
F. The problem of finding an appropriate site for the location of sanitary landfills as most people would not agree to have a site too close to their properties for obvious reasons. Landfills are therefore remotely located from the public.
G. Difficulties with transporting waste to landfill sites.
H. The need for many landfills because decomposition is slow and potentially incomplete due to their designs.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

I. Fear of a possible ground instability due to soil shifts during waste decomposition.

Characteristics of Landfill Leachate

Leachate characterization is an important factor to establish an effective management strategy for a Landfill (El-Fadel, et al., 2002). Landfill leachate characteristics may be grouped into four types of pollutant (Greenman, et al., 2009; Huang, et al., 2009; Modin, Persson, et al., 2011), namely:

A. Dissolved organic matter.
B. Inorganic macro-components.
C. Heavy metals.
D. Xenobiotic organic compounds.

Further characterization includes the following;

A. Dark colored
B. Odors
C. High organic and inorganic load.
D. High dissolved organic matter, including volatile fatty acid; refractory organic matter, humic substances .
E. Macro inorganics compounds (Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}, NH^{4+}, Fe^{2+})
F. Heavy metals (Cd^{2+}, Cr^{3+}, Cu^{2+})
G. Microorganisms from total and thermo tolerant coliform
H. High biochemical oxygen demand (BOD) (4,000-13,000mg/L)
I. High chemical oxygen demand (COD) (30,000-60,000mg/L)
J. High strength ammonium nitrogen (500-2000mg/L)
K. High BOD/COD (0.4-0.7)
L. pH of 4-8.5

Landfilling Processes Producing Leachate

Processes by which leachates are generated in a landfill are in three categories, namely;

1. **Physical Processes:** The physical processes involved in landfilling include:
    a. **Compaction and Settlement:** This is the compression of waste to obtain a reduction in size by the use of a compacting machinery and the efforts from the wastes and soil cover (burden). The settling so achieved is also partly from the loss of mass due to biological and chemical decomposition.
    b. **Dissolution and Transport:** The physical reaction of dissolution is greatly affected by the quantity of water entering the fill. Also, as water acts as the medium of dissolution of soluble material, it also serves as the medium for the transportation of both dissolved and un-decomposed materials.
    c. **Adsorption and Absorption:** These are both physical processes in a fill for the immobilization of living, non-living and dissolved pollutants.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

2. **Chemical Processes:** Oxidation and typical acid-metal reactions such as organic acids and dissolved carbon dioxide (CO_2) produced in the biological processes.
3. **Biological Processes:** The importance of biological reactions cannot be overemphasized. Its' most importance is in the following;
    a. It stabilizes the organic fractions.
    b. It converts large portions of the carbonaceous and proteins substances into gas, thereby reducing the volume of organic wastes. Biological processes are achieved by various means including the following:
        i. **Aerobic Decomposition:** This is responsible for most of the decomposition within a fill. It starts right after the waste is buried. The biological processes seem to be the most important but it is however greatly affected by both the physical and chemical processes.
        ii. **Anaerobic Decomposition:** Most biodegradable organic matter in a fill is decomposed anaerobically because the oxygen within the landfill gets depleted very fast.

Regrettably, the products of anaerobic decomposition in a landfill can be environmentally unfriendly if not properly monitored. Volatile Organic acids and gases are the principal products.

The principal gases formed are:

a. Methane (CH_4)
b. Carbon dioxide (CO_2)

Gaseous products in trace amounts are:

a. Hydrogen Sulphide (H_2S)
b. Hydrogen (H_2)
c. Nitrogen (N_2)

4. **Environmental Factors:** Main factors of influence in biological decomposition in a conventional fill include:
    a. Moisture.
    b. Temperature.
    c. Microbial content.
    d. Degree of waste resistance to microbial activities.

Factors Influencing Leachate Composition

The factors influencing leachate composition includes the following:

A. Designation of landfill for a particular waste type.
B. Composition of waste.
C. Moisture content.
D. Particle size of waste.
E. Degree of compaction.
F. Site hydrology.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

G. Climatic conditions such as rainfall, temperature, humidity etc.
H. Age of the fill/ Landfill age.
I. Design of landfill.
J. Type of liners used.
K. Waste pretreatment such as segregation or sorting, shredding, bailing of the waste.

Leachate and Soil Pollution

Quite a number of works have been conducted to investigate and determine the extent of soil contamination due to migration of leachate from uncontrolled or unlined landfill sites using geophysical and physicochemical studies (Ayolabi, et al., 2014; Kabala, et al., 2014). The extent of leachate migration and effectual soil contamination from a 17year old uncontrolled landfill in Southeastern China was assessed in a clayey soil of about 9m depth. Cutting sub-sections and analyzing soil samples for Total nitrogen, soil organic matter, chloride, sodium, and COD in the pore water. Leachate related Chloride was found in the soil up to the 3m depth, nitrogen in up to 2m depth, while sodium and COD up to between 3 –5m and 2-3m respectively (Zhan, et al., 2014). A related investigation found pollution to be a result of contaminant migration and has suggested the use of a liner under the storage basin to stop or reduce its migration (Bouzayani, et al., 2014).

Leachate and Water Pollution

Several more studies have been carried out to determine the effect of leachate pollution on water systems (Melnyk, et al., 2014). Geophysical studies for the assessment of ground water contamination by leachate from an uncontrolled landfill located in the city of Guadalupe Victoria, Mexico was conducted. Results showed a leachate contaminant plume which extended up to 20m SE and 40m NW of the landfill investigated. Although unlike the practice of using a site with low-permeability soils, the study area was of a silty sandy soil which is able to encourage the flow of leachate. Also, geochemical data of the water samples showed a characteristic sodium sulfate, sodium chloride, high ionic and organic matter (Reyes-López, et al., 2008).

(Fernández, et al., 2014), investigated both surface and ground water samples for pollution due to a leachate plume transport from a municipal landfill in Pacara Pintado, northwestern Argentina. The plume showed high concentrations of Fe, Mn, NH_4^+, Cl^-, Cr, and organic matter up to a 900m depth.

An investigation of ground water pollution due to leachate from an uncontrolled municipal landfill identified total dissolved solids (TDS), chlorine, ammonia, iron (Fe), and manganese (Mn) as to be the indicators of landfill leachate migration.(Han, et al., 2014). More data on soil and water pollution from leachates is presented in Table 6.

Leachate Pollution Index (LPI)

Leachate pollution Index (LPI) is the tool used to evaluate the leachate pollution potential of landfill sites. It is used to monitor the pollution potential due to the movement of leachate from the landfill into ground (soil) and surface waters within a given geographical location.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

Table 6. Typical leachate pollution data for both soil and water

Pollutant	Medium	Variation	Baseline	Reference
Mercury (Hg)	Soils within the mine	3.8-11µg/g (300m away from the mine)	0.03-0.05 µg/g (24km away from the mine)	(Gray, Theodorakos, Fey, & Krabbenhoft, 2015)
	Mine water run-off	7.9-14ng/L	0.05-3.1 ng/L	
Fluorescent dissolved organic matter (FDOM)	Groundwater	40% photo degradation	8% photo degradation	(Graham, Baker, Andersen, & Acworth, 2015)
Copper (Cu), from pig manure	Soil	32-164 µg/L	50µg/L	(Ostermann et al., 2015)
Cd, Pb	Soil	Highly contaminated	NA	(Wu, Leung, Pérez, Huang, & Wang, 2015)
TI		Considerably Contaminated		
PBDEs and metals	paddy soils and river sediments	Decreased PSII, affected photosynthesis, inhibited algal growth.	NA	(Nie et al., 2015)

A practical application of the concept of LPI was used to rate two active and two closed landfill sites in Hong Kong (Kumar & Alappat, 2005). It compared the leachate contamination potential of the two active and two closed sites and found that the closed sites had an equal or more contamination potential than the active sites. It is thus advised that post-closure monitoring is taking very seriously until the leachate generated is well stabilized. Also, it reported that leachate characteristics may differ greatly over time, even within a single municipal landfill site.

Because the greatest concern with leachate is the fear of a possible pollution due to uncontrolled leachate movement into the surrounding surface water and ground water or the sea. The Leachate pollution Index (LPI) is therefore a technique using a comparative scale to measure the leachate pollution potential (LPP) of individual landfill in a geographical area, over a period of time, (Kumar & Alappat, 2005). Other works have also been done using the LPI to evaluate the pollution potential of leachates especially from unlined landfill sites in relation to a resultant degradation and health hazards due to ground water pollution (Muralidhar, et al., 2014). In a related study, (Guerrero-Rodríguez, et al., 2014) found that leachates of higher LPIs were likely to exert more damaging effect than those of lower LPIs on to life. The tool was again used to determine the levels, variability and degree of heavy metal pollution in a municipal solid waste dump site in comparison with adjoining area and the waste dump site to be of higher heavy metal pollution (Essien & Hanson, 2014).

With the aid of the LPI, the following has been made possible;

A. Assessment and classification of landfill sites based on their leachate pollution potential.
B. Allocation of resources for management and control of landfill sites.
C. A continuous monitoring over a period of time using the LPI can provide the pattern of leachate pollution which can be employed in trend analysis.
D. It helps in the enforcement of standards and regulations for engineering and environmental control.
E. It provides information for scientific research and public awareness.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

The LPI has been applied in various assessment of landfill on the basis of their leachate contamination potential.

The LPI is a hazard identification tool while the other factors that need consideration include the following:

A. Dose response effect is important for consideration although it depends on the leachate receiving environment.
B. The generated volume of leachate.
C. The type of soil strata.
D. Depth of water aquifer.
E. Effective and affected population.

Leachate Management

The management of leachate essentially involves the means by which to prevent the migration of leachate beyond the site. It focuses on the containment or prevention of leachate spread so as to avoid a possible contamination of soil and water.

However, a common practice is to use an effective impermeable liner collection system. Also, leachate collection pipes are entrenched near the bottom of the liner layers and are connected to a main pipe that leads to a leachate holding tank (see Figure 4-6). The use of low-permeability soils is to minimize the convective flux of contaminants.

Figure 6. Concrete tank connected with underground pipes to receive Leachate from adjacent landfill

Essential Features of Landfill Sites

Wastes are dumped in organized layers, alternating between waste and soil to prevent odors and allow a faster decomposition. The landfill is sealed and covered with clay.

A least of four basic conditions to be met by any standard sanitary landfill in its design and operation include:

A. A full or partial hydrogeological isolation to be provided artificially using an impervious soil layer of clay or a synthetic liner, if it does not exists naturally as clay or rock bed. This is to lower leakages of leachates from the base of the site and hence lower the contamination of surrounding soil and ground water. A system of leachate collection should be provided below the base.

EBSCOhost - printed on 2/14/2023 11:45 AM via . All use subject to https://www.ebsco.com/terms-of-use

B. A proper design and preparations from local geological and hydrogeological investigations to include also a plan for waste disposal and a final restoration of the site.
C. Provision for trained staff to take control of the site supervision through the design, construction, waste deposition, regular operation and maintenance.
D. Planning and execution for waste dumping and compaction in layers to be covered with soil above each layer of waste.

CONCLUSION

Having discussed the pollution types, sources, effect and narrowing down to leachate generation, the leachate migration has been shown to pollute the soil, surface and ground waters particularly within the immediate geographical location of the landfill site. Characterization of the different types of leachate both old and young have shown a high content of contaminants which should be prevented from infiltrating both soil and water bodies particularly within the very immediate environment. It is therefore necessary to make a conscious and consistent effort towards controlling or preventing the migration of leachate. The generation of waste is obviously unavoidable, but a more decisive and collective efforts must be made by all, to reduce the volumes generated as this would mean a lesser volume to be available for treatment and hence a lesser leachate generation from landfills. Environmental authorities, especially those of the underdeveloped and developing nations, must make efforts to abolish the open dumps and uncovered landfills. They must bring on a system where the sanitary landfill is used if the landfill is desired for waste management. There must be provision to immediately cover any tipped waste to exclude unwanted scavengers and make the condition favorable for either of the means of waste decomposition within the fills, as desired. An engineered landfill, with a close, constant and continuous monitoring is advised.
